The swelling having been satisfactorily reduced, an elastic bandage made from flannel may be smoothly, snugly and comparatively tightly applied. This further reduces the swelling, and, by immobilizing the joints adds much to the comfort of the patient. The second element in the treatment is massage, which may usually be applied about the third day.

A word of caution is necessary with regard to too protracted fixation, as frequently disability, even anchylosis, may result therefrom. If our injury on the other hand proves to be a fracture, all of the indications are best met by the careful application of a plaster cast, which may be applied as well by the practitioner in the remote districts, as by his city brother.

While the X-ray machine facilitates the diagnosis, it is not essential, as a careful consideration of the anatomical points will invariably satisfy us as to the nature of the injury in this well-marked joint.

Cerebro-Spinal Meningitis.

BY HENRY N. READ, M. D.,

Professor of Diseases of Children in the Long Island College Hospital; Attending Physician to the Long Island College Hospital; Attending Physician to Sheltering Arms Nursery; Member of the Kings County Society, Pathological Society, Pediatric Society, Physicians' Mutual Aid Association, etc. Brooklyn, N. Y.

In view of the fact that a large number of cases of cerebro-spinal meningitis have appeared recently, a few words relative to the diagnosis and treatment of this disease will be of special interest.

This cerebro-spinal variety of meningitis is due to the diplococcus intracellularis. Practically, there are but two kinds of meningitis, tubercular and non-tubercular, and the prognosis is largely governed by the classification of the disease. If tubercular, the disease is, as a rule, hopeless. If non-tubercular, prognosis is less fatal, but is still very grave.

The prognosis is better in the cerebro-spinal variety than in that due to pneumococcus, trauma, or any of the mixed infections, including the streptococcus.

Diagnosis.—Diagnosis of the cerebro-spinal variety of meningitis is readily made. When the disease prevails epidemically and is accompanied with an eruption from which the old name of "spotted fever" took its origin, the mortality is very high. Cases occurring sporadically are usually apt to be much milder in character. In any event, it is a dangerous and long-continued disease, marked by a protracted convalescence, and the sequelæ may leave marks which will last through life.

The fever, as a rule, is not very high, seldom rising beyond 103° or 103½° F. The meninges of the cord are most prominently affected, and give rise to symptoms referable to lesions of the nerves coming off from the upper part of the cord, namely, retraction of the head, severe pains at the base of the brain, etc.

Treatment.—The treatment, unfortunately, does not present any very marked features by which we can hope to cure the disease and is confined mainly to the alleviation of the symptoms and supporting the strength of the patient.

Usually it is well to keep the temperature within bounds by cold sponging, and

o necessary, in my opinion, to ad-
remedies for the relief of the

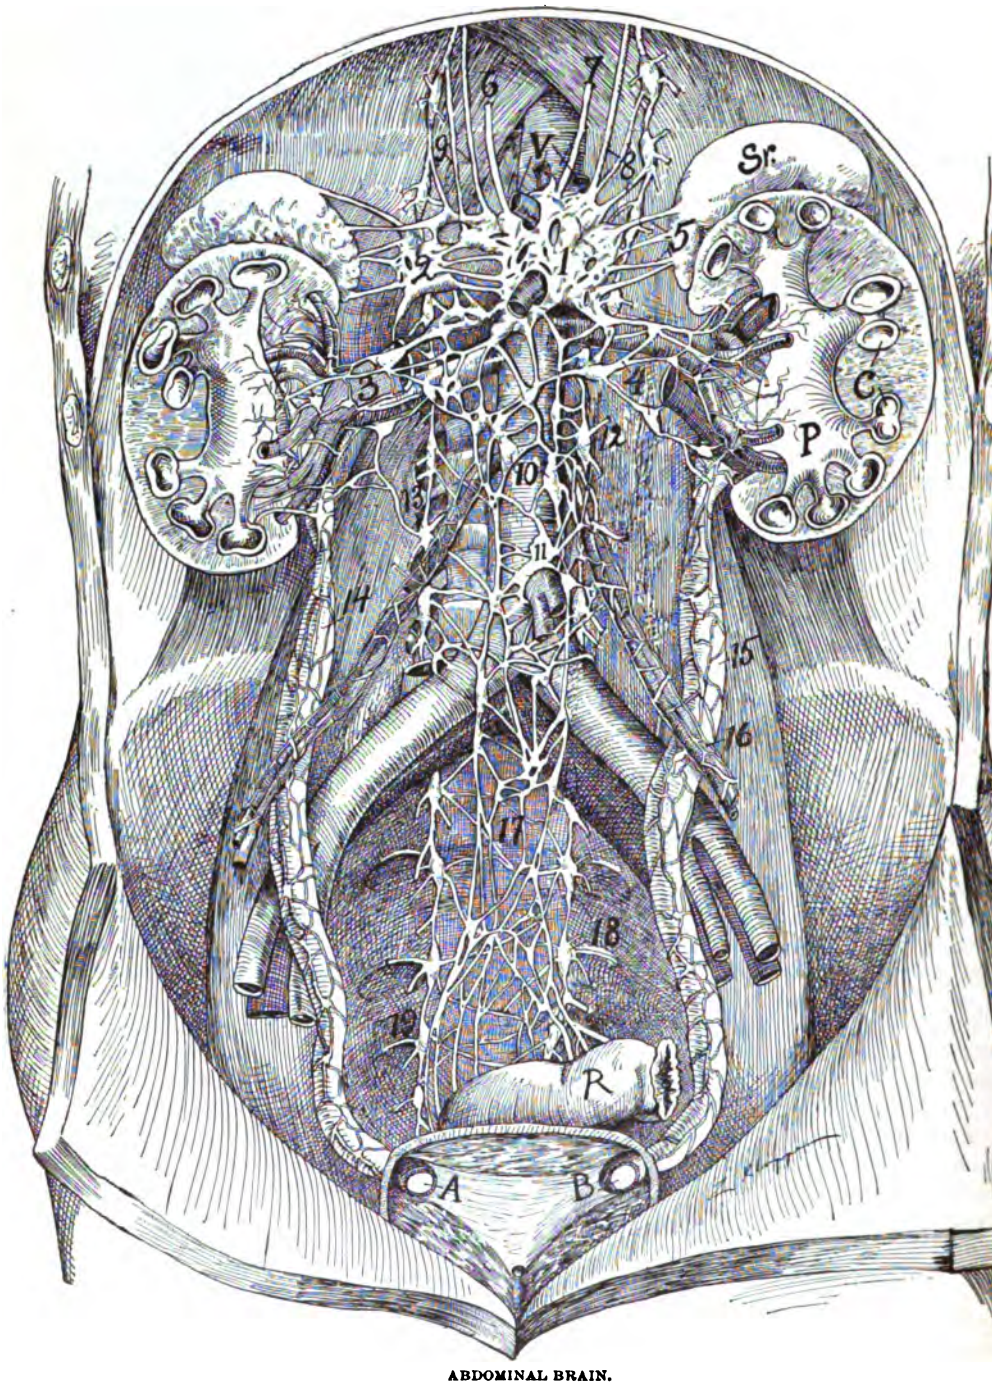
Views on the Abdominal Brain.

BY BYRON ROBINSON, B. S., M. D.,
Chicago, Ill.

Every Organ Has Its Rhythm.

In this short communication I wish to present some views on the abdominal brain, both practical and theoretical, with two drawings from nature illustrating its dimension, location, contour and distribution.

For a decade and a half I have investigated and written on the subject of the sympathetic nerve—the abdominal brain and automatic visceral ganglia. During those fifteen years I have published numerous articles and a large edition, my book "Abdominal Brain and Automatic Visceral Ganglia," is out of print. However, periodically some physician has published an article claiming new views; yet I have not read a single article containing the so-called new views that was not published in my investigations. Recently a physician claimed that the solar plexus was the seat of shock, but had never noted a reference to that in literature. This I had discussed repeatedly in my work. Another physician claimed that irritation in the ductus bilis from calculus produced spasm of the intestines. Surely such an effort has been thrashed over for years and is not new. The manifestations of the abdominal brain—anatomic and clinical—entitles it to the dignity of a nervous center—a brain. It receives sensation, reorganizing it and emitting motion. It is a receiver, a reorganizer, an emitter of nerve forces. First, we must consider the abdominal brain, the semilunar ganglia or solar plexus, in the physiology of the sympathetic. This large ganglion receives sensation and emits motion; it is a brain. It is situated (see Figures 1 and 2) at the root of the great visceral artery, *i. e.*, at the foot of the celiac axis. It lies behind the stomach and entwines itself about the aorta and root of the celiac axis and superior mesenteric artery. In short, it is located at the roots of the celiac, renal and superior mesenteric arteries. It supplies all the abdominal viscera. It is a gigantic vaso-



ABDOMINAL BRAIN.

FIG. 1 is a drawing from a subject possessing a typical large abdominal brain with the ureter, bladder and urethra dilated into a single channel without sphincters intact. 1 and 2, abdominal brain; 3 and 4, renal plexuses; 5, plexus adrenalis; 6 and 7, the two vagi; 8 and 9, the three splanchnics on each side; 10, the two spermatic ganglia; 11, inferior mesenteric ganglia; 12 and 13, lumbar lateral chain of ganglia; 14 and 15, dilated ureters wrapped by nerve plexuses; 16, arterio-ureteral crossing; 17, hypogastric plexuses; 18 and 19, lateral chain of sacral ganglia; A and B Patulous ureteral orifices.

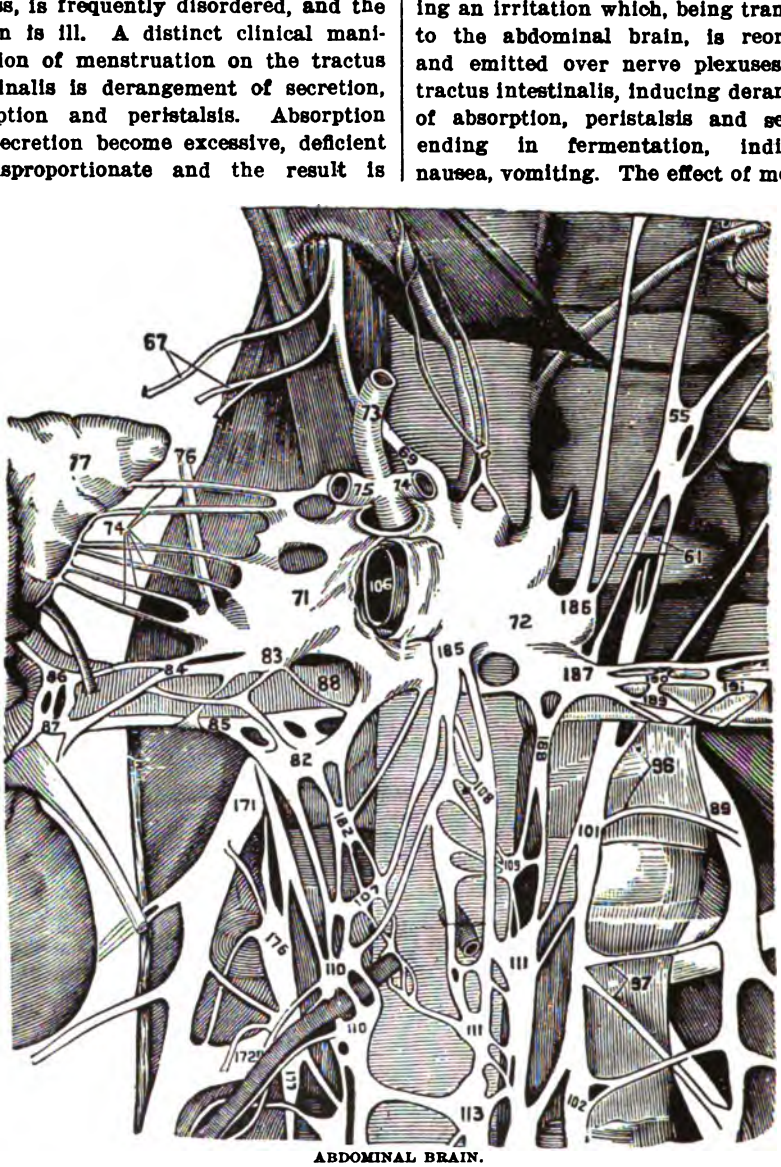
enter for the viscera, as is shown location at the roots of celiac, nd superior mesenteric arteries— at abdominal visceral blood way. nnected with almost every organ body, with a supremacy over vis- irculation, with a control over secretion and nutrition, with a nfluence over the heart that often fainting and may even lead to It commands visceral peristal- wonder that we may consider the ai brain the center of life itself, cranial brain is the center of and psychical forces.

bdominal brain, or solar plexus, osed of the aggregation or coales- a large number of ganglia. The al brain is composed of two ar ganglia—compact masses of ells, nerve cords and connective During many dissections I have at the right semilunar ganglion smaller (see Figures 1 and 2), s because it lies dorsal to the vena cava, and hence has suf- om pressure atrophy. Each of ilunar ganglia receives the great ic nerve of the corresponding he abdominal brain receives the —cranial nerves. It may be here hat although the semilunar gan- located on the sides, they are lly so intimately associated with r plexus that we insist in com- ll the names into one, viz., that bdominal brain.

exuses or strands of nerves are y to the abdominal brain. The nce of the abdominal brain in the physiology, *i. e.*, in life, may be d to that of the sun over the The influence of the sun rules ets, though they are influenced r suns and planets (*e. g.*, the spinal). The abdominal brain glion cells (brain centers), nerve (nerve conductors) and a peri- nerve apparatus (for collecting n), just as the cranial brain s all central conducting and al apparatus. The adbominal n live without the cranial (shown g fetuses with n› trace of cerebro- xis), while the cranial brain and n not live without the abdominal brain. The great sympathetic ganglia, of which the abdominal brain is the ruling potentate, is the center of life itself. So long as the forces of life, assimilation, circulation, respiration and secretion and absorption proceed undisturbed, as in health the abdominal brain remains a silent, steady, but ceaseless worker; but being unbalanced by peripheral or central irritation, it quickly manifests or resents the insult. From the abdominal brain large plexuses with numerous nerve strands pass to every abdominal viscus, connecting the viscera into a delicately balanced, nicely ordered, exquisitely arranged apparatus for the object of maintaining life. The nerve plexuses or strands are arranged along the highways of nourishment—blood and lymph vessels, vary in size according to the importance of the viscus supplied.

Second, we must consider the automatic visceral ganglia to comprehend the domain of power possessed by the abdominal brain and its clinical manifestation. The automatic visceral ganglia are lodged in the walls of the various visceral tracts and every plexus of each visceral tract leads to the abdominal brain. When the abdominal brain receives a sensation it reorganizes it and emits it on lines of least resistance, which means that the motion travels with greatest facility on the plexus possessing the greatest number of nerve strands. Important visceral tracts, significant to life, possess rich nerve strands and plexuses, as *e. g.*, the tractus intestinalis, genitalis and urinarius. A few common examples of irritation, disease in any one visceral tract, will demonstrate the clinical manifestation on the abdominal brain and the other visceral tracts. It is plain to the anatomist that the abdominal brain with its various nerve plexuses to the visceral tracts are finely and exquisitely balanced. It should be plain to the physiologist, the clinician, that irritation, disturbance, disease in any one visceral tract, will transmit the abnormal force to the abdominal brain, reorganizing it and emitting it, pellmell, disorderly, wildly on all other visceral tracts, causing disorder of secretion, absorption and peristalsis. Take, for example, the tractus genitalis. Menstruation, which should be a normal

process, is frequently disordered, and the woman is ill. A distinct clinical manifestation of menstruation on the tractus intestinalis is derangement of secretion, absorption and peristalsis. Absorption and secretion become excessive, deficient or disproportionate and the result is ing an irritation which, being transmitte to the abdominal brain, is reorganize and emitted over nerve plexuses to th tractus intestinalis, inducing derangemen of absorption, peristalsis and secretion ending in fermentation, indigestion nausea, vomiting. The effect of menstrua



ABDOMINAL BRAIN.

FIG. 2. (Byron Robinson.) This illustration, drawn from a cadaver, illustrates the location, relation and radiating plexuses of the solar plexus, or abdominal brain (71 and 72), which is built around the visceral artery—the celiac (73, 74, 75) and superior mesenteric (106) arteries; hence it dominates the visceral function as to vascularity (blood and lymph), peristalsis, absorption and secretion. The clinical manifestations of the abdominal brain are co-extensive with that of the abdominal viscera. This ganglion of the first magnitude presents radiating plexuses to all the abdominal viscera, presenting an exquisitively balanced and poised nervous mechanism, controlling vascularity (blood and lymph), peristalsis, absorption and secretion.

fermentation, gas in the intestinalis tract —indigestion. The peristalsis becomes excessive, deficient or disproportionate, resulting in constipation, diarrhea or vomiting. Pregnancy by the expansion of uterine contents stretch, compress, traumatize the nerves of the uterus, caus- tion, gestation, in the tractus genitalis, i to induce marked changes, disturbance in the tractus urinarius—the peristalsis absorption and secretion of the tractu urinarius is deranged, disturbed, dis eased; albumen occurs, excessive or defi cient urine is secreted, nephritis may

The Undulatory Theory in Therapeutics.

BY SAMUEL S. WALLIAN, A. M., M. D.,
New York.

[Paper 2.]

RATIONALE OF VIBRATORY THERAPEUTICS.

In the course of the later investigations of the nature of matter, it has been practically determined that the heat of a body is induced and controlled by the friction of its constituent corpuscles, or, if you please, *ions*, revolving or gyrating around each other and among themselves.

Any influence that will accelerate this intercorpuscular motion will increase the temperature of a body. Mechanical vibration can be made to increase the temperature of a part, therefore it is a logical inference that it increases the velocity of the intercorpuscular motion. It is also found by actual experiment that mechanical vibration can be so applied as to reduce the temperature of a locality or part.

Heat is attributed to what are termed thermal waves, and these waves are estimated to be the result of the lowest or slowest rate of undulatory or vibratory motion of which our perceptions take cognizance.

A higher velocity of wave motion or undulation produces light, and these waves are called photogenic.

Another definite increase of velocity produces chemical waves, which stand at the head of the list.

Each of these distinct variations of wave or vibratory velocity has its definite sphere in connection with vital phenomena. The respective spheres of heat and light rays have been quite generally investigated and discussed. The field of action of the chemical undulations has been under active investigation since Roentgen's discovery of his X-ray, which, with the ultra violet, is the best material exponent of the highest known, or at least the highest computable velocities. Thus far it has been demonstrated that these high-frequency vibrations are intimately associated with all the more complex vital phenomena—metabolism and tissue metamorphosis.

The velocity of heat and light waves has been at least approximately measured. The rate of the latter is given as two hundred thousand miles per second, estimated as you would estimate the speed of a railway train. This, however, gives no clue to the frequency of the vibratory repetitions. When, as in case of the X-Ray, n-ray, b-ray, d'Arsonval, ultra violet, and other so-called high frequency currents or vibrations, all of which have thus far been electrically excited, the vibrations are so rapid that they can only be hypothetically computed. All the electrical phenomena are the result of vibrations, each particular kind having its own definite rate; and the new metals, radium and polonium, emit a rate so incomputably rapid that they are called radiations instead of vibrations. It may be assumed, therefore, that radiations are vibrations having such a velocity that we have no means of measuring it.

When force is manifested in the form of heat waves, it is not usually visible. If their velocity is gradually increased it finally makes itself sensible to the organs of sight, constituting what is known as red light, the lowest division in the spectrum. The other colors of the spectrum follow in their well-known order as the vibratory velocity is increased, ending with the actinic or chemical rays, which are also invisible.

The polarization of electrical currents and exciters is but an interference or interruption in relation to their relative rapidity.

This brings us to a study of nerve currents or vital currents, and makes it at least plausible that these currents can readily become so deranged as to be called polarized impulses.

Since light rays are easily diverted, bent out of course or interrupted, as by the interposition of a simple crystal of tourmaline, or some other accidental substance, and are again restored to their primitive character by an equally simple interposition, thus illustrating how slight a cause may influence important results, so in the realm of vital chemistry, disturbed impulses may be brought back to normal conditions by influences which at first thought would be considered trivial and of no force.

Coming down to practical applications what is the scope of mechanical vibratory impulse in the amelioration and "cure" of the every-day maladies, for which the public seeks the aid of the physician?

In a sweeping way it may be said that its fundamental and far-reaching influence and capacity lies in its power to both control and stimulate tissue metamorphosis. To do this it must be able to both enhance and inhibit vital functions—circulation, secretion and excretion. This it can be made to do both directly and indirectly. Directly by being applied locally to dormant, disabled anemic or atrophied organs or parts. Indirectly by physiological stimulation of trophic nerve centers that control certain important vital functions.

First of all, it can be efficiently invoked to increase or diminish the blood-supply of a part. As regards superficial parts manual massage can be made to accomplish the same result, but possesses feeble power over deep-seated organs, requires the expenditure of much time and strength on the part of the operator, and has practically no influence over deep-seated nerve or trophic centers.

In like manner mechanical vibration can be made to stimulate sluggish or debilitated absorbents and lymph glands, and to restore dormant secretory organs to normal or even excessive function.

In any means that will definitely accomplish these physiologic and therapeutic results the student of pathology will recognize almost unlimited possibilities. No drug or class of drug remedies can be relied on to produce anything like such varied and comprehensive changes in the functional condition of an organism. Nor is it necessary to point out in detail and by name the long list of ailments to which such a measure can be adapted. Disturbed circulation can be equalized, congestions dispersed, neoplasms and hypertrophies discussed, and both secretion and excretion or elimination promoted. The diseases that hinge upon one or more of these abnormal conditions are almost legion.

with tubes should be shunned as
ld a deadly poison, for that is
what they contain after having been used, as they *can not* be cleansed.

The nipples, if they are in sections, should be taken apart and the nipple washed outside, then turned wrong side out, and the same process gone through with. Each separate part of the bottle and nipple should be washed with soap and rinsed with boiling water every time it is used, and then filled with a boiling solution of common soda, and left standing until wanted, when it should be emptied, and rinsed with *boiled* water and filled with the milk, and it is then ready for immediate use.

Every twenty-four hours, or even more frequently, the nipple and bottle should be placed in a pan and boiled for at least ten minutes.

EXCESSIVE HEAT AND CHANGES.

Sudden changes in temperature are a strong factor in the production of intestinal troubles of this nature, and should be guarded against by suiting the clothing to the temperature.

Especially is this true of excessive heat, and it is a very important factor in the troubles arising during the summer months. In the first place, the emunctories of the skin, taken as a whole, eliminate large quantities of the accumulated impurities of the system. Now, as the glands of the skin are more exposed to the sudden changes, it is through this agency that many times these troubles are brought about, for by the closing of these pores these impurities are retained in the system and Nature seeks to throw it off by the bowels and kidneys, and this overtaxes these organs of elimination, thus by this over-taxation, and the abnormal conditions existing, caused by the absorption of morbific substances into the blood, producing a nervous depression and a consequent infection of the entire system. Also, heat depresses and decreases the resisting power of the nervous system, and as a result, it is more susceptible to any abnormal changes.

And then, too, all conditions are favorable to the production of micro-organisms, and thus we have, as a result, the epidemic troubles of this kind during the heated periods.

Now, as for the preventive treatment for these troubles, since the causes have

been given, the absence of them will, of course, mean the absence of the disease.

Stated concisely, to prevent the diseases incident to the second year of childhood, give the child pure air, an equable temperature, with frequent baths; pure, wholesome food at proper intervals, generally not more frequently than every two hours. Have *absolute cleanliness* of vessels used in feeding, sterilize them by boiling, and keep the bowels clear of any matter that might be injurious, by flushing them with sterilized water.

Dentition.

Dentition is given as the cause of many of these troubles of indigestion, etc., but, while it may be, still I do not think it is the prime cause, and we will have to go deeper in our etiological research to find the logical cause.

It is true, we find that the nervous phenomena are exaggerated during the period of dentition, still, if we observe a child that is teething during the cooler months, we do not get such grave symptoms.

Dentition being a physiological process, unless there are other complications, there should be no greater disturbance of the general system than that caused by the natural development of any other part of the organism; but what we find generally, when called to attend cases of this kind, is a poorly-nourished child. If called in the beginning of the trouble, the emaciation may not be so marked, but we find a hyper-sensitive, nervous condition, which causes pathological changes, that in turn bring about a disturbance of the physiological functions.

The varied changes thus brought about are not noticeable alike in all, but are more marked in children of a neurotic diathesis, for the delicate nervous organism readily responds to any disturbance of the physiological functions, no matter how slight.

My opinion is, that this abnormal condition superinduces disturbances of dentition, and that this is the outcome of the same processes, operating in the system, which result in gastro-intestinal troubles. They are the diseased manifestations of the same abnormal functions. Dentition occurs at all seasons of the year, but it is only when conditions favor decomposition of organic matter, and which produce micro-organisms and infection, that we have gastro-intestinal troubles of this kind.

"This is the way the physicians mend or end us."
—Byron.

Prophylactic Surgery.

As the successful termination of every case of surgery depends upon the proper sterilization of the instruments, the surgeon and assistants, and the field of operation with the dressing, it is quite fitting that cognizance should be taken of it in a paper of this nature.

Instruments.

Instruments should consist only of metal, and should be without indentations of any kind. They should be constructed as simply as is consistent with the purpose for which they are designed. The only sure and safe method of sterilizing instruments is by wrapping them in some soft material to protect the edges, and placing them in a suitable vessel and boiling thoroughly for fifteen or twenty minutes in a one per cent soda solution, and when removed and cooled they are ready for use. This seems to be the most convenient, as well as the surest method.

Surgeon and Assistants.

The outer surfaces being exposed to the atmosphere can not but be infested with micro-organisms, which, if introduced into the system through any surgical or other wound, would produce serious results. We, no doubt, have all seen cases where, through the neglect of the operator or assistants, septic poisoning has been produced. Hence, it is imperative that *absolute surgical cleanliness* be obtained on the part of the surgeon about to operate.

First, the hands and forearms should be brushed energetically, using hot water and green soap, and after ten minutes' faithful work, they should be dried on a sterilized towel. A thorough cleansing of the nails is of the utmost importance. The nails should not be filed, as the file leaves minute irregularities in which microbes may find a lodging place, and are difficult to remove. We should put away all finger rings, as they are worse than useless and your patient's life may be the price paid for your foolish pride, for no

now clean and smooth the rings
ro-organisms can find a nesting

ed with a towel, which is satur-
th a solution of one one-thou-
f bichloride of mercury.
l the operation be on the feet, a
re thorough method must be pur-
cause, generally, the feet are not
as often, and the skin being thick-
ey can not be sterilized by ordin-
hods; hence, we resort to the fol-
procedure: A thorough scrub-
given for four successive days,
hich a bath in a solution of one
ihredths bichloride of mercury is
hen the feet are covered with
m acetate, and this surrounded
silk to prevent evaporating. This
is repeated for three or four days, when the thickened skin can be removed and with it the germs of infection.

It is quite apparent that mucous membranes are not so easily or perfectly sterilized, from the fact that chemicals strong enough to destroy micro-organisms, would do serious injury, so that mechanical means will have to be depended upon almost exclusively.

In operations on cavities, such as the vagina, the pudendum should be shaved and thoroughly cleansed in the manner described, and the vagina washed with sapo viridis and hot water, and then wiped with sterilized gauze, saturated with ether, or the parts may be sprayed with an ethereal solution of iodoform.

The same process may be pursued in other cavities, where operations are to be performed, although a perfectly aseptic condition of a diseased bladder or rectum are as yet unknown.

Operations on the urethra or bladder should be preceded by irrigation with a one twenty-five-thousandths solution of bichloride of mercury; this should be done every six hours for at least three days before the operation; also, the urine may be sterilized by the administration of some antiseptic, such as salol or some other disinfectant. In operations on the mouth the same precautions should be taken, the teeth should be thoroughly cleansed, then a solution of permanganate of potassium or boric acid may be used, washing the mouth thoroughly every two hours for at least two days before the operation.

In any operation, be it major or minor, the same *care* should be exercised to prevent infection. By thus preventing infection, we, to a greater or less extent, deprive surgery of its terrors, and the "grim rider of the pale horse" of many of his victims.

We know that in the past the ignorance of the laws governing surgical asepsis was the cause of much suffering, and the great per cent of fatalities resulting from surgical operations. Does it not incite every conscientious operator to use every precaution science and experience have given him for the preservation of human life and the prevention of suffering? We can only do this by careful attention to our

own actions, and by instructing the laity in regard to the possible results of carelessness in their everyday life. Many persons die from having poisoned themselves in trimming their corns with an infected knife or razor, or pricking a small abscess with an unclean pin. If they had been told that the parts should have been washed and the instruments been boiled, they would not have fallen victims to that most potent of all agencies destructive to human life, viz., *ignorance.*

Man, in health, has little knowledge of the strength of the silver cord which binds him to this physical world, and yet almost every day he sees the poetic statement proven true, that

> "'Tis the wink of an eye,
> 'Tis the draught of a breath,
> From the blossom of health
> To the paleness of death."

But, we think, as time passes, and greater enlightenment on these matters is obtained by the general public, fatalities from such causes will not then be so numerous, and the work of the surgeon, when called, will show better results.

The field of preventive medicine is limitless, and, as yet, we have only begun the task of exploration, and ideas, which we deem to-day worthy of putting into practice, in years to come will be looked upon by those who follow us as very crude and imperfect, for they will have done as we have, improved by the mistakes of their predecessors, else they will not have reached the full stature of their noble sires. For we believe it is true, as the poet sings:

> "I hold it truth with him who sings
> To one sweet harp in divers tones,
> That one may rise on stepping-stones
> Of our dead selves to higher things."

And so it is, we do rise by the stepping-stones of investigation. As a theory or idea is found to be false or imperfect it is placed beneath our feet by the master builder, and we rise one step higher, and are that much nearer the apex of that vast pyramid, whose broad and deep foundation was laid by our professional fathers.

And again is our horizon extended and we see, "not the same that our fathers have seen," but vaster fields of investigation. Like Moses of old, we may never be permitted to enter that promised land, which is so rich in everything that, to the earnest student, can be made to yield ideas, the proper and intelligent application of which will fall like a benediction upon suffering humanity. Ever since the days of Adam, when by his transgression of some one or more of the laws of Nature, and as a consequence the seeds of disease and death were sown, it has been man's constant effort to shun the one, and postpone the other, and to lengthen out the thread of life to its greatest possible limits, for life is sweet to all, and we are willing to accept the cup, and drain it to the dregs, and at last go tottering to the grave, "sans eyes, sans teeth, sans everything." And still on this, the dawn of the twentieth century, as we pause a moment, and, in a retrospective frame of mind, pass in review the many and almost miraculous discoveries made in the medical world, and compare the methods of this century with those of its predecessor, we can not but be encouraged to have greater hopes for the present one. How much better facilities has the physician of to-day to prevent and relieve human suffering than had those who have just passed off the stage of action! How much ignorance and superstition have been dispelled! How many better laws have been enacted to prevent the spread of those contagious diseases, which in the past were present in epidemic form almost continually! How much information has been gained pertaining to the laws of heredity, and the equally obscure subject of insanity, its diagnosis and treatment! What tremendous strides have been made in surgical asepsis!

And yet we can not help but realize that as we acquire greater knowledge there are greater responsibilities placed upon us.

> "Let us then be up and doing,
> With a heart for any fate,
> Still achieving, still pursuing,
> Learn to labor and to wait."

Cause of Malarial Fever.

J. MORRISON, M. D., PH. D.,

Washington, D. C.

(Continued from page 400.)

ne, commonly called marsh gas, the composition of one atom of nd four of hydrogen, is another h results from the decay of car- s matter under water, and is, no factor in causing malarial fever. he simplest of the hydro-carbon ds, is colorless, odorless and but ightly soluble in water. It ith a fairly luminous flame, ng water and carbon di- It is a constituent of coal d when mixed with air in portion of about one to ten, is explosive and forms the so- ire-damp" of coal mines. When n a pure state it is fatal to life, t very noxious when mixed with when it forms four or five per he mixture.

sulphuric acid gas, having the ion of two atoms of hydrogen of sulphur, is another very s gas, sometimes found in palu- lations, especially if any animal s present; but it may be gen- small quantities from the decay containing sulphur. This gas easily recognized by its offensive ich resembles that of rotten eggs. a constituent of sewer gas, and es of coal gas. That these gases, the first, or mixtures of them, chief factors in causing malarial ere cannot be the shadow of a cause this fever always exists in in which these gases are gen- Good drainage, thorough culti- f the soil, and the removal of rests or thickets, so as to allow irculation of air and the admis- the direct rays of the sun—na- reat disinfectant—have always alarial localities salubrious, inde- y of the presence of mosquitoes. dense forests of Africa, Central th America, localities most favor- the production of carbon mon- oxide, malarial fever assumes a malig- nant type.

Dr. Livingston, the African explorer, lost many of his men by malarial poison- ing, and he himself fell a victim to the same cause.

When the French undertook to dig the Panama canal, some thirty years ago, hundreds of the laborers perished from the same cause.

Carbon monoxide, being slightly soluble in water, is carried down by rain into the soil, which, in time, becomes thor- oughly saturated with the gas, and when such soil is disturbed, the gas is again set free, and the inhalation of it, in an almost pure state, causes a violent chill, which ends in a fatal collapse in a few minutes. It was a common saying among those employed on the work that the men digging in the trenches "stood upon their feet and died."

The same thing, but in a far less in- tense degree, happened to many of the early settlers in the western prairie States, when they first disturbed the soil by ploughing, not only along the river bottoms, but on the open prairie itself. The miasmata, set free from the freshly upturned soil, are capable of poisoning the air for miles around. A small frac- tion of one per cent of carbon monoxide in the air would, when inhaled for some time, be quite sufficient to make a pro- found impression on the nervous system, resulting in disturbance of the digestive function, in enlargement of the liver and spleen, and in that general cachetic con- dition known as chronic malarial poison- ing.

Carbon monoxide—the most poisonous element in marsh miasmata—is oxidized, or converted into the comparatively harmless carbon dioxide in the sunlight; but in the night no such action takes place. This is the reason why exposure to night air is so dangerous in malarial regions.

Malaria is never found in the vicinity of extensive pine forests, notwithstand- ing the presence of mosquitoes and the proximity of swamps and marshes. The action of the chemical rays of sunlight on the resinous exudation of the pine needles and of the bark of the young branches, gives rise to the production of

ozone, nature's most powerful disinfectant and germicide. Marsh miasmata are instantly oxidized and rendered harmless by ozone. For this reason, malaria is unknown in the health resorts among the pine forests of the Carolinas, New Jersey and elsewhere, although mosquitoes of the approved breed and all the conditions for generating marsh miasmata abound.

The presence of ozone in the air can be easily shown by any one as follows: Thoroughly moisten a piece of white porous paper in a strong solution of iodide of potassium and then dip it into a solution of starch and expose it to the air. If ozone be present, the paper will become of a blue color, owing to the fact that the ozone decomposes the iodide of potassium and sets free the iodine, which at once combines with the starch, forming the iodide of starch, which stains the paper blue. If there is no ozone present, no change in the paper takes place.

In view, then, of these facts regarding the poisonous nature of carbon monoxide gas, and of the probability of great numbers, not only of the laborers, but also of the officials directing the work on the Panama canal, being stricken down with malarial fever, or with the more dangerous yellow fever—the latter being really a pernicious or malignant form of the former—it is highly incumbent on those in authority to take such preventive measures as science and experience suggest.

In the first place, all those employed on the work should remain under cover of tents from sunset to sunrise. The tents should be large and located on high, dry ground, as far from the excavation and from ravines or marshes as practicable, and if a small fire can be kept burning in the tents all night, so much the better. Any good disinfecting fluid containing free chlorine may be sprinkled freely in the tents, but by far the best disinfectant is ozone, which can be generated by static electric machines.

If one of these machines, which costs only a few dollars, is placed in each tent, and operated for a few minutes several times during the night, sufficient ozone will be produced to destroy not only any carbon monoxide that may be present, but also any other poisonous gas o germs that may be floating in the ai This is the cheapest and most efficien method of disinfecting the air in th tents. At the same time, every on should be provided with a supply c quinine tablets; but better still, with supply of pills or tablets containing suc drugs as act on the liver—say, chionar thin, podophyllin, euonymin, strychnin etc.—for if that organ performs its fun tions properly, there is little or no dar ger to be apprehended from either mal rial or yellow fever.

Mosquito netting may be useful to kee out these pests, but gum camphor, spirit of camphor, oil of pennyroyal, or th smoke from burning pyrethrum rose tum, will be more efficacious.

The water used for drinking should b either distilled or boiled, to remove an carbon monoxide, or other poisonou matter which it may contain.

The land on both sides of the cana should be denuded of forest or jungle fo a quarter of a mile at least, and cleare out by fire during the dry season, fo reasons already stated.

All these prophylactic measures ar quite feasible and easily carried out, wit comparatively little expense.

The mosquito theory of the cause c malaria rests on some experiments mad in a malarious locality in Italy. On portion of an army spent the night under cover of tents, while another po tion remained on the open plain, expose to the night air and mosquitoes.

The former escaped, while many of th latter were attacked with malarial feve which was incorrectly attributed to th sting of the mosquitoes. This is exactl what happened to the British army i Africa, already alluded to.

The mosquito theory is an outcome c the germ theory of disease, and is one c those fads or medical vagaries whic have been the bane of the profession eve since its organization. The history c medicine, from the days of Hippocrate to the present hour, is replete with suc idle theories, which had no real scientifi basis on which to rest, which could no stand the test of experimentation, an finally vanished, like an "iridescen dream."

germ theory of pulmonary tuber- as propounded by Koch and his s, has not only proved to be a , but has given rise to an im- amount of quackery in high The mortality from tuberculosis gh now as it ever was. The ad- ation of tuberculin—a ptomaine it was thought, would kill the microbe or bacillus—has not oved useless, but has sent many ious patients to premature graves. as the treatment or cure of pul- tuberculosis is concerned, no ad- as been made during the last two e decades. The treatment is "*in tatu quo*" it was when the Roman Horace, wrote these lines, more neteen centuries ago:

* * "Macies et nova febrium,
ris incubuit cohors;
notique prius tarda necessitas,
l corripuit gradum."

germ theory of disease is already decline. The treatment predi- hereon has been disappointing. illi found on microscopic examin- ay, for aught we know, be the *re-* d not the cause, of the disease. id phthisis, for instance, no bacilli robes have ever been found, and called bacilli of pneumonia are n the air passages of healthy per- well as in those afflicted with that The presence of tubercle bacilli sputa, may prove the existence of ary tuberculosis, but at the same eir absence, or the failure to find nicroscopically, does not exclude ease, which may be present with- m as well as with them, and the ing is true for all other so-called liseases. The germ theory does tisfactorily account for those c cases of typhoid fever occurring brious localities, or for that pe- form of the same fever to which rs are liable on mountain s. There can, however, be no ut that zymotic diseases, such as l, yellow, typhoid, typhus fevers, ria, etc., can and are communi- o healthy persons by means of r germs, conveyed into the system air, water or food; but to assume inflammations, as pleurisy, pneu- nephritis, etc., or all nervous affections, as tetanus, sciatica, epilepsy, etc., are so communicated, is not credible or tenable, nor has it ever been demonstrated.

Here, for instance, is what one of these distinguished foreign advocates of the germ theory has to say in regard to diseases of the mitral valves of the heart—a disease usually the result of rheumatism, and that the result of faulty digestion:

Dr. De Grazia, in "Reforma Medica," July 8, 1903, says that in five cases of mitral disease, he found the following germs, or bacilli, in the lungs, viz.:

"The staphylococcus albus in all; a variety of diplococci and two other diplococci, similar to the micrococcus of Jaeger-Huebner; the micrococcus tetragenes in all five; the staphylococcus aureus in two; the streptococcus of mucous surfaces in one; the ordinary streptococcus in one; the monococcus in two; the influenza bacillus in one; the pneumococcus of Friedlaender in one; various bacilli in two; and the streptothrix in one." All of which is as convincing as the mosquito theory of the cause of malarial fever. What a flood of light the above sheds on the cause and treatment of mitral disease!

The savant says he will extend his researches which, he thinks, will doubtless bear fruit. We hope so.

[Written for the MEDICAL BRIEF.]

Epilepsy.

BY H. D. FAIR, M. D.,
Muncie, Ind.

At first glance, there may appear statements in this article that partake of the nature of egotism, yet, after careful consideration on your part, I feel confident that the idea will be banished from your mind, for what I know I know as well as anybody, and if I can prove to you that our so-called recognized authorities are not always correct, and that textbooks can not always be relied upon, it does not necessarily follow that I am egotistical.

From my earliest recollection epilepsy had an irresistible fascination for me; terrorizing me in my young boyhood and

intensely interesting me as a student. Because of neighborhood environments I was brought continually in contact with the dread disease and early learned of the universally considered hopelessness of treatment. Long before I had mapped out a medical career I had determined to learn all that was possible to know regarding this peculiar affliction.

My first great surprise came when I discovered how unsatisfactorily, even vaguely, epilepsy was handled by our text-books. No apparent progress had been made, either in diagnosis or treatment, for ages. The meager findings of generations past were handed down as authority, and the conclusions accepted as final. So, disregarding and to a great extent ignoring the teachings of the fathers in medicine, I started out on independent lines and have been well-rewarded for my efforts.

One of the greatest hindrances to an increased knowledge of this disease is the fact that so many writers seem to take it for granted that epilepsy requires the same treatment the world over, no matter what the cause or condition. This is an unfortunate mistake. There may, for a few weeks or months, be some stir when a new remedy is brought to the notice of the profession, but in a short time the general practitioner or specialist falls back on the old standby, bromide.

Of course, in the epileptic attack, no matter when or where occurring, there is great similarity and it is entirely unnecessary for me to go into details and give you a picture of typical *grand mal*, for you are all more or less familiar with it, so I will proceed to the main purpose of this paper.

I noticed a statement in one of our medical journals, written by one of our prominent physicians, as follows: "After all, we have no better treatment for epilepsy than the old reliable bromides of sodium and potassium, either singly or in combination." Now, let me ask whether you think this doctor's statement is true or not. If it is true, I pity the poor, unfortunate victims of the disease.

When I inquire of any physician or set of physicians in private practice, hospitals or asylums, having used this mode of treatment: "What has been your per cent of cures in serious cases? Has it bee seventy-five per cent?" You answer, "No. "Has it been fifty per cent?" Again yo answer, "No," and are finally compelle to admit that it does not reach thirt per cent. Now, to my mind, a remed that gives no better results than that far from satisfactory.

I do not wish to cast reflections on th honest endeavors of any one, nor deci any physician who has done his best; bu when a prominent practitioner, who ma be an expert in other diseases, states tha the old reliable bromides are the best an almost only treatment for epilepsy shows a lack of research, investigation experience that is not justifiable in on who pretends to be authority, or to teac others the way. My standpoint is simpl this: If a practitioner makes a speci study of epilepsy and concludes that the is nothing better than bromide, he is no qualified to treat serious cases; or, if h has *not* given the subject special atte tion, he is not competent to decide an should not allow such a statement to b made public over his signature.

It is a reproach to the profession tha such a statement gains publicity, comin from a supposedly reliable source, uncha lenged. I have more than once been ce sured for expressing my positive views, an even ridiculed by the "follow-your-leade class of physicians; but I can point results, which is more than the most them can do.

I have spent the best years of my li studying this disease, visiting institution where these patients are cared for, an gathering information from every sourc possible, and have been astonished tha physicians who are usually keen to arriv at safe conclusions in regard to the m nute details of every other disease, co sider epilepsy simply as epilepsy, no di ference whether it occurs in a frail chil or a robust man; no difference whethe the spasms are caused by scalp wound in an old soldier, or by disordered me struation in a young girl, the patient dosed with the bromides of potassium sodium until the brain is benumbed b the medicine, if not previously by the di ease. I have treated many patients wh conscientiously believe they have take

of medicine, and whose latter was worse than the first.

firm believer in symptomatology, day become more and more con- at symptoms, and not diseases, treated. This is particularly ilepsy. Of course, not every one fits is an epileptic, and we have ht that the bromides are "good but I have yet to learn of one genuine epilepsy that was ever bromide, and it is with great on that I notice Dr. Spratling, superintendent of the Craig Col- ew York State, who has had a le experience with this disease, actically the same statement.

ime to time, when making the my investigations public, and amples demonstrating my prem- have done in several medical I have received letters of in- n physicians all over the United d Canada in regard to cases in ctice, and many of them became tience when I requested some- nite, the detailed symptoms and fore I could outline a plan of . Now, what does this show? idently thought that climate, x, temperament, habits, condi- environments had nothing at all h the treatment.

never treated two cases alike in ulars and in the last eight years n successful in seven cases out ten. I have no "plan" of treat- d know that my per cent of uld be greatly reduced if I did have my favorite remedies, as e has, that have proved reliable able in these conditions, but positively nothing that will "cure the cause is found and removed. y of illustration I wish to cite vo or three cases taken at ran- n my records, omitting all de-

., of Ohio, forty years old. Had ht to forty convulsions every nd they were hard ones. She mides regularly, always taking she laid down for a nap during otherwise she would have a fit leep. She had been treated for the "best physicians in the coun- try," and spent money liberally, but with absolutely no lasting results. I cured her with one-drop doses of specific tincture sanguinaria, given four times daily, and less than one and one-half ounces did the work.

About six years ago a father and mother brought their nineteen-year-old daughter to see me. She had been having convulsions since she was eleven years old, and they were getting more severe, in spite of the fact that she had taken gallons of liquid from "I-cure-fits" men in different cities and that nearly all the local physicians had a chance at her. The etiology, as given by these men, was wonderful, both as to variety and uniqueness. I secured her personal history and all the facts bearing on the case possible, and requested permission to make a clinical examination, which was promptly refused by the mother, who said, "Many older doctors than you have treated her and never considered an examination necessary." Consequently, I refused to prescribe and they went away. Six months later they brought her back and asked me to proceed in my own way.

I went over her carefully and was about to give up in despair, when in the rectum I discovered a hard substance. When this was touched the girl had a fit in the chair. I had found the cause. An open safety pin had been embedded in the mucus fold of the rectum for more than ten years; a continual source of irritation, especially as she was inclined to constipation. The pin was removed and the trouble ceased; no other remedy being given than a general tonic.

How foolish it was to pour bottle after bottle of medicine into that girl, while the cause was actively present all the time. But, you may say this was an exceptional case. I say it was not. There is always a cause, but we so seldom take the trouble to find it. Time and again a simple operation, doing away with reflex irritation, was all that was necessary to effect a cure. However, there are times when the removal of the cause will not be immediately followed by a cessation of the convulsions. There is such a thing as the fit habit, and it is sometimes necessary to use considerable discretion in order to break up or change a routine

that has been long established, but it can be done.

A sixteen-year-old Pennsylvania boy had averaged two attacks every thirty-six hours for a little more than two years. Being well-to-do, the parents consulted able physicians as soon as the trouble began, but without benefit. The consensus of opinion was that the fits had some relation to puberty. I was asked to see the case in consultation. The family lived on a farm and raised hogs, sheep, poultry and cattle, and had meat on the table three times daily. I ate dinner with them and was impressed by the gluttony of the patient. I later told the physician and the mother that if they would place the boy on a vegetable diet the fits would soon stop. "We can't do that," said the mother, "for meat is about all he eats." I argued for a thirty days' trial. She thought one week would be long enough. We finally compromised on twenty days. I advised a placebo, which was given. There were but two attacks following the withdrawal of meat from the diet. At the end of the twenty days the mother, who contended that the placebo did the work, allowed him to again eat all he wanted, and the fits returned. So long as he avoids meats, he has no trouble at all.

Gaining the confidence of your patient is decidedly essential. As a rule, they are a class who have nearly lost courage, or have been swindled out of larger or smaller sums of money by quacks and newspaper advertisers, who prepare their one kind of medicine in advance, which is to cure the patient in the North, whose trouble was caused by severe fright; as well as the victim under the tropical sun, who is afflicted as was his father and grandfather before him.

When meeting a new case of epilepsy I study it as carefully as if it were the first of the kind I ever saw. I analyze the urine, give the whole organism a thorough examination and inquire into every detail that I think could possibly throw any light on the subject. I seldom place explicit confidence in what the patient tells me, as I have found some of them to be notorious liars. There are times, also, when the testimony of friends is unreliable.

Electricity is an important factor the successful treatment of many case even when it does not of itself cure, aids and assists the indicated remedie General faradization or central galvani ation, or both, may be employed. Son cases need functional stimulation ar others sedation. As a usual thing, th galvanic current, with the positive po on the spine and the negative pole at th epigastrium, is the preferable method.

The great point, however, is the reco nition of the fact that every case is rule unto itself. Let out-of-date precede influence you little or not at all. Obser how the attitude of the profession changing as to small-pox. It will son day be the same with epilepsy.

Therapeutic Suggestion: What Is It?

BY HERBERT A. PARKYN, M. D., C. M.,
Chicago, Ill.

(Continued from page 414.)

"The method of treatment by which patient is cured is generally the one which he afterwards pins his fait Therefore, when a cure is really made b suggestion, and is credited to some oth agency, the faith aroused is a false on Far different is it with a patient cure by 'directed suggestion.' He understand exactly why and how he has been cure He learns to observe a number of Nature important laws, the effect of the min upon the body, the control of his thought etc., and it is a rare thing to find an i telligent patient seeking relief a secon time, for a trouble of which he has one been cured by suggestion."

As stated before, we receive all in pressions or suggestions through th senses, and these impressions may u consciously interfere with or assist bodil functions; for instance, the sight of horrible accident or a disgusting scen will frequently retard digestion, or na sea may result. A disgusting sight or u inviting looking food may instantly r move a splendid appetite. Pleasant scen and bright faces, the sight of good foo etc., will remove unpleasant thought make one feel happy, and stimulate app

digestion. The sight of a deli-
ses the saliva to flow. Through
e of hearing, news may be re-
which may depress and produce
ause worry, grief, nervousness,
of these conditions will remove
ite, and retard digestion, or pro-
niting, and sometimes diarrhea
yuria. Good news, inspiring
right stories, cheerful voices, etc.,
ove depression, assist digestion,
te an appetite. Some odors call
easant memories, which produce
ng lines of thought, while others
ay be obnoxious enough to nau-
remove an appetite. On the
nd, the odors from some flowers
happy, and a savory odor from
will often stimulate an appetite
y dull.

few illustrations demonstrate
hat we continually receive many
ble impressions, which, if re-
the active mind for a time, are
interfere with the process of di-
or by destroying the appetite, in-
with the amount of food usually
d. In either case, the amount of
nent would be diminished, and
ne line of thought of an individual
a mental condition be changed,
l likely become a nervous dyspep-
onstipation would likely follow,
ion would become imperfect, and,
ervous prostration and insomnia
y result.

harles Gilbert Davis, of Chicago,
luable article read before the
Congress, at the World's Fair,
at he believes nine-tenths of the
hich the human race is heir, are
ct or indirect results of an out-
onscience.

owledge of suggestion enables the
n to discern the influence a pa-
nind has upon his health, and in
ase to secure its intelligent co-
n.

tain the best results from thera-
uggestion, a thorough knowledge
omy, physiology, chemistry, path-
nd diagnosis is necessary.

orce which heals a man is within
and when understood may be con-
by himself; and just as the activ-
he propelling force within a man
who walks a mile is stimulated or depressed by the nature of his thoughts, so, also, will suggestion, when properly directed, arouse the healing force within man, and on the nature of the suggestions given will depend the extent to which it is aroused. Many a patient has lived for days after the "physician's allotted time" expired, sustained only by some stimulation of his vital force. For example, an intense desire to see some loved one, hastening to bid farewell. It is often this remnant of vital force, which, when intelligently directed by suggestion, suffices to arouse into activity some organ which for a long time has been hopelessly dormant, but which, when aroused, enables the patient's internal organism once more to resume its normal action, and draw him back from the very jaws of death.

Some of the conclusions which may be drawn from the facts mentioned in the above article are:

That the vital force which heals a patient is within the patient himself.

That the vital force is generated within the patient himself, by the digestion and assimilation of food.

That the amount of vital force generated depends on the quantity and quality of food introduced into the stomach.

That anything which will interfere with the necessary supply of properly selected food, or the digestion and assimilation of food after it has been received by the stomach, will interfere with the generation of the vital healing power.

That the digestion may be retarded or completely stopped by certain mental states.

That the food supply should be regulated by a correct knowledge of the requirements of the body.

That knowledge is stored in the mind, and that mind is created and influenced entirely by suggestion.

That the creation, expenditure and control of vital healing force are directly or indirectly dependent upon suggestion.

That if one would intelligently direct this healing force, he must have a thorough knowledge of the effects of suggestion. He must understand the simple means for ascertaining the individuality

and suggestibility of his patient, so that he may determine in advance the mental and physical effect any given suggestion is likely to produce.

Parisian Medical Chit-Chat.

BY THOMAS C. MINOR, M. D.,
Cincinnati, Ohio.

Peter and the Clinic — The School of Lyons—Tuberculosis—Robin and Kelsch—Endemic Diseases of Japan—Japanese Students.

In 1890, the great clinician, Peter, observed: "We are in a period of experimentation where the laboratory wishes to replace the clinic and seeks, by means of the guinea pig, the secrets of therapeutics in men. This excess of bacteriology will most surely lead us back to full clinical observation."

This medical foolishness still persists, but its wings are filled with lead.

The school of Lyons has instituted a very useful department of hygiene. The pupils in their third and fourth years, have grown skilled in three years. How is that, you inquire? Under the teaching of Professor Courmont they do the following work: Chemical analysis of the air, bacteriological analysis of air, investigations in the Eberthe bacillus, the colibacillus, choleric vibrion, etc.; investigations in waters, hematozaires, mosquitoes, anopheles, trypanosomes, etc.; studies on ventilating and heating apparatuses; experimental work on the toxicity of alcohols, essences, etc.; researches in animal tuberculosis; analyses of flour, wine, milk, butter, cheese, preserved meats, etc.

These poor young doctors have not a moment's time to study the sick. They see no patients. They give prizes in this highly scientific school (?) to all those who discover spider-webs in the brain—medical spider wébs.

You will see at this school young men with the talents of the mocrographer, engineer, chemist; as for doctors, they have none who cure diseases. They let this class of so-called medical men loose on the poor of the community, to experiment and practice there in order to learn their medicine. They must have a diploma *de omni re scilili*. They must know everything except real medicine. Happily an awake ing came. Robin and Kelsch proposed, tuberculosis, to take the declarations real doctors, and not those of the ba teriologists. They have proved to th satisfacton of thinking men that here where the real domain of medicine hold without bacteriological credulity an charlatanism. On the other hand, whe the science of real medicine holds its en pire, they know the real hygiene, privat and public as well. Charlatans in th regular profession are numerous. The abound especially in the laboratory. Me without practice, on a salary, who dia nose disease with a microscope alon Never mind their fallacies, their foolis ness. The true physician is not alway on the lookout for some unknown me theoretical microbe; not that he does n admit that certain organisms of an i constant kind are observed at times, but h knows such organisms can not exist wit out a proper soil to grow in; a morbi predisposition. That is true medicin Professor Robin has first victorious established that the discovery of th famous bacillus of Koch, by abandonin clinical medication and replacing it by s called antiseptics to destroy the microb only caused deception, for it is one thin to kill microbes under a glass and anoth thing to attack them in living tissues.

The bacteriologists followed a wron path. The bacillus of Koch is harmle if it does not meet a proper soil in th human organism. The Koch bacillus ma be found in the most healthy people.

Always the assailant and the assaile Give strength to the assailant. To th assailed give pure open air, good foo and the clinical remedies used by th fathers of medicine, those remedies tha experience and time have shown to b most valuable. Dante placed in the mout of Saint Thomas those beautiful words o which all good souls may well meditate "Let the errors of the past serve thee f a lesson and do not fear to tread wit slow steps."

Let us pass to the inspector of ou armies, Dr. Kelsch. He does not den what is called contagion of tuberculos in the army, but holds that the invasio by the bacillus is insufficient if it has n the consent of the organism. To him, co

oes not play a great part in tuber-
n a regiment of soldiers. Phthisis
troops is almost constantly the
an auto-infection rather than of
l of direct contagion.
lmost always the feeble soldiers

for unfruitfulness. Let the world have fruitful husbands who may serve it on numerous occasions." The Mormons of the southwest United States will presently outnumber the Gentiles because the former propagate their species as a duty under the best of sanitary conditions, while the Gentiles are given to abortion and the sexual crimes of matrimony.

"*La Revue Medicale du Canada*" contains an interesting article on the "Endemic Diseases of Japan." We translate the following excerpt:

"There are only four contagious diseases endemic in Japan, but three of them are important, *i. e.:* leprosy, small-pox and syphilis, and an ulcerous affection called *Ka-sa.* Leprosy prevails in all portions of Japan as well as on the Island of Nippon. As in the extreme Orient, it has prevailed from most ancient times. It is the poor and lower classes that suffer, as will be noted by the numerous beggars one meets, eaten by leprosy, along the public roads from Miaco to Yeddo. Many of these persons have almost lost the resemblance to humans. Their physical condition is worse than the patients at the Sammarang and the Chinese Leper Hospital of Batavia.

"Nevertheless, leprosy is less spread in Japan than in Java and Sumatra. There is about one leper to every ten thousand inhabitants, which represents about thirty-five hundred cases in a population of thirty-five millions. Leper hospitals, such as were known in Europe during the middle ages, are entirely unknown in Japan.

"Although the Japanese know full well the first symptoms of leprosy and the terrible affections that ever follow its primary manifestation, they give it little attention at the commencement. Persons slightly affected still cohabit in their families and follow their usual avocations. It is only much later, when the malady is fully developed, that they seek isolation or live by themselves, often keeping to their own private rooms. The beggars whom we mentioned, having no means to sustain themselves, are banished from society, leading the sad life of mendicants, without any aid from the Japanese Government. Some of them live in caves and holes dug in the ground, covered by straw.

When they hear some passer-by on the high-road, they pop their heads from the hole and beg alms. They are absolutely naked and so deformed as to crawl on all fours, like animals. They act like wild beasts.

"Small-pox has existed in Japan from times of most remote antiquity. According to Japanese authors, it first appeared about the year seven hundred and thirty-five of our era, and has remained endemic to the present day, manifesting a ravaging epidemic tendency at certain periods. It was introduced to Japan originally from Korea, where it has been endemic since 626 A. D. In Japan, the most violent outbreaks occurred in the years 790, 833, 904, when the islands were devastated by the disease. In the nineteenth century, the worst outbreaks of small-pox were in 1803, 1848 and 1849, and the Island of Nippon was almost made desolate. The Japanese think one should have the malady at least once in this life. In some Japanese provinces it is the custom to place those attacked in some retired mountainous place, there to remain until such a period as they are cured. This isolation plan is ever followed by good results. The public in Japan is informed of the presence of small-pox by a bamboo bow placed over the door sill. The Japanese Government pays little attention to the malady, cure, or for vaccination, or rather, innoculation. The Chinese and Japanese claim to have known the method as far back as the year 1014 of our era, while in Europe it was an eighteenth century discovery. A curious fact—the Japanese, until very recently, performed vaccination on the end of the nose.

"The introduction of true vaccine lymph from the cow met with great opposition in Japan at first. It was introduced there by the Dutch, and had no very good results in their hands. It was not until 1848 that the best results were obtained; since which time the employment of vaccine lymph has given satisfaction to all those who cared to employ it as a method of prevention.

"Syphilis was introduced in Japan by the Portuguese in the sixteenth century. It is to-day widely spread throughout Japan and as prevalent as in Europe. The Japanese make no mystery of it and a tach but little importance to the malad Despite the incompetence of most of t Japanese physicians, there are rare any tertiary consequences of a serio nature. Syphilis in these later years Japan has grown to be a milder affecti than the form observed in Europe. T healthful climate of Japan may ha something to do with this. A very hi temperature constantly never lessens t gravity of the malady. For example, Java, the affection is much more serio than in Japan. Japanese doctors, w are ever very boastful, deplore the ign ance of the native physicians of Jav One must admit, however, that nati Japanese doctors are more learned th those of Java, who are known as *Do kons.*

"In Japan the air is always pure a but very slightly charged with humidit although it rains frequently. An atm phere filled with sea water vapor acco panied by high temperature is partic larly unfavorable to the treatment syphilis. In Europe, the proof of this shown at Venice, a city located amo marshes, and a place in which syphilis never cured, and Venice has some of t most skillful medical men in the wor The syphilitics of Venice who desire be cured know full well that they mu leave there and retire to the heart of Its for perfect treatment.

"Regular medical visits to prostitut do not exist in Japan, except in certa locations. Each house of ill-fame has own particular physician to attend to t sick girls. Even this measure preven to a limited extent, the spread of syphi and other venereal disorders. Let us a another measure used in the pub houses of Japan, *i. e.*, in these hous 'Zgoloja,' and the tea houses 'Tsja j are to be found the only prostitutes lowed. There are no resorts or clandestine places. Even the young actresses a watched by the police. These actress 'Seko,' and the dancers, 'Odoriko,' a prevented from falling, if possible, there are doubtless a certain number th escape police vigilance. In Japan, even the great cities, there are but few wom who live by themselves and are kno prostitutes. There are no kept women

the European sense of the word, nese public morals permit a man several women, beside his wife, in se, but Japanese morality will w a man to keep women outside domicile. The police watchful- r such matters in Japan is not ny moral sense, for the Japanese ne, nor is it due to hygienic Its origin is exclusively politi- Japan, public houses are part of e department. They serve it to eir various people behave in their f abandonment. Each visitor to house in Japan must sign his or e on a register, together with the e, and a penalty is attached for istration. Pneumonia.

BY J. D. WEDDELL, M. D.,
Kansas City, Mo.

I was very much interested in what Dr. E. B. Pennington, of Mohawk, Tenn., had to say on the subject of pneumonia in March MEDICAL BRIEF for 1905.

He says he is amazed at the mortality of the disease. So am I, but not any more than I am amazed at the opinions of some men who are considered high up in the profession; teachers in our best medical schools; men who are looked upon as "authority." I do not know how these men of "authority" treat the disease, but I quite agree with Dr. Pennington, that it is one of the easiest to treat successfully. The intrinsic tendency of pneumonia is to recovery, and whenever I hear of a death caused by it, I always think they would have recovered if they had been given a chance, unless it was in a very weak and debilitated subject. I believe the mortality is greater now than it was years ago. Is it because of the improved (?) methods of treatment? If so, why not abandon it and adopt something more rational and successful? As Dr. Pennington has said, the men of the profession have gone off after fads and have not yet returned. If the serum treatment is the correct thing, why do so many people die? Why follow a line of treatment that sends so many of your patients to the undertaker?

I have practiced medicine thirty-three years; twenty-four years in the country, and nine years in this city, and during that time I have had three patients die who had pneumonia. The first occurred at the end of the second week in a case of typhoid fever, and I am unable to say whether death was due more to the pneumonia than the typhoid fever. The second occurred in a maiden lady forty years of age; very weak and frail. She was taken down with a severe attack of la grippe and pneumonia of both lungs.

The third occurred in a young man about thirty years of age, who was suffering from diabetes and pulmonary tuberculosis; a mere skeleton. He was taken in Chicago with a severe attack of la grippe and pneumonia, and came to Kansas City before consulting a physician. The disease invaded both lungs. Except in a very weak and debilitated subject, I never have any fear of a case of pneumonia dying.

I know this will be looked upon by a majority of the profession as a great boast, and perhaps by many, as a great big lie, but that will not alter the facts in the least, for what I have said is true. This is no assurance that I never will lose a case, other than the kind I have described; I simply say that I have lost none.

I will give a general outline of my treatment which has given me such good results. First, give a sufficient amount of calomel to stimulate the liver and move the bowels. For the first two days, I usually give lobelia in sufficient doses to impress the system, with tincture aconite in minute doses, frequently repeated to keep down temperature. If patient has a weak heart, give digitalis from the start. I use hot turpentine stupes to the affected lung until the skin is reddened; then omit for two hours and begin again, and keep it up for twelve to twenty-four hours, according to the severity of the case. Keep the chest enveloped in flannel throughout the course of the disease. Give some form of opium to relieve the pain. In the second stage, give an expectorant containing carbonate or muriatic ammonia and tincture digitalis. Do not omit the digitalis, and do not be afraid of it. Digitalis has given me better results as a heart sustainer than anything else, and to sustain the heart is one of the main features in the treatment of pneumonia.

Never, under any circumstances, use poultices; they are heavy, and they embarrass respiration, and can do no possible good. Keep the room well ventilated, and at a temperature of 65° to 70° F., and give plenty of concentrated nourishment, and your patient should be on the road to recovery in five or six days. I have had complete recovery take place in several cases in four days. Treatm must be varied to suit each indivi case. I never use quinine, except in s cases during convalescence, in tonic do

Questions of Interest to the neral Practitioner Regarding Prostatectomy.

BY M. R. BARKER, M. S., M. D.,
Chicago, Ill.

family physician, in the great ma- of cases, first sees, prescribes for vises these cases. They may seek at the onset of enuresis, or they stpone until total urinary obstruc- kes place, and are, as a rule, ignor- their true condition. Before the of prostatectomy, the physician t one course to pursue. Pass the r, relieve the patient and teach e of the same to him. Then fol- the catheter life, at first inter- but later continuously, with its ble train of bladder and kidney s and consequent invalidism, ren- the declining years of these old n many cases, almost unendurable. ere is now a better way. The phy- has a brighter hope and a fairer t to offer these sufferers. But is e to this? Does he fully compre- his truth? Or is he floundering quagmire of doubt, and for reason , withholding the advice his pa- so much need. It is the object of per to elucidate as much as possi- operation of prostatectomy, and e faithfully what may reasonably ected from it, neither emphasizing ongly the good, nor attempting to the bad. Sometimes the examin- of these cases is mystifying, and o a doubtful diagnosis. This is the following: There are three t forms of hypertrophied prostates. rge, soft variety, due to hypertro- the muscular tissue of the gland, over-cell growth. The mixed va- ue to a hypertrophy of the muscu- d fibrous tissue. This is much than the preceding. These two es are most common. The third due to hypertrophy of the fibrous This is the smallest of all, and ard. The physician would proba- ve no trouble in assigning the f the patient's trouble to the pros- all of the tissues of the gland are enlarged, but this is not always true. The irregular outline of an enlarged prostate is well known and is due to the unequal enlargement of the tissues of the gland. Enuresis, or a complete stoppage of the urinary flow, may be due to the enlargement of a lateral lobe, or to both lateral lobes, or to the enlargement of a median lobe, or a median lobe with one or both lateral lobes.

The whole trouble may also be due to a fibrous band encircling the urethra at the neck of the bladder. Hence, upon examination the physician may be misled by finding a much smaller mass than he had expected to find. If, however, he finds some enlargement, or perhaps nodules, and there is not a urethral stricture (rare at the age of these patients), he may be very sure that the cause of the trouble lies in the prostate. The variety of the hypertrophied prostate, in any case, has some bearing on the prognosis, in case of prostatectomy. The small, hard gland can not be enucleated. I mean by this it can not be shelled out of its capsule. It must be removed by morcellement. This requires more time. There is more hemorrhage and traumatism consequent upon this operation than with the other varieties. For reason of this, the unfavorable conditions hereinafter mentioned, are more liable to follow in this class of cases.

When is this operation indicated? It is a well-known fact that hypertrophy of the prostate is a slowly-developing condition and that in every case, before obstruction to the urinary flow is caused by it, the trouble has existed for a number of years. There is never any hope that it can be cured except by surgical measures. These facts, together with the well-known disasters that inevitably follow catheter life, should impress one that the operation is indicated as quickly as the disease is discovered. The patients at this time are usually in such condition as to reap the best results from the operation. Is the catheter then to be discarded in these cases? The physician must relieve his patient with the catheter and continue to do so until the patient can go to a hospital for the operation. The patient should not be taught the use of the catheter at all. This should be the rule; of course

there are some exceptions to it, but they should be very few. If once taught the use of the catheter the patient will continue it, and not only bring upon himself years of suffering, but lose the best opportunity to have his trouble removed.

Among other important questions which interest the physician, whose advice is sought in these cases are the mortality following the operation, and the chances for complete recovery if the patient survives. Workers in this field have from time to time, during the last six years, made estimates of the percentage of mortality by taking the cases operated upon by the surgeons of the world, using all reported cases. The mortality thus estimated has steadily decreased from ten per cent to, at the present time, about five per cent. These estimates, we must remember, have not been based upon the work of specialists in this line, but upon the work of all general surgeons and specialists together. The reason for the reduction in mortality is due to the better condition of the patients when presented for the operation, and the improved technique which time and experience have produced. I believe we can reasonably expect when patients have the operation when the disease is first discovered and they are in the best possible condition, the mortality in these cases will not amount to more than one per cent.

As to complete recovery. From the reports of surgeons over the world, complete recoveries, within a month, result in about seventy per cent of the cases. By this we mean: The patients have recovered from the operation with control of the bladder, having no residual urine or other urinary trouble. In other words, the conditions for which the operation was done have been met by the operation in seventy per cent of the cases in a month. Of the other thirty per cent the greater proportion of them are troubled with incontinence of urine. This is probably the greatest trouble to the greatest number. But all of these patients recover from it, but not all within a month. Some are troubled, more or less, for six months, but these are very few. Hardly any complain of it after the third month. The trouble which is next to this in frequency, is perineal fistulæ, the opening in the membranous urethra through which the prostatic tractor is passed into the bladder failing to completely heal within a month. The patient has control of his bladder, but at the time of micturition a small quantity of the urine passes through this fistulous opening and out through this perineal wound. These, however, all recover within three or four months. In my last seventeen operations I have been able to overcome this by draining the bladder for two weeks, immediately after the operation, by means of a catheter passed through the penis into the bladder and retained there. This catheter is changed every day for a sterile one, and is as large as can be used. The bladder is washed and treated as indicated in each case, through this catheter. By this method the urine never passes through the perineal wound, and a fistula is not formed. This catheter has other advantages. It keeps the patient, dressings and bed unsoiled from the dribbling urine. A few cases of recto-urethral fistulæ have been reported; only a very few, however; possibly due to undue traumatism in doing the operation, causing the rectal wall to slough.

A few cases of epididymitis and orchitis have followed the operation, but all have yielded to the proper treatment of those troubles without undue delay. The question of the virility of the patient, after the operation, is always to be considered; though in nearly all cases a subordinate one. If the patient is in vigorous manhood, the question might seem to him a serious one, and he might choose the catheter life, and seek the operation after this had failed. It is unfair, however, to charge the operation with the sterility of these patients. The operation only removes from the body tissue that we have a right to suppose, in many cases, has been functionally removed by disease long before, and that sterility was as complete before the operation as after.

Very much time and thought have been spent trying to devise a method of operation that would enable the removal of the prostate and not interfere with the anatomy of the sexual system to the extent of causing sterility. There has been no demonstration as yet that these efforts

cceeded. It is true that for reason endeavors the operation is now ormed that erections, coitus, and ions are the rule with these pa- fter the operation. But so far, no s been reported to have repro- fter the operation. The destruc- a greater or less portion of the urethra is almost certain with oval of the prostate body, espe- ith middle-lobe involvement, and is the ejaculatory ducts must be d to a certain extent, no matter ethod the operator may use. Then nt it would be overstepping the of reason or fact to hold out to atients the hope of reproduction eration.

bjections to the operation that were ged, that stricture of the urethra llow the operation, have not been Ample clinical experience has hat stricture does not follow the n. When a portion of the roof rethra is left, it is easy to under- ow the normal membrane may reproduced from this. But when section of the whole circumfer- the prostatic urethra is destroyed, metimes is, it is not so easy to for the good part Nature plays estoration. It is probable in these at the torn ends of the urethra ght nearly into apposition by the g of the walls which surrounded state and unite, thus forming a with its normal walls. The above ns, resulting as above stated, are hich the physician may consider ing prostatectomy. In summing and magnifying them as much ble, the unpleasant things dwindle gnificance which follow the oper- mpared with the dire results en- the disease, which the operation . Other questions besides the ten have to be considered by the n before advising the operation. nt among these is the age and n of the patient. Age, however, should not be made too promi- ge is only relative. Some men of re younger than others at sixty. our best results was in a patient vo years old. A man of eighty ve a better prospect of living ten more years than a man of sixty has. The old, decrepit, feeble man of eighty would not be a good subject for the operation, neither would the man of sixty under similar conditions.

A patient suffering with marked kidney lesions, or with diabetes, or malignant trouble, should be given the same consideration as in any other proposed surgical procedure. Extreme sepsis, due to absorption of residual urine, is not a contraindication for the operation. A patient of mine sixty-eight years old had all symptoms of sepsis; chills, fever, sweats, loss of sleep, cystitis marked, constant desire to pass urine, catheter life for eight years. I tried to pass a catheter, but could not. I then tried to pass a filiform bougie, but failed. There was almost constant dribbling of urine. The patient was only a shadow of his former self. This was his condition when I first saw him. I took this patient to the hospital at once; made a suprapubic cystotomy, with cocaine anesthesia; drained the bladder, washed it out twice daily, and at the end of two weeks removed the prostate through a perineal incision. This patient made a complete recovery and has remained well ever since. This was six years ago.

Another patient, over seventy years old; catheter life for six years; history of cystitis a number of times. I saw this patient during an attack of senile pneumonia. He was suffering with sepsis and cystitis. They had been using the catheter, but the time had come when they could not pass it, and there was complete occlusion of the urethra. I took this patient to the hospital when so feeble he could not turn over in bed without assistance. I opened the bladder through a suprapubic incision, drained and washed it. The patient improved for four days, when symptoms of the pneumonia returned and he died. I am sure even in this desperate condition this patient would have recovered if the pneumonia had not returned.

I simply recite these cases to show what can be done in cases of sepsis, due to absorption of pus-ladened residual urine. Not at all that I approve of allowing these patients to get into these extremes, in the light of our present surgical triumphs in

this disease, without showing to them a better way.

Complications.—The most common and distressing of these is cystitis. This complicates every case sooner or later after catheter life begins. Though it is true that patients become in a sense immune; in other words, many of them use the catheter for a long period of time with impunity. They do not infect themselves because of their vigilance in observing antiseptic precautions, because they do not do this, but they have become, as it were, immune. This immunity, however, only lasts a variable time. All become infected, and cystitis is the invariable rule of catheter life sooner or later. The advent of this complication dooms the patient to suffering the rest of his life, unless relieved surgically.

Kidney troubles probably stand second as complications. They are usually secondary to cystitis, though this is not an invariable rule. Vesical calculus is not an infrequent complication. The conditions most favorable for the formation of these calculi are found in the residual urine of these patients. It is always accompanied with a more or less marked cystitis. It is difficult for one who has witnessed the suffering of these patients, when cystitis and sepsis complicate, to discuss them with moderation, or think of them calmly. Yet we have tried to maintain our equanimity and discuss the favorable and unfavorable phases of the subject with equal candor.

These patients are seldom emergency cases, hence they can be individualized and the preparation for operation applied in each case as best suits it. This is very important. Upon the proper preparation of each case depends largely the success of the operation. The operation must sometimes be preceded by treatment for some time. For instance, the cases we have cited. If there is cystitis and sepsis present the patient can not be put in condition for operation until they are relieved. Any condition that can be removed or modified, that may add to the hazard of the operation, should be dealt with before the operation is done.

Different operators use different methods for doing the work. And different instruments have been devised for aiding the operator. I have always used the i verted U perineal incision. It gives t maximum of room, enables the operat to see every step of the operation, a enables me to best meet the three esse tials in each case, viz: Time, the mi mizing of hemorrhage and the least p sible traumatism. I have devised a pr tatic tractor, which I use in preferen to any other, and with great satisfactio After the operation, not one jot of t alertness of the surgeon is to be abate Complications may arise at any time, f the first few days, requiring prompt a tion. While these complications are n common, yet the fact that they do appe should keep the surgeon ever watchfu We have only hinted at the technique the operation in this paper, and have on mentioned in the briefest manner t after treatment of the patients. The p per has not been prepared for surgeo alone, but for the family physician, gi ing him an idea of what he may reaso ably expect for his patients from t operation of prostatectomy. The abo observations are based upon the expe ence of the author, in thirty cases, a upon the published records of other su geons. In my cases I have not only do the operation, but have prepared t cases for the operation, and taken ca of them personally after the operatio I have lost one case, the one above d scribed, who died from pneumonia wh being prepared for the operation.

[Written for the MEDICAL BRIEF.]

"What Is Suggestion?"

BY AXEL EMIL GIBSON, M. D.,

Los Angeles, Cal.

Reply to Dr. A. A. Lindsay's Paper, Publish Under the Above Heading in MEDICAL BRIEF, January, 1905.

Suggestion, when taken in its technic sense, stands for a phase of mental th apeutics, by which personal influence m be transferred from stronger minds weaker, while the powers of judgme and volition of the latter are held in te porary abeyance. And as the same defi tion holds good with regard to hypnotis it follows that in principle and essen

o processes are identical, and that tion simply means hypnotism ap- o definite therapeutic ends.

is paper referred to above, Dr. y describes a case of moral de- which he cured by "developing an hypnotic subject upon which be demonstrated every phase of l suggestibility, such as the re- of the sense of pain, producing sy, and also show the various phe- of hallucinations."

these statements it would cer- appear that as far as Dr. Lindsay erned, suggestion and hypnotism constitute different names for l processes—a circumstance which rably simplifies matters, as dan- volved in the practice of the one, e involved in the other.

ubstance of Dr. Lindsay's paper is ption of the certainly painstaking of the author in his finally suc- effort to cure a young man from ness, gambling and bad habits in

r, so good. The young man is enjoying the victory over sin and hich the unremitting labors of his n won for him. It is the old, ed and questionable doctrine of s atonement again brought into his time under the auspices of science and scholarship.

o the processes of natural evolu- nction results which are brought y vicarious atonement, *i. e.*, by the some entity reaping the harvest y another? Is it not true that throughout all her operations lentlessly enforces the law of the l of the fittest; not only on the l plane, but likewise on the men- moral? And this because of the at it is only in the high efforts in a life-and-death struggle, that rvival value, with the attendant tation of character of each indi- is rendered possible. Any degree ngth and beauty, present in the of natural evolution, have be- ossible only by virtue of a struggle stile environments.

as the great ever-present aim of n is the formation of character, ven at the expense of form and structure, it follows that any interference, removing the means by which such an end is to be made obtainable, so far from benefiting the entity, leads to its ultimate failure of holding its own, in the relentless advance of evolution.

Our first inquiry into the real nature of Dr. Lindsay's suggestion-cure would naturally concern the character of the changes brought to bear in the young man's moral evolution. Virtue, like the strength of Siegfried in Niebelungen, springs from a slain dragon; a thought which Maurice Maeterlinck, in one of his later essays, expresses in the question: "Show me a virtue which is not a transposed vice?" Or, in other words, out of the struggle between the moral consciousness of the individual, and the temptations held out to him by his environments, proceeds the unfoldment of character.

Hence we must avoid making the mistake that external ease and freedom from friction constitute the *sine qua non* for inner growth. For may it not rather be that moral storms means moral growth, what physical storms means to the trees in the forests of the North? Conditions and methods by which strength, adequate to the individual resistance put forth, is added to the nature of the successful struggler.

Thus, from the standpoint of evolution, there is nothing illogical or immoral in the thought that the environment from which Dr. Lindsay removed his patient, by the very terror of its extremes, must sooner or later quicken his moral nature into healthy action, as the invincible logic of evolution points to the alternative, ultimately facing dissipation—individual restraint or dissolution.

For no man on his career to degeneracy is left without repeated opportunity of conscious choice. A religious tract stuck into his hand, a word of warning from some street preacher, the constantly recurring examples in the commonwealth around him of civic and moral decency constitute guideboards, flaring at the individual from every cross-road, and from which at some time the truth of life shall strike knowledge—self-conscious knowledge—into his bewildered nature. And, on the other hand, as long as the soul of

the transgressor fails to heed and respond to these moral appeals, the fact is plainly evident that he has not yet reached that stage of retrogression where the pains and agonies of an outraged moral and physical nature have succeeded in arousing his sleeping conscience to the seriousness of the situation.

The practitioners in hypnotism, failing to recognize man's evolutionary necessity, rushes headlong in on the scene. To save his man from the impending danger of wandering astray, he bandages his eyes, not realizing that just such a measure will prevent the thus treated individual from finding a safer road for the future. Everything is made smooth and easy. The moral heights he was to climb he is led around, or carried over in a litter; and the estate of peace which he set out to conquer is given to him free of charge and effort; to occupy, not as king and sovereign, but as slave and beggar. From a hero, wrapped in adventurous strife, he is transformed into a moral eunuch—safe from vice, but also safe from virtue.

And Dr. Lindsay proceeds to relate how through his hypnotic suggestion he blunts the young man's appetites, and by removing trying environments also removes conditions which were to compel him to volitional efforts, and self-conscious choice. Dr. L. fights all the battles, defeats all the foes, and leaves the young, morally weak and undeveloped man to reap a victory which he is altogether inadequate to manage.

The false safety of the young man's mind will last as long as the hypnotic force holds his nature under its spell. It may last for years, during which time the young man finds himself in some state of moral administration, depending for his inner equilibrium on the super-imposed subjugation of his animal nature. He has practically gained nothing, but, on the contrary, by being "saved" from the bracing tonic due to moral struggle, is losing opportunities of self-conquests and character development during every moment of his life. In the great economy of Universal Nature the entities render adequate efforts for every attainment, and there is no more reasonableness in the power of Dr. Lindsay to generate the tremendously deep-wrought soul qualities of character, will and conscience of his p tient, than it is for an animal trainer develop in the domestic hen the flyin capacity, visional keenness and power endurance peculiar to a mountain eagl

The individual virtue evolved by hy notic suggestion is comparable to th tameness and quietude brought about the conduct of a horse by cutting off som of his means of locomotion. For the vi tue of hypnotism is negative; it reform by lowering the vital strength of its sul jects, and turns sinners into saints b making them too weak to sin.

The aim of evolution is to round ou and strengthen every power and functio of its entities. It is not the *inability* sin that constitutes true virtue, but th power, gained through vital experienc by which the individual may be able to analyze the phantom of vice that i hollowness and sham are unmistakabl and its attractiveness forever turned int moral disgust.

And to reach this end the healer teacher must appeal to the judgment an reason, heart and conscience of his sul ject, and to trust to his soul-nature to d his part. It surely needed no hypnoti suggestions to change a Saul into a Pau and the conversion from darkness int light of this persecuting Jew on his wa to Damascus forms a more or less episod in the life of every human soul.

But though hypnotism in its relation progress is purely negative, its relatio to regeneracy is fatally positive. Henc the action which took effect in the conve sion of Paul sprung from powers nativ to the individual soul in its relation the divine ideal, and hence beyond th scope of hypnotic influence; while on th other hand, to turn the soul in an opp site direction, to convert a disciple Christ into a fiendish hypocrite, a Juda betraying his Master's life for a sordi sum of money, requires the influence a will and conscience-deadening hypn tism.

And here we arrive at the very hea and center of the subject. For, while th hypnotic suggestion is powerless change the slave into a man, it contin ally proves itself capable of turning me into slaves. Encountering too much r sistance, too hard work, and too slow r

in his appeals to the refractory, -moved reason and judgment the tizer chooses an easier way and ds under the cover of an induced state and by the power of a d, self-centered will, to break through otective coverings of the mind of bject. Having thus effected an en- into the sacred domain of anoth- ind, he assumes the tremendous re- bility to change its *modus operan-* suit his own motion, without re- o the individual needs and necessi- eculiar to any entity of evolution. astes and inclinations are intro- in the executive offices of the sur- ed mind, and organized and co-or- d into cerebro-spinal mechanism, so eave the impression of constituting l, self-generated impulses.

mines of conversion being thus nd properly adjusted, the healer aws from the field of operation to the moral explosions and watch esult in the formation of character. aced within himself of having saved dividual from threatening moral he little realizes that the rupture h which he effects his entrance in octored" mind remains wide open. t is in this connection we find one gravest mischiefs of hypnotism. is through this breach in the in- ment of the subjugated mind that age is established, inviting for time me any straggling nondescript t or slip-shod notion to take up rs and direct the vital activities in urped "chambers of the mind."

susceptibility of hypnotism after aving been subject to its influence xtend throughout the rest of the dual's life, though the permanence "cure" itself seems to depend upon e of the healer, and wear off with it. ver, it can safely be said that an dual, once "successfully" under the tic treatment, will never again find lf in possession of the courage, of freedom and power of choice, was his even under the most dis- ng environments.

eighbor of mine, whose wife had be- impatient with the tardiness and erestedness her husband showed regard to her domestic affairs, de- cided, on the instigation of a hypnotic "class professor," to take lessons in his strange, alluring art, and when proficient, also teach her imperfect other half a few of them.

Possessing a fairly good power of concentration, she soon got a grip on the practice, and immediately proceeded to subject her husband to its influence. Results were soon forthcoming. The docility of the subject became extraordinary. He found no service at home too mean for his attention. Dish-washing, carpet-beating, chamber-maid work, etc., became to him occupations as grave and dignified as the signing of an international treatise, and equally long-winded. In fact, he spent so much time in his domestic duties that his down-town business began to suffer. He had to be told not only when to commence, but also when to quit. A code of observance which had to be extended even to his operations at the table, where he, if left alone, would indulge until his face and bloodshot eyes showed signs of threatening apoplexy. He gradually had to be guided like a child, and at last got a permanent refuge in the insane asylum at Highland, not far from Los Angeles.

Another occurrence of a similar character is recently reported from St. Paul, Minn., where, during a public hypnotic exhibition, a boy of eleven was made subject to the "suggestion" that he was a rabbit. The suggestion "took" admirably and the audience had a thoroughly good time in watching the little victim's antics.

When the time came to awaken him the "professor" went through the usual manipulations, but failed. He promptly decamped, and is still decamped, while the boy is still a rabbit; that is to say, he is a lunatic, and whether or not he recovers, it is doubtful that the traces of the outrage can ever be wiped away from the workings of his mind.

But these are only two cases out of thousands. Scrupulously or unscrupulously practiced, hypnotism as a consciously and personally directed force, used for the purpose of bringing about changes of the mind in the individual, is irredeemably and unconditionally bad. Let us direct our reformatory and soul-saving ef-

forts to the self-conscious, self-willing, self-choosing man; let us appeal to his reason, his conscience, his heart, but always under the auspices of his own judgment. One single step taken by the man himself is of more evolutionary value than thousands under the gauge and assistance of hypnotism. Civilization and progress are indebted for its historical success to men who neither received nor administered hypnotism, but appealed to the manhood, judgment and conscience of their fellowmen.

[Written for the MEDICAL BRIEF.]

Medical Laws.

BY D. S. MADDOX, M. D.,
Columbus, Ohio.

In the current number of the BRIEF appears a communication from Dr. A. M. Richmond, in which the laws regulating the practice of medicine in the various States are condemned, and suggesting national legislation as a proper remedy. I heartily agree with the writer that our medical laws are absurd and unjust, but the remedy he suggests is, I believe, altogether wrong in principle.

We do not need any Federal laws to regulate the practice of medicine. Federal legislation would prove a bigger mistake than have our present State medical practice acts. We do not need *more* laws on the subject, but *fewer* laws.

I doubt whether a Federal law of this nature could be passed, for it would certainly interfere with the constitutional rights of the sovereign States to regulate their own internal affairs. Each State in the Union has, and ought to have, the right to regulate its own affairs, medical and otherwise.

The destruction of State sovereignty and the centralization of power at Washington would be inimical to our liberties, and might result in the ultimate overthrow of our present form of government and the establishment of an oligarchy, or worse. The way to remedy the medical legislation evil is not by Federal interference. To attempt to do so would, I firmly believe, be jumping from the frying-pan into the fire. The State legislatures are the bodies that make these vicious medical laws, and it is to them tha the profession must look for relief. Abou ten years ago medical legislation becam a fad, or craze, which spread all over th country, and State legislatures, egged o by irresponsible medical politicians, vie with one another in turning out thes queer and unnecessary laws to regulat the doctors. But there are signs that th craze has now reached its limit, and tha a healthy reaction is about to take place

The rank and file of the medical pro fession are at last waking up to a realiza tion that they have been most shamefull bunkoed by the medical politicians. Th laity, also, are beginning to see that thes laws, which they were told were for thei protection, are delusions and snares; tha instead of affording them any sort of pro tection they merely deprived them o their inalienable right to employ medica attendants of their own choosing. Th sentiment against these iniquitous medi cal laws is rapidly growing, and there i already in every State a large body o liberal-minded physicians whose influenc and concerted action will soon be felt State legislatures will be asked to so mod ify these laws that the profession wil nc longer be at the mercy of arbitrar boards of health, and boards of examina tion and registration. If the liberal ele ment in the profession will only stand to gether and work for the common weal State medical trusts and boards of al sorts, that are now oppressing the people will soon be things of the past.

A diploma from a respectable medica school is *prima facie* evidence that th holder is qualified to enter upon the prac tice of his profession. No examinatio by any State board can lessen or increas the holder's qualifications. State exam inations in such cases are unnecessary unjust and altogether absurd. No on is benefited by them, save the examiners who, in most cases, receive a fat *per dien* and mileage. Moreover, this remunera tion is in many instances in excess o what some of the examiners are capable of earning in the same time by their pro fessional efforts.

In conclusion, I venture to predict tha the time is not far distant when this craze for restrictive medical legislation will subside entirely, and when a physi-

liploma will be the only license re- to practice in any State in the I may be too optimistic, but then m is only another name for hope, thout this spiritual quality within may not expect to accomplish re- or win battles.

Written for the MEDICAL BRIEF.]

olic Acid a Scientific Magic.

BY ROBERT GRAY, M. D.,
Pichucalco, Chiapas, Mexico.

time since, I read in a French journal a flaying criticism of Dr. Brodnax, Brodnax, La., because essionally affirmed that pure crys- olic acid, liquefied by a hot bath uncorked bottle, was a hundred more effective and less painful one per cent solution, and abso- non-toxic, whether externally or rmically applied to human y.

t Dr. Brodnax in New Orleans a young man, and accidentally ufficent of his subsequent history fy me that he was incapable of ing a medical hoax, fraught with ous possibilities, as his French undoubtedly and honestly believed. ong afterwards, I was called to see ictims of a common country free- in Central America, classically revolutionary warfare. There x of them well hacked up by edged s; plenty of deep, gaping cuts, g, as horses dead for a week, ap- y gangrenous, the truth of which no attempt to ascertain. Their was appalling, even to me, then ured to horrid scenes in that dis- country. I was at my wits end, remedy, when I recalled what I d about Dr. Brodnax. I reasoned thing could render their physical more intense; that death was in- under existing circumstances, t if the acid killed as quickly as cution, as the French scientists would be the consequences, its ght prove a blessing to my hapless s. Hence, I mopped the wounds of most nearly dissected thoroughly re liquid acid, using a big feather, s astounded to see that he grew tranquil and went to sleep at once, while the fever, which must have been 41° C., fell to normal within an hour. Acid used was not weighed, but was at least two hundred grains—toxemia in solution for a host of men—applied freely and directly to naked flesh. There were no toxic symptoms, nor heart disturbances. The remaining five were at once thus treated, with results equally propitious. It is almost superfluous to say that the nauseating stench at once disappeared. The wounds healed rapidly without more pain or medicine.

Subsequent microscopic examination, same day acid was applied, proved that as soon as it passed the putrid and touched the healthy flesh, an impenetrable albuminate was formed with the blood serum, rendering any degree of absorption out of all question.

I have since used, times unnumbered—am using almost every day—pure liquefied crystal, in all classes of wounds, ulcers and old sores, with results that no other remedy approaches. Applied to fresh burns the pain subsides at once and the cure is prompt. Injected into boils, ulcers and tumors of any character, while growing, they are aborted and die painlessly.

Syringe should be charged with warm acid, and kept in hot water till ready to use, to prevent crystallization in the needle. Quantity depends on requirement of disease—three or four drops in small boils, etc. When the inflammation is very large and much aggravated, it should be injected at various points.

Do not be afraid of it—not even in ulcers, fistulas and abscesses of the rectum and anus, where one application almost always suffices. You have people using sixty-five per cent solutions with sweet oil, glycerin and the like, in diseases of the rectum and anus, among them, Dr. Monroe, of Louisville, if I remember correctly. Why thus diluted, I am unable to conjecture, as the pure article is less painful and entirely harmless to the physical anatomy. You have your speculums, syringes, needles and lights and anesthetics, necessary for rectal work, while French makes are the vogue here. There is no hypodermic pain more than that caused by the en-

trance of the needle, the acid being an anesthetic of matchless quality, that kills the agony where it is applied, instantly, in the most painful boil or ulcer.

Equal parts crystal acid, chloral hydrate and camphor gum constitute a compound deadly to ringworm, other skin diseases and rhus poisons, that causes slight inconvenience to patients, the pure acid being unsuitable for delicate, tender cutaneous surfaces, though less painful than the compound. Caustic action of pure acid destroys the healthy skin, which the compound does not injure. Extensive application of the compound produces no toxic symptoms, which would certainly supervene from similar quantity of a much weaker aqueous solution. Alcohol perfectly antidotes carbolic acid externally and internally.

Brother readers of the BRIEF, prove out the possibilities of pure carbolic acid, as revealed by Dr. Brodnax, and you will combine and rear him a magnificent monument, as a benefactor to the profession and the human race. I will contribute my part on demand.

The scientific Frenchmen ridiculed Dr. Brodnax, probably because he was a rural physician in the United States, rather than a brilliant medical light in a big European city. The same Frenchmen lauded Koch to the skies, but could not sustain him in the temple of fame after his marvelous theories passed the crucial test of inexorable practice, where all methods and men stand or fall on the strength or frailty of intrinsic merit. I owe Dr. Brodnax more than all the text-books and medical writers of the age can claim at my hands, though I saw only the criticism of his contribution to medical science, and I am not ashamed nor afraid to make the confession.

I forgot to say earlier that compound crystal, chloral and camphor, equal parts, with olive oil, makes the best catarrh remedy I ever saw. I have perfectly cured several chronics; and for colds or influenza in head, there is no equal. What sticks to tip of finger over mouth of vial put well up into each nostril and energetically snuffed two or three times daily, is my way of using it. It is not painful, as one might suppose, with some seventeen parts pure crystal acid.

Regular Board Medical Examiners State of Georgia—Atlanta, Ga., April 5, 1905.

E. R. ANTHONY, M. D., Griffin, Ga., President.

F. D. PATTERSON, M. D., Cuthbert, Ga., Secretary and Treasurer.

MATERIA MEDICA AND THERAPEUTICS—W. I TRAVIS, M. D

1. Name chief indications for the use o opium.

2. Give symptoms of opium poisoning an treatment, and show with what diseased co ditions these symptoms might be confounded.

3. Name two respiratory stimulants an two vaso-motor depressants, with indicatio for use, dose and usual method of admini tration.

4. What ratios do hypodermatic and rec dosage bear to that by the mouth?

5. Name two best diuretics, and give dose

SURGERY—J. B. S. HOLMES, M. D.

1. Define surgical shock. (a) How woul you treat it?

2. Describe an operation for the radic cure of oblique inguinal hernia.

3. Describe Halsted's operation for the r moval of the breast.

4. Describe an operation for amputation o the thigh at the middle third.

5. What is Colle's fracture? (a) Ho would you treat it?

ANATOMY—F. M. RIDLEY, M. D.

1. Give origin, course and distribution o pneumogastric nerve. Name groups of spina nerves and number in each group. Describ solar plexus. Give brief general description o sympathetic nervous system.

2. Give divisions of spinal vertebra. Ho would you identify bones of cervical vertebra of dorsal vertebra? Name bones of carpus; o tarsus. Name bones of pelvis.

3. Name muscles comprising quadriceps extensor-femoris. Describe triangles of nec by diagram.

4. Describe circle of Willis. What is rela tion of external to internal carotid artery Name branches of external carotid artery.

5. Describe diaphragm. Describe heart Give names, and relation to bones and muscles of blood vessels found on cross section a middle of thigh.

CHEMISTRY—DR. E. R. ANTHONY.

1. What is a normal salt? An acid salt A double salt?

2. Differentiate sulphates and sulphites.

3. What is the chemical name of Epson salt? Glauber's salt? Give the formula o each.

4. How does hydrogen dioxide act as an antiseptic?

5. Complete the following equation and name each resulting compound:

B_2O_2 plus H_2SO_4=

PRACTICE—DR. F. D. PATTERSON.

[Written for the MEDICAL BRIEF.]

Miscarriage.

BY W. L. KREIDER, M. D.,
Prairie City, Ill.

In the March number of the MEDICAL BRIEF, on page 222, I read an article giving directions how to manage a case of miscarriage, in a word, every time from one month to nine.

The method of terminating gestation.—The method, as directed in that article, to my mind, is a very dangerous one, to say the least. I do not believe it is ever necessary to dilate the cervical canal. A female sound, when properly used, is all that is necessary in any case. Then give Nature sufficient time to do the work, and you will always be on the safe side. Irritate the parts as little as possible. I have practiced medicine for more than forty-eight years, have attended many cases of confinement, from one month to nine; have attended as high as ten cases in a week, and have never lost but one case. She was regularly confined, had twins, both male, and both lived. Two hours after confinement she had a convulsion, and had twenty-seven more, and died twelve hours after the first convulsion. I think this is a remarkable record, and that any physician should feel proud of it. Many physicians nowadays are using strong antiseptics. I fear frequently they do much harm. I never have used anything but warm water to keep the parts clean, without soap or anything. Water alone will cleanse the parts perfectly, when properly used, and will leave them in a much healthier condition than when antiseptics are used. I look upon it as bad practice to keep a woman in bed two weeks after a mis-

carriage. When all goes well, three or four days is long enough.

I would ask my medical brothers to stop and think. I have thought out things that were as new to me as though some one had told me. Rely on your own good judgment and do not follow the fads of the day.

[Written for the MEDICAL BRIEF.]

Various Types of Typhoid Fever.

BY J. W. BRYANT, M. D.,
Shamrock, Mo.

Do we have a true type of typhoid fever west of the Mississippi River? Some doctors have an abundant crop (?) of it in early summer, mid-summer and autumn. I have had cases that approached typhoid in their course, but the bowels presented no symptoms of the lesions described in the text-books. And again, I have had cases that are ordinarily designated as typho-malarial where there was a copious, watery, bilious diarrhea without hemorrhage, but with much tympany of the bowels. The evacuations of the bladder would be green. Duration of illness from five to eight weeks. Convalescence followed by loss of hair.

The question continues to present itself to my mind, why the old-fashioned name of bilious fever would not still be more correct (certainly more descriptive) than typho-malarial, when there is such a lack of typhoid symptoms?

In September, 1902, I was called to see a girl, twelve years old, living on a hill, near a water course. I found her with a remitting type of fever. She had quit school ten or twelve days before I saw her, on account of the fever coming up; and her folks had been trying to break the fever with domestic remedies. I put her upon an anti-malarial treatment, and after a more or less worried course, dismissed her on the twenty-fourth day from my first visit. In six days I was called back. Her temperature was 104° F., pulse one hundred and twenty. She was vomiting bile, and voiding bile from both bowels and bladder. The relapse was brought about by her folks giving her all the fruit she could eat. I had a very bilious case on hands for another twenty-nine days. Counting up, we have ten days before I saw her; then, twenty-four days under my treatment; six days I was absent; then, twenty-nine days under treatment again; making a total of sixty-nine days. There was no delirium, no hemorrhage from the bowels, no petechia. The skin was of an icterode hue. The hair fell out in convalescence. There was some nervousness, but it was due to an overtaxed system.

While I was treating the above case, I was called to see a negro man, aged twenty-two, who had, the day before I saw him, been brought to his home in Callaway County, Missouri, from Jacksonville, Illinois. I found him with a temperature of 104° F., pulse one hundred and ten, coated tongue, a bloody-watery diarrhea. Under the opiates to control his bowels, he had a mild delirium. His parents asked me if he would not have inflammation of the bowels by keeping them locked so long. I warned them that perforation of the bowels might result from a movement. The first week, the bowels were controlled nicely, but the continued delirium of the patient frightened the negroes—that and the fear that inflammation of the bowels would set up by the enforced constipation. The second week, they began to neglect the bowel remedy; the intellect cleared up, and the bowels began to move. Two considerable hemorrhages brought the negroes to their senses. They began to give bowel remedy regularly, and the hemorrhages were brought under control. After the hemorrhages, the pulse reached no higher than ninety-two, temperature no higher than 101° F. But the man was endowed with a strong constitution and made a rapid recovery.

This case of typhoid was imported from Illinois.

Last May I attended a case (that extended well into June) that had all the symptoms of typhoid, except bowel symptoms; there was mild delirium, subsultus tendinum, and the rose-colored spots; dry, cracked tongue. Constipation was so persistent that I resorted to a mercurial purgative about twice a week during the twenty-one days he was under treatment.

ter treating this early summer case, ember brought me a series of cases, similar to the case with which I ed this article—the bilious type. there were two walking cases of a grade of fever; thick, yellow coating ongue, moist skin, constipation, no ium, no subsultus. A chronic ma- l toxemia.

hen I was fortunate enough to reach se at the outset, I gave a stirring urial, and followed with four-grain of quinia sulph. regularly, and nti-pyretic remedy. The case would r be aborted or much shortened. A 's neglect would be followed by a tedious attack. The time (in the e of a case of fever) that a physi- is called has much to do with the of treatment. When a case enters a chronic course, strychnine and ic are indicated. The patient is not apable of bearing the heroic doses lomel and quinine as he was at the . I find that the present coal tar dies are quite effective in high fe- No rule of treatment holds good in ases, because each case has an indi- lity of its own. Fevers in the city features dissimilar to kindred cases he country. Malaria is a more or complication of all fevers in the ry, while typhoid approaches nearer e type in the crowded city.

[Written for the MEDICAL BRIEF.]

Some Practical Items.

BY E. R. ELLIS, M. D.,
Detroit, Mich.

hile there are many things in the ice of medicine and surgery which not any one invariable rule or od thereon, there are some in which easy and simple means are best, and sometimes overlooked.

epistaxis, I have frequently found directing the patient to press his r against the side of the nostril n does not bleed and instruct him to in deep, full breaths over the bleed- urface, and expire through the open h, quickly stops the hemorrhage. him first blow his nose freely, so remove clots, and then inhale and exhale rapidly for several minutes as above. The cool air goes in over the raw surface and comes out warm through the mouth, and cool air, as we all know, is one of the best hemostatics.

In the syncope, or collapse, which often attends the giving of chloroform, or other anesthetic, a method which is always at hand and may be instantly used, is that of inverting the patient. Let his head hang to the floor, and jig him up and down in this inverted position, as you would rinse an empty milk bottle—will speedily cause him to catch his breath and remove all danger. I tried this plan over thirty years ago, and it has never failed me since. What is peculiar in these cases is that those which are most fatal generally attend on the first or second inspiration of the anesthetic. The drug seems to paralyze the heart, the blood settles away from the brain, and the syncope or collapse which follows is most alarming and sometimes fatal. Inverting the patient, as above, turns the blood back to the brain and is the remedy which is always at hand and effectual.

A modern fad among surgeons is circumcising boys, and even babies. This is a most cruel, brutal and unjustifiable procedure. All male children should be looked to frequently to see whether or not they have constriction or adhesion of the prepuce—one or both. In such case it is not difficult to completely remove the trouble without mutilating the organ in the least. Where there is adhesion, the part can be torn loose by forcibly pushing the foreskin back over the glans and cleaning out the smegma which is very sure to have collected there. If the foreskin is too much contracted to be pushed back, the contraction is confined to the mucous, or inner layer, and not to the skin proper, or outer layer. In this case, strain back the outer layer as far as it will easily go, and with the knife or sharp scissors, inserted under the mucus lining, slit it up on the dorsal side freely. Then insert a stitch at the sharp angle of the inner and outer layer with one or two more stitches on the sides, and you have a perfect job. The skin, or a portion of it, turns under and eventually changes to mucous lining, enabling the foreskin to move freely back and forth, whereby the glans can be kept

clean and protected by the cover which nature has provided.

Circumcision leaves the glans bare and subject to much irritation from the clothing with an uncouth fold or ruffle of tissue about the organ. Ten years ago, I drew up a bill and sent it to our legislature, making the circumcising of a child or minor a crime. It was not acted upon, as I expected, for I mainly wished to call public attention to this brutality, hoping to discourage, and even prevent it. I was induced to do this from witnessing the screams and frantic actions of children of Jewish parents, who had been recently thus mutilated, on the sight of a doctor or strange man, for a long time afterwards. A man, be he doctor or not, who will thus mutilate a helpless child ought to be very much ashamed of himself, if he is not prosecuted. As a religious "rite" it is absurd, when forced upon a child, and can have no "saving" effect. After adult age is reached, a man should have the operation performed on him if he desires. But how many would in such case? Very few, I am sure.

20 Wilcox Street.

Summer Complaint.

BY J. C. BRISTOW, M. D.,
Wayne City, Ill.

I must tell you of a new treatment used in this place for summer complaint in a child that a woman brought to me for treatment. I asked the grandmother, who brought the child, what it was that was tied around the child's neck. She said that it was a mole's foot that was tied on the back of the neck and a chunk of brimstone tied under its chin. The child looked like it was at death's door, but of course, it got well. I am in the eightieth year of my age and the fiftieth of my practice; had lived in Kentucky in the "good old slavery days," knew the rabbit-foot charms, and of other hoodoo doings of the slaves, and had also read of some wonderful remedies of the Celtic Druids, but it seemed to me that this mole's foot arrangement outranked them all.

[Written for the MEDICAL BRIEF.]

Placenta Previa—Drug Addiction.

BY W. S. ROBINSON, M. D.,
Nashville. Ark.

We can not select a plan of treatment suitable to all cases of placenta previa. The state of the cervix, the degree of hemorrhage, the variety of the placenta previa, would determine the course of action in any given case. With an undilated cervix, the placenta being central or a large margin over the os, we are confronted with a grave emergency, requiring judicious and prompt treatment.

I believe that it is agreed among obstetricians that as soon as the cervix is dilated, version is the ideal treatment.

Usually placenta previa announces itself by profuse hemorrhage, the patient is partly exsanguinated, and the cervix, as a rule, is sufficiently dilated to introduce one or two fingers. I have never seen a case in which two fingers could not be passed through the cervix when there had been profuse hemorrhage.

The central variety should be handled with the greatest expedition. It is this type of cases that is most serious from the standpoint of hemorrhage during and after labor. Sure, you must not waste time with tampons or your rubber bags or any artificial means to plug the cervix, but dilate sufficient to introduce your fingers and do bipolar version.

"That man will have the best results in placenta previa who least regards the life of the child."

We should have at hand the appliances to treat this alarming condition. The insertion of the utero-vaginal tampon from the fundus to the vulva, should be kept in place for twenty-four hours and gradually removed.

We do not meet the cases under ideal conditions, and I doubt the possibility of making a diagnosis of placenta previa before hemorrhage occurs and at a period of pregnancy when the child is viable. Hemorrhage before viability is very rarely serious, and as a rule we may carry the woman to the end of the seventh month, but hemorrhage beginning before the end of the sixth month should make us look very closely for placenta previa centralis.

It should be given three or four
efore the expected period, and con-
until the flow is free. In amenor-
is also one of our most efficient
In rheumatism of the uterus, to
false pains, or the many unpleasant
ions attending pregnancy, it has no
n the *materia medica*, and becomes
partus prepurator.

Bartholow says there is little doubt that it increases the contractility of unstriped muscular fiber in a manner similar to ergot, but much feebler. It stimulates the venereal appetite in man, and promotes the menstrual flow in woman.

In a practice of more than twenty years, following the indications for the use of macrotys, I have never been disappointed. In treating cases of threatened abortion, before the membranes are ruptured, alternated with specific viburnum, I have not had a failure. I have used macrotys in cases of false pains that sometimes come on a few weeks before the time for true labor with unvariable success.

For the pains and unpleasant sensations that occur during the last months of gestation, give five drops, three or four times daily. It will give great relief, and your patient will bless you when she comes to her confinement. I would say to the young doctor, give this remedy a thorough study, and a fair trial, and it may be that a wider range of usefulness may be found for it than we now have any knowledge of.

A Plea for More Thorough Examination in Stomach Troubles.

BY W. J. HODGES, M. D.,
Pineville, Ky.

I take it that there is scarcely one of us who would attempt to diagnose or prescribe for any kidney lesion without having made a chemical examination of the urine.

But on the other hand, however ready we are with pencil and blank to scratch off our favorite mixture of strychnine, acid and pepsin, or arsenic pancreatin and rhubarb to every one who comes to us with stomach symptoms, and in the most cases adding fuel to the fire, simply because we do not know the chemistry of the contents of the stomach for which we are prescribing.

Why the difference? The chemistry of the stomach secretions are as well known as is the chemistry of the urine, and the analysis is as easy in the one case as the other, it being equally as difficult to arrive at a proper diagnosis without a chemical analysis in either.

Then why show preference to the kidney lesion? Certainly it is not because we can do more for them. The reverse is true. Then let me plead with you to analyze the contents of patients' stomachs and see how many of your favorite digestive compounds are worse than useless.

Hemorrhoids.

BY CHARLES L. CRIDER, M. D.,
Crooksville, Ohio.

Hemorrhoids which, for various reasons, do or can not be treated surgically, may be successfully treated, and seventy-five per cent permanently cured by the internal administration of ichthyol in from ten to fifteen minim doses every four hours, in pill or capsule. Never attempt to give ichthyol per orem other than as above prescribed, as it is very disagreeable and the patient will either not take it at all, or very irregular.

Treatment of Acne.

BY L. G. DOANE, M. D.,
New York City.

Dr. A. H. Ohmann-Dumesnil, an eminent physician and dermatologist, of St. Louis, uses the following ointment for acne:

℞ Sulphuris	1	drachm.
Acid Salicylic	½	scruple.
Resorcin	½	scruple.
Vaseline	1	ounce.

M. Sig.: External use.

Face baths of warm water, correction of the secretions, regulation of the diet, and punching out of acne pustules complete the treatment. Every specialist knows what is necessary, and will suggest such means and methods as are necessary.

Multiple Examination.

LINCOLN, NEB., April 4, 1905.

EDITOR MEDICAL BRIEF—Allow me to congratulate you on the stand that you have taken against multiple or dual examination of physicians every time he crosses the boundary line of a State. The physicians in every State should feel an interest in this important question, and thank you for the stand you have taken and presented through the MEDICAL BRIEF. Multiple examinations required of physicians who have graduated from reputable medical colleges (who, for reasons best known to themselves, move from one State into another, and there be subjected to re-examination, sometimes by catch questions and incompetent boards) is an insult to the educated physician. If every State used different text books on anatomy, physiology, pathology, surgery, *materia medica*, etc., or if the treatment of contagious, infectious and all other diseases would have to be changed, etc., then re-examinations would be justifiable, but under existing circumstances those multiple examinations are humiliating to the educated physician who has complied with all the requirements of a reputable college, viz., four years in college and final examination as to his proficiency to practice medicine. I believe, like the Editor, viz., we ought to have some national legislation to regulate this injustice. Let every physician send in his protest with *bracketed* interrogation points (?). WM. PROTZMAN, M. D.

To Abort Pneumonia.

BY J. M. FRENCH, M. D.,
Milford, Mass.

1. You must be called in the first stage, the earlier the better.

2. Apply a mustard paste to the affected side and follow this with a hot poultice, using any of the formulas having kaolin as a base.

3. Secure elimination by giving calomel in divided doses, followed by a saline.

4. Treat the fever with aconitine or veratrine, guarded if necessary by strychnine and digitalin, in solution, and dosage for effect.

5. As a respiratory antiseptic, administer carbonate of creosote, one teaspoonful in hot milk four times a day to an adult.

With this plan, begun early and carried out faithfully, you can abort a large proportion of your cases of pneumonia.

rly Surgical Interference In Gall-Bladder Disease.

BY WILLIAM H. CARMALT, M. D.,

fessor of the Principles and Practice of Surgery in Yale University; Fellow of the American Surgical Association; Member of the American Medical Association; Secretary of the Congress of American Physicians and Surgeons, Etc., Etc., New Haven, Conn.

A few years ago surgeons operated only suspected or assumed stones in the l bladder and ducts. Investigations this subject have brought to light a nber of conditions which require sur-al intervention, our knowledge of them ing been derived by what Kehr speaks of as "autopsies in vivo," unsuspected conditions found in operations, instead of knowledge derived from the *post-mortem* table. We are learning to make exploratory operations for conditions that may be relieved long before it becomes so serious as to suggest a *post-mortem*. A distinguished member of our profession, in a neighboring city, suffered for nearly twenty years with what he supposed to be attacks of dyspepsia, or indigestion, as he called it, more or less severe. The suggestion having been made that there might be a gall-bladder disease, an operation was resorted to, and a large number of unsuspected stones were found in the gall bladder; the gall bladder was thickened and eroded, there was a fistulous opening between the gall bladder and the duodenum. Cholecystectomy done, the hole in the duodenum was sewn up, and he has for the last two years enjoyed health that he had not had for the previous twenty years.

We must learn to operate before these conditions exist, if possible, and the early symptoms of gall-bladder disease studied with more acuity than heretofore.

I do not propose to go over the symptomatology of gall stones and gall-bladder disease at present. That has already been done by many good men, and I simply now wish to call attention to the excellent chart which Professor Brewer has published in the transactions of the Congress of American Physicians and Surgeons in the volume for 1903.

Infection of the gall bladder is so easily accomplished from either the colon bacillus or the typhoid bacillus, that one should always be suspicious of intestinal disturbances in the upper abdomen, particularly in patients who have had typhoid fever, and although we know stones may exist in the gall bladder in great number, not presenting symptoms calling attention to them during life, and found as surprises at the *post-mortem* table, there are patients who have suffered for years with suspected simple indigestion, duodenitis, etc., who really are suffering from infection of the gall bladder containing stones. The presence of stones offers increased opportunity for infection, but infection may come without the formation of calculi, and much can be done in the way of operative procedure directed towards the relief of the local conditions arising in the upper abdomen.

Malignant disease of the gall bladder, as is well known, may be caused by the presence of stones which, of themselves, give rise to very few objective, or even subjective, symptoms. Surgeons wonder in these days, after their cholecystectomies, what the gall bladder is for, so much relief is obtained by its removal, and so little ill-effect is produced thereby. Cholecystitis has widespread effects where the disease extends upward, perhaps, into the hepatic ducts, gall ducts, or by continuity, through the common ducts into the pancreatic ducts, producing a chronic interstitial pancreatitis, and even without this, adhesions, more or less firm, between the gall bladder, the duodenum, the stomach, the colon, ascending and transverse, extending down not infrequently often involve the cecum and the appendix. Two cases operated upon recently showed simultaneous, or consecutive, one can not say which, involvement of the appendix with cholecystitis, and it is quite possible that some of the unsatisfactory results following operations for chronic appendic were due to the fact that we had not tended our exploration far enough along the cecum and the colon to expl the gall bladder, and relieve conditi there. In both the cases just referred the prominent symptoms were toward right hypochondriac region, and the op ations undertaken in order to relieve s pected conditions there, whether stones simple cholecystitis, was not definitely termined beforehand. In both, chro inflammation of the gall bladder was vealed, without stones, but firm adhesi of the colon to the gall bladder, contrac and thickened gall bladders, and the flammation was traced down along ascending colon until the appendix found involved in a series of adhesio which justified the removal in both stances.

We should operate to relieve conditi that threaten trouble, without waiting the actual trouble to begin. Comparis between gall-bladder disease and app dicitis has been made, and the conditi are sufficiently alike to allow us to tr them in the same way. The compa tively less danger of acute suppurat cholecystitis, as compared with acute s purative appendicitis, is due, of cou to the fact of the more protected situat of the gall bladder, as compared with appendix, the appendix lying almost f in the abdominal cavity, and when it comes the seat of acute suppurative flammation from the colon bacillus, a g eral peritonitis is likely to occur, unl the omentum comes down and prote as, fortunately, it frequently does. gall bladder is enclosed, has thicker wa it lies in contact with other organs the vicinity, adhesions form quickly, p tecting the general cavity, and while do not have general peritonitis follow suppurative cholecystitis as frequently we do suppurative appendicitis, it lays foundation for many local conditions t require interference later.

One has only to look over the statist given in Mayo's recent articles on t subject to appreciate the great variety conditions which may arise, calling the highest surgical skill for their rel and yet which might have been preven by a more timely interference. My obj

ing these few words is to urge upon ofession, both medical and surgical, alert for early symptoms of gall- r disease, and take the steps neces- o prevent its wider development.

Since this ttack she complained of general ess, loss of appetite, general indis- n, and claimed she was unable to to her household duties. Shortly he second attack she was curetted. resented herself to the clinic Octo- 1904. Stated that five weeks ago d last menstruated, but for one day which was the first time that she er menstruated so short a time. temperature at that time was F. General appearance was fair. mplained of pain and tenderness lower portion of the abdomen. Tu- bout two inches in diameter was found to the right of the uterus. This was fairly sensitive and apparently slightly fluctuating. A diagnosis of extra-uterine pregnancy was made, and on October 10, 1904, the abdomen was opened, and it was found to contain a small amount of fluid blood, and the tube was found the seat of an ectopic gestation, which was removed. The abdominal wound was closed, and the patient made an uneventful recovery.

Case 2.—Miss S., twenty-three years of age, single, presented herself at Lebanon Hospital, October 17, 1904, stated that she had never had any illness previous to the present one, which dates from September 11, when her menses appeared one week after the usual time. On careful questioning she stated that she thought she had been pregnant, and had taken medicine which she believed was the cause of the appearance of the menses. She stated that there had been no mechanical interference. The flow continued, more or less irregularly, until she entered the hospital. Shortly after it commenced she noticed a few small pieces of material in the blood discharged, and the physician she consulted curetted her, believing that she had had an incomplete abortion. Following curettage, she complained of slight pain in the left side, and had quite a good deal of fever. On examination there were decided evidences of inflammatory disease, involving the pelvic structures, and it was believed that she had pyosalpinx on the left side, and very probably an extra-uterine pregnancy on the right. In spite of the fact that she had never had severe fever; temperature was about one hundred, and her general appearance fair.

October 20, the abdomen was opened, and the above diagnosis confirmed. The infection was so severe and the clots in the ectopic so fetid that the abdomen was drained. She made an uneventful recovery.

Last winter it was my fortune to operate on seven extra-uterine pregnancies in five weeks, and I believe that was quite largely due to the fact that at Lebanon Hospital sepsis following abortion and pregnancy at term are admitted. Several of these cases of extra-uterine pregnancy were believed to be sepsis following

abortions, as will be noted was the case in the two histories just cited. This diagnosis is justified, when superficial examination of the symptoms is made. For in both cases you have symptoms of early pregnancy. In both cases you have a discharge, frequently continued some time; usually in extra-uterine pregnancy the escape of blood is not excessive, but that is not always the case. In one instance I found it necessary to tampon the uterine cavity to prevent the patient from bleeding to death. In both extra-uterine pregnancy and sepsis following early abortion, you have a slight rise of temperature, and you have in both instances the escape of more or less solid material and clots, which many times are not very carefully examined. Of course, in an extra-uterine case you would never find a fetus.

In my experience one of the most important symptoms of extra-uterine pregnancy is a slight irregularity in the menstrual flow, and when the flow comes it is of very short duration at first. Another important one in quite a large percentage of cases is cramp-like pain, which may be very intense in one side or the other, associated with fainting, or a condition very closely approaching it; at the same time there is usually a discharge of blood from the vagina. The patient usually recovers from this attack, and in from five to ten days has another very similar one, again recovers, and again the attack returns. These attacks become more and more severe as time goes on, and if allowed to persist will frequently cause the patient her life. With these attacks there is a marked blanching of the face, which is usually the result of the abdominal shock, due to the escape of blood into the peritoneal cavity. In more rare instances, and always late in the disease this blanching is also due to loss of blood.

It is needless for me to give a description of a classic case of extra-uterine pregnancy, as my idea is simply to throw out a few hints to assist in making a differentiation between extra-uterine pregnancy and early abortion.

[Written for the MEDICAL BRIEF.]

Uterine Polypi.

BY H. HUGH HELBING, M. D.,

Professor of Gynecology and Abdominal S gery in the American Medical College. St. Louis, Mo.

These growths are of two gene classes, determined pathologically. Th are either glandular or fibrous. The f mer, also, denominated mucous polyp usually develope from the cervix, origi ally, and are due to a proliferation of t cervical glands. The latter, as a rule, iginate as sub-mucous fibroids in the fu dus, or body, of the uterus, and are gra ually forced downward during their d velopment. It is of this form of polyp to which we wish to direct your atte tion.

The causes of fibroid polypi are son what obscure. They may be due to sor irritation of the uterine wall. Negro are more apt to be afflicted with fibroi and age, also, is a predisposing cause, f they usually appear about the time t patient is approaching the menopau The reason for this is the fact that th are slow in growth, requiring eighteen twenty years before they attain sufficie size to cause disagreeable symptoms.

A uterine polypus is manifested by tw leading symptoms, pain and hemorrha The former is produced by the contra tions of the uterus in its efforts to exp the tumor. The latter are due to a thi ning of the lining membrane, and a co sequent exposure of the uterine vesse Besides menorrhagia, metrorrhagia a dysmenorrhea, the patient may suff from pressure symptoms, due to encroac ment on the bladder, or rectum, so t patient may complain of pain in the sa ral region, reflex headache, etc. She ma have lost so much blood as to exsangui ate her, leaving her exhausted and an mic. The diagnosis should be made bi-manual palpation and inspection. the growth occupies the uterine cavity an is small, it will be difficult to determi whether the wrong be polypi or e dometritis; it may be impossible, u less we can introduce the finger hig enough in the cervical canal, to feel t growth. If it is sufficiently large, say t

a walnut, we might with a sound
ne the diagnosis by outlining the
and its pedicle. With the sound
an increased depth of the uterine

nately, by the time the growth
sufficient size to occasion trouble
atient, the polypus presents in the
canal so that we may discern it
ection, or it may be seen by di-
the canal. According to my ex-
e there is no relationship between
of the growth and the amount of
hage it will produce. The very
t, perhaps only the size of a pea,
use as much hemorrhage as one

ive ergot, or ustilago maydis, to
e uterine contractions, and force it
f hemorrhage is severe we may
he uterine cavity with iodoform
which will stimulate contractions.
mia exist, administer soluble ci-
of iron, or the peptomanganate;
ny other medicines that may be in-
l.
tric treatment is more of a pallia-
ture than curative, looking to time
menopause, when we hope the
s will begin to atrophy and hemor-
ease. However, this rule is more ap-
plicable to other forms of fibro-myoma than to the sub-mucous, or to polypi. Suffice it to say that galvanism, positive pole active, and the use of ten to twenty milliamperes may be used for checking the hemorrhage. The only curative measure that can be instituted with any degree of success is surgical in its nature.

The reason for presenting this subject to the readers of the BRIEF is the fact that I recently secured one of the largest polypi that I have ever seen on record, and a picture of which I herewith present.

The specimen measures twenty-two centimeters (nine inches) long, and eleven centimeters (four and one-half inches) in diameter. The longest diameter of the pedicle, which was ovoid in shape, was two centimeters. It was attached to the left lateral border of the external os.

The patient, who was thirty years of age, was being treated by Dr. J. L. Ingram, who had observed it protruding from the vulva the day previous to its expulsion from the vaginal canal. At first appearance we thought it might be an inverted uterus, but upon closer examination we located the cervix and pedicle of the growth. It had evidently been

expelled from the uterine cavity during a period of two or three days, all of which time there were hard labor pains. We merely ligated the pedicle, after transfixing and severed it. The patient recovered promptly. Examination with the microscope of sections of the growth showed it to be a fibroid, and non-malignant. Other methods of severing the pedicle are by torsion, or with the ecraseur, usually adopted where the growth is attached high up in the wall of the cervix, or body of the uterus.

[Written for the MEDICAL BRIEF.]

A Contribution to the Pathology of Alcoholic Neuritis.

BY HARLOW BROOKS, M. D.,

Assistant Professor of Pathology in the University and Bellevue Hospital Medical College; Curator to Bellevue Hospital (4th Div.); Pathologist to the Montefiore Hospital for Chronic Diseases; Fellow of the American Association Military Surgeons; Member of the Neurological Society; Pathological Society; Fellow of the Academy of Medicine; etc.; etc. New York City.

James Jackson, of Boston, in his paper on "A Peculiar Disease Resulting from the Use of Ardent Spirits," published in 1822, first described alcoholic neuritis. Magnus Huss, in 1852, in his classical work on chronic alcoholism, described the condition much more fully, and ascribed the symptoms of this peculiar type of paralysis to lesions of the central nervous organs. This theory held for a considerable length of time, until investigations of the peripheral nerves established the presence of lesions here, the first of these cases being published by Dumesnil. Numerous observations by subsequent investigators showed the constancy of these peripheral changes, and now the conception of the disease became that the peripheral lesions were the basis of the paralysis, an idea that is still generally advanced in nearly all the text-books, most of which still classify alcoholic neuritis as a primary condition of the peripheral nerves, and generally occurring without lesions of the central nervous organs, except such secondary ganglionic alterations as necessarily follow degeneration and death of the peripheral portion of th nerve fibers.

According to this idea, the disease, a regards its pathology, is generally su divided under two classifications, namel a parenchymatous neuritis, in which th earliest or chief alterations are in th nerve fibril, that is, degeneration of th axis cylinder process and interstitial typ in which hyperplasia of the endoneuriu and perineurim are primary; pressur atrophy following in the axis cylinder pr cess. It is, also, generally stated tha these changes are found independent o any alterations in the brain and cord; i other words, that the condition is purel a peripheral one, and that it is never, o rarely, accompanied by degenerations i the spinal cord and brain.

The great impetus given to researc concerning changes in the ganglion ce following the announcement of the "Neu rone Theory," and the important contribu tions of Neisl, by means of which it wa made possible to study with at least som degree of accuracy the finer and earlie changes in the ganglion cell, produced a once a large number of studies concernin the alterations in the nerve cells in alc holism. Van Giesen, Ewing, Berkeley and many others, showed definitely tha alcoholism produces changes in the gan glion cells of the cerebral cortex, of th spinal cord and spinal ganglia, whic while of no definite, or specific type, wer such as to seriously interfere with th proper function of those cells, and whic if continued, must eventuate in death, o such serious crippling that axis cylinde degeneration must follow.

Now, accepting this incontrovertibl evidence, we are forced to the conclusio that either the neurone theory is wholl erroneous, or that those alterations in th ganglion cells, in cases of chronic alc holism, must cause degenerations of th axis cylinder processes in the tracts o the brain, spinal cord and peripher nerves.

With the view of substantiating o overthrowing this theory Lambert and have been conducting a series of invest gations on; first, cases of typical alcohol neuritis, occurring, as the disease mos frequently does, in young women; an second, a series of consecutive cases o

y chronic alcoholism, with the
n these instances of ascertaining
urrence of degenerated fibers with-
ious clinical manifestations.
d very briefly, we have found in
s of alcoholic neuritis marked de-
ive changes in the cortical cells of
ebrum, particularly in the motor
accompanied by degeneration of
ing fibers in the internal capsules,
descending columns of the spinal
ot a true tract degeneration, but
isolated and somewhat widely
ed fibers.
e spinal cord extensive cystoplas-
eneration has been shown in the
n cells of the anterior horn, those
entro-lateral group being specially
and degeneration of isolated fibers
nterior nerve roots being invaria-
nd.
ional degenerated fibers have also
und quite commonly in the ascend-
ts of the spinal cord, particularly
nore pronounced cases, this degen-
being undoubtedly accounted for
rations, sometimes very marked
the ganglion cells of the posterior
nglia.
quite unnecessary to say that the
in the peripheral nerve trunks
pical in each of these cases, for
se they would not have been se-
or this series of studies, and from
ve lesions it is perfectly apparent
peripheral nerve changes are con-
upon, and not primary, to degen-
in the ganglion cells of the spinal
d posterior root ganglia, and that,
y to the rule, these cases usually,
ys, show degeneration of the de-
g fibers of the brain.
r second series of cases we were
show in a considerable percentage
descending degenerations in the
cord and, occasionally, in the as-
tracts, as well; sometimes with
netimes without degenerated fibers
peripheral nerve trunks, which are
mmonly involved in alcoholic neu-

these facts, which are corrobor-
numerous other investigators, it
perfectly clear that we must modify
nception of alcoholic neuritis and
theory corresponding to the incon-
testible lesions, and confirming the original conception of the earlier writers; namely, that the disease is of central origin, due to primary ganglion cells degeneration, especially of the cells of the anterior horns and posterior root ganglia, caused by alcoholic toxemia.

There can be no doubt but that this association and interdependence of central and peripheral changes explains satisfactorily the "Korsakoff Syndrome."

Though we believe that these are the primary alterations of all cases of parenchymatous alcoholic neuritis, it is quite possible that certain cases of primary interstitial neuritis do exist in alcoholism; perhaps from the proliferation of the endoneurium and perineurium following the chronic inflammation of the arteries nourishing the nerve trunks. It is, however, most probable that the interstitial hyperplasia is, in most cases, due to a primary degeneration of the nerve fibers, and a compensatory proliferation of the connective tissue of the trunks.

Implantation of Omentum in Inguinal Hernia as a Radical Cure.

BY WALDO BRIGGS, M. D.,

Professor of Surgery and Dean of Faculty of St. Louis College of Physicians and Surgeons; Consulting Surgeon St. Louis City and Female Hospitals; Chief Surgeon Jefferson Hospital; Member American Medical Association and St. Louis Medical Society, St. Louis, Mo.

In operation for the radical cure of hernia, especially the inguinal variety, I have had, as no doubt others also have had, great difficulty in making a permanent cure in a great many cases, no matter what method was used. It is conceded by the majority of surgeons, I believe, that the most satisfactory results have been obtained by the Bassini method. Previous to two years ago I invariably used this method, with varying success, in a great number of cases. The results were satisfactory in every respect, but in some there was a return of the hernia, although the technique was quite correct, I am sure, and for this reason I have devised a new method, which makes a permanent

result, and also simplifies the operative measure. It consists simply in the usual procedure as to incision, with excision of the sac and withdrawal of the omentum, which is secured in the inguinal canal by fixation. In dealing with the sac it is necessary to transfix the neck with double ligature, and thereby ligate the two sections of the neck of the sac before fixation. After this has been done we withdraw the omentum through the inguinal ring, fasten it in position by a suture through the pelvic ring. I have used this method in a number of cases in the past two years, and the results have been very gratifying. I invariably use silk for transfixation and ligature, the same material in the closure of the wound, as my experience has taught me that material such as catgut is too rapidly absorbed, causing frequent failure.

The following cases are of surgical interest:

Hysterectomy Following Perforation of Septic Uterus With Either Probe or Curette.—On entering hospital patient was in a most critical condition, emaciated, temperature subnormal, pulse one hundred and twenty, weak and thready; respiration, twenty-eight; facial expression, pinched and anxious.

History.—Abortion at fourth month of gestation, occurring about eight days previous to consultation. A curettage about three or four days after passing fetus for retained placental tissue. Examination revealed abdomen distended, dullness over entire pelvic cavity, uterus enlarged and exuding a copious purulent discharge through the vagina. Uterine sound readily passed beyond the depth of the handle, evidently into the abdominal cavity. Abdominal exploration was immediately decided upon, and the patient was quickly prepared for operation. The usual incision was made and the uterus lifted into the incision, a perforation through the fundus presenting, supposedly made by probe or curette. The tissue of entire organ was almost disintegrated, and the pelvic cavity was filled with pus. With the entire field in view we passed the forceps through the vagina, clamping on either side of the uterus. After remov we irrigated the cavity with normal sa solution, established drainage through v gina and abdomen, closed the incisio Patient was so extremely weak that stim ulants had to be administered frequentl during the operation. Injections of no mal salt solution were made at interval of six to eight hours during the fir twenty-four. She made a good recover and is now in excellent health.

An Unusual Appendix.—Boy, fourtee years of age. The little patient wa brought to the hospital for treatment recurrent appendicitis. History of cas revealed attacks at different intervals fo several years. During attacks temper ture would range from 103° to 105° Examination elicited tympanitis over en tire abdomen, with dullness over lumba and hypogastric regions.

Operation by vertical incision over bo der of rectus muscle. On entering cavit found extensive inflammation, with adh sions, the appendix being completely bu ied. Enucleating appendix, found it e tended into the hollow of the sacrum then over its rim to the left inguinal r gion. Length of the appendix, eleve inches. Incision closed after usua method. Patient made an uninterrupte recovery, incision healing by first inte tion.

500 North Jefferson Avenue.

The Use of Bromide in Sea-Sickne and in Combination with Drugs.

BY CONSTANCE V. CURTIS, M. D.,
Phoenixville, Pa.

Bromide given, five to ten grains, thr times daily, a few days before sailin quiets the vomiting centers.

If the sea-sickness develops later t bromide should be given in effervesci draughts.

Bromide of potassium given in com nation with quinine, or salicylic acid, w prevent cinchonism; is, also, used to all the depression and nausea which foll the use of opium.

rlet Fever—Its Etiology and Channels of Infection.

SEPH PRIESTLY, B. A., M. D., D. P. H.,
Officer of Health, Lambeth Borough;
orary Secretary of the Incorporated
ociety of Medical Officers of Health,
London, England.

ere is now strong and increasing evi-
that, at least, the later desquama-
f scarlet fever is not infectious.
ological researches indicate that the tonsillar and buccal mucus, not only in the early, but also in the later, stages, is the principal source of infection in scarlet fever (as well as in diphtheria)."

Such is the latest *dictum* of the Society of London Medical Officers of Health, and the standing of the society, and the professional eminence of its members, are sufficient guarantees that careful consideration has been given to the subject of the infection of scarlet fever, before such resolutions were approved as the society's opinion.

Such an opinion is warranted to stagger the old practitioners, even to shock somewhat the young practitioners, and would certainly cause those of the profession who are dead and gone to turn uneasily in their resting-places were they to hear of such advanced doctrines being held by any one! Bacteriology is, in part, to blame, coupled with more exact and careful investigations into the sources of the alleged infection-channels of scarlet fever.

Scarlet fever (or scarlatina, as it is sometimes designated) is a specific infectious disease, due to the entrance into the body, from without, of a germ (or germs) derived from a previous case of the same disease (human or bovine). The *incubation* of the disease is short, varying from a few hours to a few days (generally three to four days); and the *invasion* is sudden, consisting of high temperature, headache, vomiting (sometimes), sore throat (palate and tonsils), flushing of face, suffusion of the eyes; followed by the appearance, in a day or two, of a rash, consisting of fine, red points, closely aggregated together over wide areas of skin, which has a flush all over it. This rash appears, generally, on the second day, is well-marked on the third to fourth day, and begins to fade on the fifth to sixth day, to be followed by desquamation of the skin on, or about, the ninth day; such desquamation lasting, at times, as long as six to eight weeks.

The rash begins on the neck, face and chest, extending to the trunk and limbs, and disappears, momentarily, on pressure. The glands at the angle of the jaw are enlarged and tender during the early stages of the disease; whilst the tongue

rapidly becomes furred (with enlarged papillæ), giving rise to the well-known "strawberry appearance."

The complications and sequela of the disease are well known, and are simply mentioned as important factors in dealing with the morbidity (as distinct from the mortality) of the disease.

Scarlet fever was first recognized as a separate and distinct disease about two and one-half centuries ago, and it is to Sydenham and Fothergill that this honor belongs; although the disease must have been scattered throughout Europe (more especially the Northern portions) for many centuries past, appearing in epidemic form every few years, and with a malignancy which the medical men of today can hardly realize, but which must have caused a mortality rate of twenty to thirty per cent (as compared with the present three to five per cent).

The Registrar-General of England first separated the statistics of scarlet fever and diphtheria in 1856, and taking the returns since then, as already published, we find as follows, for England and Wales:

Scarlet Fever—Death rate per million living at each year of age under five:

Decennia.	Under 1 year.	1 yr.	2 yrs.	3 yrs.	4 yrs.	Total under 5.
1861-70	2026	5172	5907	5687	4667	4624
1871-80	1414	3965	4535	4286	3469	3489
1881-90	671	1896	2112	2048	1706	1669

Scarlet Fever—Death rate per million living at all ages, and at quinquennial groups of ages, up to twenty-five years of age, subdivided into males and females:

1. Persons:

Decennia.	All ages.	0 —	5—	10 —	15 —	20-25.
1861-70	972	4621	2182	501	153	93
1871-80	716	3489	1515	325	104	63
1881-90	334	1669	762	153	41	26

2. Males:

Decennia.	All ages.	0 —	5 —	10 —	15 —	20-25
1861-70	1011	4745	2220	468	149	80
1871-80	750	3591	1554	318	107	55
1881-90	346	1712	758	148	43	23

3. Females:

Decennia.	All ages.	0 —	5 —	10 —	15 —	20-2
1861-70	934	4503	2144	534	157	105
1871-80	683	3387	1475	330	101	70
1881-90	322	1627	765	158	40	28

From the above three tables the follo ing important and interesting conclusio may be drawn:

(*a*). The annual mortality from sc let fever has fallen steadily and marke from nine hundred and seventy-two three hundred and thirty-four per milli of the population at all ages, during period of thirty years.

(*b*). The fall applies to both ma and females, the males from one thousa and eleven to three hundred and for six, and the females from nine hundr and thirty-four to three hundred a twenty-two, respectively, per million the population at all ages.

(*c*). The mortality from scarlet fe is higher amongst *males* than amon females; both at all ages, and also in c dren under ten years of age.

(*d*). The mortality from scarlet fe is higher amongst *females* than amon males, in the case of persons aged years and over.

(*e*). The mortality from scarlet fe in children under five years of age *lowest* in those under one year of age, a *highest* in those between two and th years of age.

(*f*). The disease is a disease of c dren, and extremely fatal to those tween the ages of one and five years.

As to the cause of the steady marked fall in the annual mortality fr scarlet fever, there are two opinions, (1). Diminished prevalence of the ease, and (2) diminished severity of disease in recent years. It is difficult decide which of these two views is correct one, though hospital statist and the recent notification statis (which are now available, since the ease has been notifiable), appear to fa the latter. Thus, the returns of the L don fever hospitals show a decline the case-mortality (*i. e.*, deaths per cas from twelve and one-half per cent 1872-6, to three per cent (or less) to-d though the numbers of notifications

during part of the time, during the disease has been notifiable in) have steadily increased, year by

Paris statistics, too, show a persis- low mortality from scarlet fever, back as records are available, *i. e.*, the past twenty-five years; a con- of things partly explainable by nparatively small proportion of n under ten years of age to the population. In diphtheria, the op- obtains. American statistics tell ne story, viz.: A lessened mortality carlet fever, and the published re- rom Christiania, where notification sted since 1860, show that there e mortality has varied from an of 17.8 and 14.3 per cent during nd 1870-9, to 9.04 and 5.56 per cent 1880-9 and 1890-9, respectively.

probable that both views are cor- nd that the decline in mortality carlet fever is due to both dimin- prevalence and diminished viru- Whether or not improved sanita- nd hospital isolation account for ady diminution in the prevalence ulence of the disease, it is difficult le definitely, and the subject will rred to again.

incidence of scarlet fever on the ion at different age-periods is ob- from the notifications received, hich it appears that the greatest ce is on children in their fifth becoming rapidly smaller and with the advance of years. The to attack is small in the first life, though the mortality-rate at ticular period of life is very high. hout the whole period of life the sex is more liable to the disease e male sex, but the attacks in the re, as already pointed out, more to terminate fatally, both at all l, also, in children under ten f age. Forty-five per cent of the of scarlet fever are amongst chil- nder the age of five years.

is way there is a double gain in ng a child from scarlet fever in- especially during the first few f life. Every year of escape ren- e child less and less susceptible, ter a certain age the child is prac- tically insusceptible; whilst, when the disease is contracted, every year that the attack is put off reduces the danger to life that such attack brings.

The seasonal prevalence and mortality of the disease deserves notice. The mortality is greatest in October and November, and least in March and April, at least so far as England and Wales are concerned; though the opposite is found to be the case in New York. The prevalence of the disease follows the same lines, but to a more marked degree, showing that when most prevalent the disease is least fatal, and *vice versa*. A condition of things due to the large numbers of mild cases that occur during epidemic times. In fact, these mild cases (many unrecognized) prevent a true mortality rate being obtained, and render it probable that the present rate is much below three per cent. These mild (unrecognized) cases are so well known that there are some physicians who hold that there is a form of scarlet fever without eruption, the so-called *scarlatina nil eruptione*. This is doubtful, however. There is no doubt, on the other hand, as to these mild cases causing the disease to spread in schools and elsewhere.

Meteorological conditions do not appear to affect either the prevalence or mortality of scarlet fever, though some observers (Longstaffe and Gresswell) think otherwise, holding that there is an *inverse* relationship between scarlet fever and the annual rainfall, and a *direct* relationship between the disease and a large amount of aqueous vapor in the air, especially with a concurrent diminished barometric pressure).

One attack of scarlet fever is, undoubtedly, protective, rendering the patient immune for life, as a rule.

As to the bacteriology of the disease. Different views are held. Thus, Klein, Fränkel and Freudenberg describe the germ as a *streptococcus*. Klein claiming that his own particular streptococcus, when injected into calves, causes death with lesions in the kidneys, indistinguishable from those seen in human scarlet fever. He describes it as non-motile, arobic, or anarobic, non-spore-forming and easily killed by drying and by exposure to sunlight. Edington, on the other hand,

states that the germ is a *bacillus*, which, when injected into rabbits and guinea pigs, causes erythema of the skin, followed by desquamation. Other observers, again, claim that the germ is a *protozoon*.

In view of these different expert opinions, it is safer to regard the actual germ, or germs (*i. e.*, the *causa causans*), of scarlet fever as not yet discovered.

Marmorek has made an anti-streptococcic serum, which is stated to give good results in the treatment of scarlet fever.

Whatever the exact germ, or germs, may be, the infection is given off in the breath (mouth and throat secretions), and from the skin, both in the early stages of the disease (even the prodromal stages) and, also, in the later, though it is probable that the desquamating skin is not infectious. The infection may last as long as six to eight weeks, *i. e.*, during convalescence, as well as in the acute stage; it being greatest in the latter case. The length of infection, due to (1) the persistency with which the germs cling to the follicles of the throat, and (2) the frequency with which complications and sequela are met with, more especially of the kidneys, middle ear, nose, etc. In this connection it may be that the urine is infectious, as it has been proved to be in typhoid fever.

With regard to the non-infectivity of the desquamation of scarlet fever, an experience of the writer of this article is unique. During the time of the smallpox outbreak at Leicester in 1891-3, it was decided to empty the scarlet fever hospital, and, consequently, not less than one hundred and twenty children, in various stages of desquamation after scarlet fever, were sent to their homes in the various parts of the town. Such a condition of affairs was favorable to a widespread outbreak of the disease, many *foci* of what is generally regarded as infectious skin, being scattered throughout a population of one hundred and eighty thousand and sixty-six persons (estimated), of whom one-fourth were children under ten years of age, and one-ninth children under five years of age. The disease ought to have spread broadcast. What are the facts, however? No single second case arose at any of the houses to whic the one hundred and twenty childre were sent, although they were careful watched for a period of three month This was a serious and dangerous exper ment, that had, compulsorily, to be mad and the results are significant. It ma be that it was a pure coincidence, an that were the experiment again made, u der different epidemic conditions, the r sult might be quite the opposite. Assur ing, however, that the experiment just fies a conclusion being drawn from th result, what ought that conclusion to be The farthest we can go is to say tha "particles of dead desquamating epith lium, or mucous membrane, are not infe tious *per se*, but that such particles ma act as carriers of infection, in the sam way as the hairs, or clothes, of a patie may; in other words, a desquamatin scarlet fever patient is not, necessaril a source of infection to others; but, o the other hand, a desquamating patie may be infectious, despite such desqu mation."

This is the only logical conclusion th can be drawn, and the only one that ca be safely drawn at all, as far as prese knowledge goes. This represents th opinion of the advanced school of medic experts in England (medical superinten ents of hospitals, medical officers health, etc.). There is no positive ev dence that desquamating epithelium *p se*, is a source of infection, and too mu importance has been attached to it in t past. Even the streptococcus of Kle or the bacillus of Edington have n been found in the desquamating cutic Further, the desquamation is the aft effect of the erythema that is the mo important diagnostic sign (though not ways seen) of the disease, and represen the death of the outermost layers of t cuticle, due to the trophic chang brought about by the scarlet fever p son, which circulates in the blood. Co pare, in this respect, the greater or less desquamation that takes place in all cas of erythema, especially marked in t so-called *erythema scarlatiforme desqua ativum* (a skin disease of a non-infectio nature), and least marked (as far as t eye can judge, but well-marked mic

ally) in the transient teething rat-
infants and children.
nnels of Infection.—These may be
d into two classes: (*a*) Direct,
person to person: (*b*) Indirect,
h the medium of clothes, food, ani-

Direct Infection. The throat and
ecretions in the early stages are
infectious, and the poison is read-
rried from person to person by the
, kissing, etc.; the commonest mode
pagation of the disease from one
to another, *e. g.*, in houses, at
s, etc. This mode of infection is,
es, difficult to combat, as the disease
e so slight as to be not recognized,
ongly diagnosed, as a trifling, non-
ous, catarrh or sore throat. In
hese mild, unrecognized and undi-
d cases cause the disease to be al-
with us, assuming, at intervals, epi-
proportions whenever the suscep-
lement (children between three and
ears of age) accumulates.
it be claimed that this mildness of
s the result of the efforts made in
st and still being made by sanitary
rities to prevent the disease? What
as general sanitation, hospital iso-
etc., played in bringing about such
e of affairs, if this be so? Unfor-
ly, no statistics are to hand to en-
a satisfactory conclusion to be
. The result is that two extreme
is have recently arisen in England,
ese may be called the *Hospitalites*
e *Anti-Hospitalites*. The former be-
that hospital isolation is all-im-
t in battling with scarlet fever, and
tter holding that hospital isolation
ard to this disease has proved a
(and has been, consequently, a
ss financial outlay). Between these
xtreme schools are all the interme-
views held by different experts, and
. For the present, at least, I recom-
the readers of this article to re-
er the advice given centuries ago:
edio tutissimus ibis."
. Indirect Inspection. The medium
gh which infection may be carried
. It may be (1) food, (2) clothes,
ng, etc., (3) animals, or (4) other-

Let us consider these various media somewhat at length, taking the most important, or, at least, the most interesting, first):

(1). Food (chiefly milk). It is now well-established that the poison of scarlet fever (be it germ or toxin) is, at times, conveyed to human beings through milk; the milk being infected either by a previous scarlet fever patient, or by the cow itself. Milk is, undoubtedly, a most suitable medium for the growth of the poison, which rapidly multiplies, when it gains access thereto. Such infected milk carries infection broadcast amongst its consumers, and an outbreak, or epidemic (thereby caused) is recognized by the suddenness of onset, the incidences of attacks, and the rapidity with which the disease is arrested when the supply of infected milk is stopped. The persons affected are the consumers of the milk, and comprise, chiefly, therefore, children and invalids; at least, as a rule.

The scientific interest connected with milk-borne scarlet fever rests on the opinions (expressed by some) that a bovine disease is capable of being transmitted through milk to human beings, in the form of scarlet fever.

An outbreak of scarlet fever in London (and elsewhere) in 1885 was traced by the officials of the English Local Government Board to a disease of cows on a farm at Hendon. The cows were found to be suffering from a vesicular eruption (with ulcers) on the teats and udders, from which Dr. Klein, the board's bacteriologist, obtained his *streptococcus*, similar in all respects to the streptococcus which he obtained, also, from scarlet fever patients (diseased tissues and organs). Cultures of this streptococcus (obtained from man), when injected into calves, caused death, with renal complications indistinguishable from those found in human scarlet fever, and when injected into newly-calved cows, caused ulcers on the teats, with other symptoms. This bovine disease is called the Hendon disease, and appears to be the same as, or nearly allied to, scarlet fever in man; at all events, the Hendon disease in cows causes the scarlet fever in man, under certain conditions. Other outbreaks of scarlet fever have since been traced to

bovine diseases, which are, if not the same as, at least similar to the Hendon disease, *e. g.*, Macclesfield (1889), Sutton Coldfield (1891), Glasgow (1892), etc.

Significant as the above facts appear, it is only fair to state that there are experts who maintain that, in the instance quoted, the scarlet fever outbreaks arose through milk, which was contaminated and infected by previous *human* scarlet fever, and that the bovine disease was *vaccinia*, and in no way connected with the scarlet fever.

Many veterinary surgeons maintain that there is no disease in cows similar to scarlet fever in man, or in any way comparable with it.

Whichever view be taken, and it must be remembered that the "facts" connected with the Hendon outbreak satisfied the chief officials of the Local Government Board of England, there can be no shadow of doubt but that scarlet fever can be transmitted from person to person through the medium of milk (and what applies to milk, applies also to butter, cream and cheese). In investigating outbreaks of scarlet fever this channel of infection must be borne in mind, and inquiries made at the dairies and farms suspected, including a careful and minute inspection of both the employes and the cows.

2. *Clothes, Bedding, etc.*—The poison of scarlet fever is persistent, and remains attached to clothes, bedding, etc., for long periods of time, retaining its vitality. In this way the disease has been spread from person to person through the medium of clothes, bedding, etc., which have been infected by a previous scarlet fever case and not efficiently disinfected afterwards. All health officers, in the course of their experience, are cognizant of many such sources of infection, more especially where a garment worn by a scarlet fever-infected child, previous to such child being removed to hospital, has been put away carefully without previous efficient disinfection, and brought out again when the child returns home, causing a fresh attack, or attacks, of the disease in others (brothers and sisters or friends). Laundries and dress-making establishments may spread the disease. The lesson to be learned is that *efficient*, prompt disinfection is required in connection wi scarlet fever, even when the attack is mild as to be almost unrecognizable.

3. *Animals.*—Apart from the questi of the transmission of scarlet fever fr cows to man, it must be remembered th the poison may adhere to the hairs a fur of pet animals, and may be there transferred from person to person. Ca and dogs, which are allowed to be fo dled by children suffering from scar fever, and then to mix with other ch dren, carry the disease oftener than supposed. In the same way flies m mechanically carry infection from pers to person, as they do in cholera and phoid, and in, probably, other diseases.

4. *Otherwise.*—Toys, pictures (a other), books, etc., also, deserve attentio as common vehicles by which the pois of scarlet fever may be carried from p son to person, and the necessary preca tions should at all times be taken to p vent such sources of infection.

"Return" Cases of Scarlet Fever a Post-Scarlatinal Diphtheria.—No artic dealing with scarlet fever is comple without mention being made of (*a*) "R turn" cases, and (*b*) post-scarlatinal dip theria.

(*a*) *"Return" Cases.*—When a fre case of scarlet fever (or other infectio disease) occurs in a house (previous infected) within a certain definite ti (two, three or four weeks) of a p tient's being returned there from a h pital, convalescent from the same disea it is known as a "return" case, *i. e.*, secondary case, and is supposed to be, some way or other, connected with t return home of the previous case. Su "return" cases are well known to health officers, and are attributed gen ally to maladministration (*a*) of the h pital authorities in prematurely discha ing their patients, or (*b*) of the sanita authorities in disinfecting invaded hous and infected clothes and bedding, e The former view is supported by hea officers, who quote the fact that patie are, at times, discharged from the hospi with "peeling" skins, "running" noses ears, inflamed throats, etc.; whilst t latter view is supported by medical perintendents of infectious hospitals, w quote the fact that "return" cases oft

ır after some garment, or some article bedding (or clothing), has been ught out for use of the particular pa- t, or patients, on their return from ospital; such articles having been put y in an insufficiently-disinfected state.

he number of "return" cases varies siderably under different conditions, may, even in a well-regulated, and efully-administered hospital reach as a figure as three to five per cent of total cases discharged.

heoretically, such cases should not oc- at all; *practically*, they do. Indeed, difficult to see how they are to be vented, as they appear to depend upon rlety of causes, *e. g.*:

Premature discharge from hospital atients with "running" ears or noses, eling" skins, sore throats, etc.

Transference of convalescents direct n acute wards to their homes, thereby wing the infected air, which fills the s of such returned patients, to infect rs with whom they may come into act—mechanical carriers of infection.

Overcrowding in the wards of hos- ls, leading to delayed elimination of on from the patients, or the re-infec- of the patients, or to other infecting litions.

Imperfect, or inefficient, disinfection by the hospital authorities, *e. g.*, nes, hair etc,; (*b*) by the sanitary au- ities, *e. g.*, bedding, clothes, etc.

Unknown factors, still waiting dis- ry and investigation.

he above are the generally-accepted s as to the reason for "return" cases, the more experience one has the more cult it becomes to decide, definitely satisfactorily, as to the cause, or es, of such "return" cases; more es- ally, if the view be taken that (at t, late) desquamation in scarlet fever ot infectious, and that, consequently, nt "peeling" of the skin in a dis- ged patient does not necessarily mean ger to those with whom such patient come into contact. It is clear that patients with "running" ears, noses, should be discharged from a hospital hout careful precautions being taken he home, or homes, to which such harged patients return. Bacteriologi- , such ears and noses are a suitable *nidus*, in which the germs of the disease may lurk, hidden, in an active state, for a long interval of time, and so cause infection in others.

The seasonal influence of the disease must be remembered in dealing with "return" cases.

(2) *Post-Scarlatinal Diphtheria.*—This is a form of diphtheria that is liable to attack patients who have been in a scarlet fever hospital for a long time, and who are, generally, convalescent from the disease. The age-incidence is the same as, or resembles, that of primary diphtheria, though the fatality is higher, much higher, at times.

The disease is capricious in its occurrence, and may be due to one or more of the following conditions:

1. Insanitary conditions of hospitals (defective drainage, want of ventilation, etc.).
2. Overcrowding of hospital wards.
3. Aggregation of acute cases in hospital wards.
4. Transference of infection from diphtheria to scarlet fever wards by (*a*) medical staff, (*b*) nurses, (*c*) laundry.
5. Mixed infection; a patient suffering on admission into a hospital from both scarlet fever and diphtheria.
6. Contact in hospital with mild, unrecognized diphtheria cases (diagnosed as mild scarlet fever).

Anti-toxin has worked marvels in lowering the death-rate of post-scarlatinal diphtheria; the patients being injected at once, as soon as they show symptoms of the disease. In this way the best results are obtained from the anti-toxin treatment.

[Written for the MEDICAL BRIEF.]

The Principles and Practice of Embalming the Dead.

BY JOHN GEORGE GARSON, M. D. (EDIN.),
Vice-President of the Anthropological Institution of Great Britain; Honorary Corresponding Member of the Anthropological Societies of Paris, Moscow and Rome; Adviser on Identification to the Home Office; Late Swiney Lecturer to the British Museum, and Lecturer on Comparative Anatomy at the Charing Cross Hospital. London, England.

[No. 3.]

We have next to consider the mode of applying externally, preservatives to the body, a branch of the art of embalming

of much importance. For this purpose a strong solution of bichloride of mercury in spirit should be prepared and rubbed well into the skin of the head, about the roots of the hair, with a painter's brush, and the whole of the body should be painted over several times with a mixture of one part of the concentrated sublimate solution to about six or eight parts of glycerin.

If no further injection of the vascular system be required, ligatures may be placed around the artery immediately beyond each end of the double cannula, and tied. The cannular is then to be removed, and the edges of the external opening are to be brought together neatly and sutured closely with fine silk. The operation being completed, the body is to be replaced in the shell, along the bottom of which should previously have been arranged a thick layer of sublimate wood-wool.

In the foregoing description it has been assumed that the condition of the body has been favorable for the operation, and that no hitch has occurred during its performance. Things do not always run smoothly, however, and the operator must be prepared for less satisfactory conditions being present, and for accidents happening, and he must be ready to meet each and every emergency, just as he would do should they occur in the course of a surgical operation he was performing. It is only possible here to mention some of the complications which may confront him and render the operation more difficult.

Perhaps the most frequent complication which occurs in the course of an ordinary injection operation is the rupture of an artery. It generally takes place in the thorax, or the abdomen, and is usually the result of disease of the vessel, or organ, in which it occurs. In such cases one or other, or both, of these cavities must be opened in the manner to be described presently when a *post-mortem* examination of the organs has to be combined with an embalming operation, and the ruptured vessel secured by ligature, or otherwise; in some cases the organ in which it is situated must be removed, or its blood supply ligatured. Rupture of a vessel inside the skull is of little consequence, that being a closed box, and strictly limited in capacity, the extravasation of preservative fluid is small and the operation is not interfered with. In other parts of the body the vessel can more or less readily be got at and tied in which case the rupture does not materially interfere with the operation. Such accidents are, fortunately, not very common when the pressure with which the solution is introduced into the system is kept low. The important point is to recognize when a rupture has taken place so as to be able to deal with it.

The most troublesome cases to deal with are decidedly those in which general anasarca is present. Before attempting to inject preservative fluid into the vascular system, under such circumstances the dropsical condition must, as far as possible, be got rid of, otherwise the solution will not flow through the vessels into the tissues, owing to the coagulation of the albumin in the serum, which immediately results from contact with the preservative, especially if the base be corrosive sublimate, or chloride of zinc. The best course to pursue in these cases is to begin by making the incision in the abdominal wall, to expose the abdominal aorta; then if ascites be present, the fluid contained in the abdomen should be syphoned out with an India rubber tube. While this is being done the limbs should be elevated as much as possible, and then tightly bandaged from their distal extremities upwards towards the trunk with a broad India rubber bandage, such as is sometimes used in the treatment of callous ulcers. The bandaging may with advantage, be carried onwards beyond the limbs and made to include the greater part of the trunk. In most cases the inferior vena cava should be incised and punctures made where necessary, to let the serous fluid escape; the thoracic cavity should, likewise, be tapped from the abdominal opening by puncturing the diaphragm, and any fluid which it contains should be removed. After the condition of the body has been improved as much as possible, the abdominal aorta may be opened, the cannula inserted and the injection of the preservative solution proceeded with. It will be found, generally, that the injection has to be made under considerably higher pressure than

linarily required, and the risk of re of a blood-vessel is correspond- increased in consequence.

uld much difficulty be met with in g the injection to enter the system, y be necessary, after as much pre- ive has been introduced as can be to the arteries, to supplement this aking subcutaneous injections into uscular and cellular tissues at nu- s points over the body, as well as ne cavities. In bad cases it is, per- better to use hydrate of chloral dis- in alcohol and a little water. Cy- of mercury, or a solution of formic rde, instead of corrosive sublimate, oride of zinc solution, as being less to produce immediate coagulation albumin of the serum infiltrating ssues and clogging of the blood-ves-

en death has resulted from the ng of an aneurysm in the thoracic, dominal cavity, the injection should rformed from the ruptured vessel, has to be exposed for the purpose. *ost-mortem* examination of the vis- as well as the preservation of the by embalming, may be required. In case the injection of the vascular n, and the external application of rvative should, if possible, be done the application of preservative solu- to the visceral cavities being post- until after the *post-mortem* exam- n has been made. The latter should ke place before the lapse of twenty- ours after the injection of the vas- system. But circumstances some- demand that the *post-mortem* shall ne first, before any chemicals have introduced into the body. In this the best plan is to begin by making ong incision from the top of the um to the pubes, then to divide the um longitudinally, and forcibly to ate the thoracic walls as far apart ssible, fixing them in this position eans of two pieces of wood placed at end of the sternum. The space thus ned is limited, but by dexterous pulation it will be sufficient to en- the operator to reach the heart and , and to remove them. The aorta ena cava should be divided close to eart, a thread having previously been passed through each and the ends brought to the surface of the thorax, so as to facilitate the subsequent recovery of these vessels. The trachea should be divided just above its bifurcation; in doing so care must be taken not to injure any of the blood-vessels of the neck. The nerves and other structures having been divided, the heart and the lungs are then to be removed carefully, without disturbing their surroundings more than necessary. After their examination has been completed they should be washed and immersed in preservative solution. The esophagus and rectum are then to have double ligatures placed around them (the former just above the stomach), and divided between the ligatures; the digestive tract, with the pancreas and the spleen, are then to be removed; the arteries having been ligatured, one by one, as they are divided. A ligature should be placed on the inferior vena cava, above and below the liver, and on each of the other vessels these are then to be divided between the ligatures and the liver, and the latter removed. The kidneys are to be removed, after their vessels have in like manner been ligatured. The examination of the viscera having been completed they are placed in preservative solution for some hours, and, when the injection of the vascular system has been accomplished, they are to be returned to their respective places. If the brain is also to be examined the scalp is divided from ear to ear over the vertex and drawn forward and backward, with the periosteum and the muscles, and the calvaria is sectioned horizontally, without injuring vessels of the dura mater. In removing the brain the arteries should be divided sufficiently far above the base of the skull to permit of it being easily ligatured. On the examination of the brain being completed it should be placed in preservative solution. The interior of each of the cavities opened, having been carefully washed and dried, a systematic search is to be made for all divided vessels, and such of them as have not already been ligatured must now be secured; the foramina of the base of the skull, also, must be tightly plugged from above with cotton-wool, moistened with a thick solution of gum acacia. A large cannula is then to be introduced

into the aorta and firmly secured; the injecting apparatus having been attached to it, the injection of the vascular system may be proceeded with. Although apparently all the principal vessels have been tied, yet when the injection solution is turned on, it will be found to escape at numerous points where divided vessels have been overlooked, just as takes place in an amputation of a limb when the tourniquet is slackened. These must be secured by ligatures or compression forceps, as rapidly as possible.

In consequence of the loss of preservative solution which inevitably takes place, notwithstanding the pressure with which it is injected has been reduced to the lowest possible point, considerable more will be required than in ordinary cases, where the embalming is done in the first instance; the operation is also greatly prolonged, and much patience has to be exercised in performing it. There is, however, no reason why it should not be successful, if thoroughly and carefully carried out.

[Written for the MEDICAL BRIEF.]

Proctitis.

BY CHARLES J. DRUECK, M. D.,

Professor of Rectal Diseases at Harvey and National Medical Colleges; Rectal Surgeon to Lakeside, People's and Emergency Hospitals. Chicago, Ill.

Proctitis, or inflammation of the rectum, is quite commonly met with in general practice, and requires careful diagnosis and prompt treatment. Several different varieties are distinguished, although the symptoms in general are much the same in all, and the case frequently terminates in fistula.

Proctitis is divided into acute and chronic varieties, each of which has several forms, according to etiology or development. Thus, the acute consists of the catarrhal, dysenteric, diphtheric, and gonorrheal; the chronic, of the catarrhal, syphilitic, tubercular, papillomatous, and stenosing.

The catarrhal acute form of proctitis is due to intestinal disturbances, and occurs chiefly in children, although occasionally it is found in adults. Usually the mucous membrane alone is involved, l ing congested, even tumefied at times, a the epithelial layer may be shed off du ing the engorgement. In dysenteric pro titis, the whole colon is frequently volved, especially in the tropical varie The rectum, like any other mucous me brane, is liable to the invasion of dip theria, but infection is rare.

Gonorrheal proctitis is more frequent found in women, on account of the clo proximity of the vulva and rectum, and usually the result of uncleanliness, s omy or abscess of Bartholin's gland th has ruptured into the rectum.

The catarrhal chronic proctitis may sult from repeated attacks of the acute, may begin as a deeper and chronic infla mation. Constant reinfection and irri tion, together with a sluggish venous flo tend to prolong any inflammation in t rectum. In aggravated cases, the surfa is granular, with multiple ulcerati points. Hypertrophy of the glands curs, causing papillomatous growt which project into the lumen of the r tum (papillomatous proctitis). When t inflammation extends deeper than the m cous membrane, and involves the areol and muscular tissues around the rectu a constriction results later, from the co traction, and we have a stenosing pr titis.

In adults, proctitis may result from cal impaction in the rectal pouch, ex sure to colds, as sitting on a cold or w seat; foreign bodies in the rectum, ha substances in the fecal mass, as fish bon pins, hulls of cereals; injury from the of the syringe, strong purgatives or senic. bichloride of mercury, irritati suppositories, the extension of inflamm tion or colitis, or the irritating discharg from the bowel above. Esmarch repo a case of proctitis as a symptom of go the rectal inflammation alternating wi other symptoms. Proctitis may also sult as an extension of inflammation fr hemorrhoids, prolapse, or eczema abo the anus. Both acute and chronic proc tis may result from inflammation neighboring organs, as the bladder, pr tate, vagina, or uterus.

Symptoms.—The symptoms vary wi the severity of the attack, and the du tion of the trouble. The chronic for

ess painful and tender than the acute. ensation of weight, heat or fullness ars in the rectum, and may amount tual pain which, in severe cases, may lve the uterus, bladder and sacral re- and even radiate down the thighs. this tenesmus, a constant and in- tual desire to empty the bowel oc- and this continual straining fre- tly produces a prolapse of the mu- membrane, especially in children. Ir- ion of the trigonum vesicæ causes fre- t micturition, or sometimes retention. his time the engorged membrane is ing, perhaps with a mere streaking e passages, or occasionally considera- ischarge of clear blood.

lsey reports a case where this loss ood was the first symptom that at- ed the patient's attention. A case of itis with hemorrhage, without any ne antecedent symptoms, is rare. , mucus and pus are voided. Exam- on at this stage reveals ulceration to extent. It may be very superficial imited to one or two small points, or many focuses, some of which may be deep and involve the whole thick- of the mucous membrane, or even rate the bowel. When ulceration oc- above the peritoneal fold, it results ritonitis, and when below that line, ss and fistula. A chronic proctitis in this way, cause a stricture.

all forms of proctitis the anus is red painful, the sphincter and levator ani les irritable and spasmodic, and as- ted with the local symptoms there is ys more or less constitutional dis- nce. In chronic proctitis, the symp- are less marked, diarrhea alternates constipation, and the discharge oc- only with defecation. The inflamma- may be limited to only a small part e rectum, or may be more diffuse and ve all the organ.

e symptoms of dysenteric proctitis similar to the catarrhal chronic, ex- that more of the bowel is involved, the systemic influence more marked. n the diphtheric variety is found, the members of the patient's family ld be cautioned about using the same t. The gonorrheal form has its char- istic free, creamy, white discharge ng from the anus, the rectum becomes hot and swollen and the pain is burning and intermittent. The anus chafes and the sphincter is spasmodic. The proctitis is usually of short duration, and can easily be differentiated on account of the presence of the disease in the vulva, or urethra, and by finding the gonococci in the pus. It may, however, if untreated, degenerate into a chronic proctitis. The discharge is freer and contains more pus than any other form of proctitis. It must be remembered, though, that gonorrheal proctitis is rare. Gosselin saw only one case in three years at Louccine.

The following case in my own practice, some time ago, gives a vivid picture of this form of trouble:

Case 11.—Referred to me by Dr. G. W. W., and first seen by him; suffered from gonorrheal infection of the whole genital tract. Abscesses had developed in Bartholin's glands and, rupturing into the rectum, had produced labiorectal fistula on either side of the vagina, from which there was considerable discharge. The examination revealed sinuses into the rectum above the external sphincter. Examination showed, on inspection, a free discharge from the vagina, and, also, from the rectum, when the patient was requested to bear down; although the sphincter, which was spasmodically contracted, would ordinarily retain the discharge. The anus was quite inflamed. The digital examination showed that the rectum was tender and disclosed an abrupt stricture about two and one-half inches above the anus. This stricture was at nearly the lower level of the internal sphincter muscle, and was annular in shape and diaphragm in form, that is, a thin membranous septum. No marked induration was felt at any point, but as the finger was withdrawn it was covered with blood and pus and a few shreds of mucous membrane.

The observation through the speculum was especially instructive. The active inflammation began immediately above the external sphincter and appeared localized below the stricture spoken of. The whole mucous membrane had a honeycomb appearance, and was covered with white fibrous shreds resembling the "tripper fäden" of urethritis, only much lar-

ger. They were easily removed, but left the mucous membrane inflamed and bleeding. As the rectum was dilated, the stricture could be seen to stretch and tear. The trouble appeared to be localized within the lower two inches of the rectum.

Prognosis.—Proctitis is not very serious, as a rule, unless the cause can not be found and removed. When the cause is removed the case usually heals kindly, unless complicated by ulceration, abscess, or fistula. Sometimes a perirectal lymphangitis or phlebitis may protract the case or cause a fatal termination. Acute proctitis will pass off in ten days or so, leaving no appreciable, permanent alteration in the bowel, except in those cases where ulceration, or gangrene, has occurred. Chronic proctitis is liable to continue indefinitely, unless the cause can be removed. The mucous membrane is thickened and indurated, and loses its sensibility, more or less, so that a large bolus of feces may collect without stimulating the rectum to expulsion. Stricture of the rectum generally has some chronic proctitis associated with it; below the stricture the mucous membrane is congested and covered with pus or mucus, while above the stricture ulceration occurs.

A thorough examination of a case of proctitis is important, and a digital examination should be made in every patient presenting a chronic diarrhea, because many of the causes given above as predisposing to, or exciting proctitis, may be promptly determined. When the patient is placed in the knee-chest position, the proctoscope is well-oiled and introduced, and as the obturator is withdrawn the air rushes in and dilates the bowel, and by turning the proctoscope from one side to the other, and gradually withdrawing it, the whole surface of the rectum may be carefully and thoroughly explored.

Treatment.—The treatment of proctitis varies considerably with the exciting cause, and, therefore, before instituting any treatment a thorough examination must be made. The parts being irritated and inflamed, the examination is very painful unless an anesthetic, either general or local, is administered. In many instances, where, for various reasons, chloroform should not be given at th time of the examination, the patient ma be relieved of most, if not all, of the pai by applying a two per cent solution of co caine. A general anesthetic has much i its favor, because when the patient i asleep the sphincters may be thoroughl dilated, thus relieving the tenesmus an greatly facilitating subsequent examina tions or treatment. At the same time, an local trouble or cause of the proctitis ma be removed, thereby accomplishing tw things at one sitting.

Acute cases require absolute rest in bed because when the patient is up and abou his duties the dependent position of th vessels, together with the thinness o their walls and the associated congestio and inflammation, produce a venous sta sis which seriously impedes, or prevents regenerative changes.

The diet should be plain and of such variety as will insure soft, or semi-soli evacuations. It is also advisable to main tain a largely absorbable dietary that th bowels may move infrequently, thus spar ing local movements of the parts. Twic each day the bowel should be douche with two quarts of cleansing solution, a hot as can be borne. To begin with, temperature of 105° F. may be used, an the temperature raised each day. Plain boiled water, with the addition of a hand ful of salt, has given me the best result I have devised a douche tip of my ow to be used in these cases, because I hav found it impossible to obtain a free retur flow with any I have been able to find and unless the exit is large the fluid wi pass up into the colon and carry the in fection up with it, instead of washing i out. By practical experience I find tha douching in this manner washes out large amount of infectious material, suc as secretions, fecal accumulations an hordes of micro-organisms; dissolves mu cus and pus, flushing them out as shreds contracts the vascular structures, thereb stimulating circulation, and relieving th local congestion and depleting the tissue

Following the douche, about tw drachms of astringent antiseptics, o other medicinal mixtures, are injected, an the patient instructed to retain it. Silve nitrate, hydrastis, glycerole of tannin, o acetate of lead, in various combination

strengths, according to the case, are most reliable drugs. If the pain and mus are not relieved, laudanum and h water may be injected every two hree hours until the patient is re-d. From twenty to sixty minims are needed in this way.

t fomentations applied over the hypo-ium give much relief when the nmation extends over a large area, when there is general, diffuse pain enderness. In mild cases limited to ower end of the rectum, the applica- of cold to the anus and perineum, or njection of cold water into the rec- relieves the congestion promptly.

hen the proctitis is due to thread ns, injections of lime water, or salt r, and the administration of santonin nally, will be enough. Gonorrheal itis, like its counterpart in the ure- is especially intractible. Silver ni- solutions, one three-thousandths, d be used to douch the rectum, but ame conditions must be observed as mentioned above in speaking of the l douche. The strength is to be grad- increased as a tolerance is obtained a three one-thousandths solution is

Following the douche the whole us membrane is swabbed with bal- copaiba, or a suppository containing m copaiba and iodoform, each five s, may be inserted.

e chronic forms of proctitis are some- different. Barring the very mild it may be said that unless carefully ed they all become chronic. The ing should be instituted in these the same as in the acute cases, be- of its alterative effect. The exces- secretion is controlled with applica- of alum, zinc, or silver, or any of combined in a suppository with orm, or one minim of oil of turpen-

en ulceration, periproctitis, or any complication exists, it requires its treatment, which, for obvious rea- can not be entered into in this . Syphilitic cases are associated ly with strictures, which may re- surgical treatment, although I have astonishing changes occur under gen- internal medication. Tubercular itis is usually secondary to disease higher up, and is accompanied with so much ulceration, together with the general systemic infection, that treatment is unsatisfactory. The treatment of proctitis, due to cancer, is surgical, of course, and can not be considered in this paper.

Proctitis, in either the acute or chronic form, is always a serious matter, deserving of the physician's most careful attention, because the inflammation itself may debilitate, and especially because complications which may invalid the patient are prone to occur. Each case is a law unto itself, and this article can not go into the details that may perplex the attendant, but simply tries to give the reader a clear clinical picture in general, and to lay down the main lines of treatment.

[Written for the MEDICAL BRIEF.]

The Medical Practitioner and Dental Diseases.

BY ORION W. BEDELL, M. D., D. M. D.,

Professor of Operative Dentistry and Dental Embryology, Dental Department of Washington University.
St. Louis, Mo.

While the etiology and pathology of some dental diseases may not be clearly understood, the relation between them and some diseases coming under the observation of the practitioner of medicine is so clearly defined that it becomes important for him to have a good knowledge of such relation, in order to give his patients the best possible service.

The dental diseases thus associated with other troubles, either as causative factors, or, at least, intensifying them, may be classified under two general headings:

First. Those in which the disturbing factor is other than some definite infection.

Second. Those in which infection can readily be proven, and are usually accompanied by the formation of pus.

Under the first heading may be mentioned those disturbances of the pulps of teeth, which cause obscure, reflected pain of a neuralgic type, located by the patient in the ear, eye or temple region.

Under some forms of irritation it is found that the dental pulp undergoes de-

generative changes, resulting in the formation of calcific nodules within the mass of the pulp, and many of these formations, when they impinge upon the nerve tissue of the pulp, give rise to a distressing form of disturbance which is very hard to trace to its cause, especially as the teeth in which these nodules are located may be perfectly sound.

The patient may complain of severe pain about the side of the head, or it may even be located by them down the side of the neck, into the shoulder, or chest.

Pulps are also the seat of many vascular disturbances, which may set up a train of symptoms that are extremely hard to trace to the teeth; their greatest disturbances being reflected, or transferred, to parts at a distance from the site of the trouble.

Patients who habitually neglect the teeth, allowing carious conditions to remain uncared for, and calcareous deposits to collect in large and offensive amounts, may become the victims of digestive disturbances which, instead of being the cause of the unhealthy condition of the mouth, as is sometimes supposed to be the case, are really *produced* by the repeated partaking of food masticated improperly in this unhealthy oral cavity.

In the treatment of persistent neuralgias and digestive troubles that do not seem to yield to drugs, the physician should call to his aid the services of the dentist, whose training and appliances may be of great service towards the successful handling of the case.

Under the heading of infective troubles, there are diseases involving the pulp, the pericementum, and many tissues connected with the oral cavity.

Suppurative pulpitis, or pericementitis, causes some of the most severe suffering to which the human family is heir; especially is this true in connection with those cases where a considerable quantity of pus is formed about the roots of teeth, accompanied by swelling of the parts until the face is much disfigured.

In the hands of many physicians these cases seem to have been improperly handled, they having advised the patient to delay any operative procedures until the swelling had subsided.

These physicians would probably co sider it poor practice to allow any foreig body causative of suppuration to rema without heroic treatment. In a sens these teeth have become foreign bodie and are the source of irritation. If th teeth are not valuable enough to warra their treatment and filling, the indicati is to remove them as early as possibl as this affords the very best way for eva uation of the pus, and the use of indicat antiseptics. Many of these teeth, by ear and careful treatment, can be made usef for many years.

Suppurative conditions about the roo of upper teeth, posterior to the cuspid may result in the extension of infecti to the mucous membrane of the Antru of Highmore, with symptoms pointi only to persistent and foul catarrhal co ditions of the nasal fossa. Such cas should be carefully examined, especial when the catarrh presents the sympto of being unilateral, with an offensive d charge from one nostril. .

Suppurative conditions of the lower ja may result in the pus burrowing in th direction of least resistance and, aided b gravity until the abscess breaks on th side of the face or jaw, leaving a most u sightly scar that remains for life.

I believe it is a safe practice to nev place a poultice of any kind on the ou side of the face, in cases of dental absce but all poulticing and lancing shou be done from the inside of the mouth.

A case once came under the writer's n tice where the physician had poultice and lanced an abscess of this charact on the outside of the cheek, and had the maintained drainage from this fistulo opening by means of a silver wire, held place for eighteen months with adhesiv strips. The lady during this time suffe ing both bodily and mentally on accou of the condition. The tooth was extracte "which had been the original cause of th trouble," and almost perfect healing fo lowed within a few days. Of course, a unsightly scar remained.

The limitations of an article of th character preclude the possibility of pro erly setting forth all the diseases of de tal origin for which the practitioner medicine is called upon to prescribe. F the dentist to attempt the treatment

s of pneumonia, or diabetes, would oubtedly be a great mistake; so, also, he medical practitioner to attempt to all cases having a possible dental n without asking the co-operation of lental brethren, may result in his not ding the very best service possible.

[Written for the MEDICAL BRIEF.]

ronic Hypersthenic Gastritis.

ILLIAM VAN VALZAH HAYES, PH. B., M. D.,
ssor of Diseases of the Digestive System,
New York Polyclinic.
New York City.

ronic hypersthenic gastritis, often d acid catarrh of the stomach, is a se which, because of its prevalence the suffering it produces, is well wor- of consideration.

thology.—In its pathology, according an Valzah and Nisbet, the predom- ng changes are as follows: prolifer- of the border and chief cells of the ic glands; a variable infiltration and feration of the connective tissue, h in late stages of the disease may fere with the blood supply of the ds, thereby diminishing their num- ; and thickening of the mucous mem- e, which is covered with mucus, and times stained with blood.

iology.—Among the most important ors in the production of this of gastritis are indulgence in ol and tobacco, the excessive use of iments, the swallowing of coarse, operly masticated food and irregular excessive eating. It may follow tional disturbances of the stomach in h there is supersecretion. Long inued mental worry may readily be ctor in its production.

mptoms.—The symptoms vary in a derful degree. In some cases the se is undoubtedly present for months out giving much, if any, discomfort, here may be evidence only of bowel gestion or general nervousness, or the ptoms may be so severe as to make patient's life seem scarcely worth g. The most frequent symptoms are taste, regurgitation of sour food, rtburn, oppression in the chest, full- ness, weight, distress, nausea, headache, dullness, drowsiness and vertigo, usually coming on from one-half to two hours after the meal, lasting for a variable period, ordinarily decreasing in proportion as the stomach empties itself. The appetite is usually good, and it is frequently abnormally large, the patient desiring to eat heartily, but fearing to do so. These symptoms may only follow some unusual liberty in eating. Frequently they come after each meal and cause so much annoyance as to wear decidedly on the patient's nervous energy, and render him unfit for his duties.

This trouble is found in one of three stages. In the first stage, in which the stomach is able to empty itself in the normal time, the symptoms commonly do not last more than an hour or two. In the second, in which gastric digestion is prolonged, there is a corresponding prolongation in the symptoms frequently lasting from the onset until the next meal, unless some remedy is taken for its relief. Because of the prolongation of digestion in these cases fermentation with gas formation is apt to be present in a marked degree. In the third stage, in which the gastritis has progressed to such a point that its cure can not be hoped for, the symptoms vary, depending upon the degree to which the mucous membrane has been destroyed by the ravages of the uncontrolled disease. Ordinarily the distressing symptoms are diminished or relieved by the taking of food or some alkali.

Although the manifestations of this disease are more characteristic than those of many gastric troubles, yet a satisfactory diagnosis is commonly impossible without a study of the functional signs. Chiefly by means of the functional signs Van Valzah and Nisbet distinguish the three periods of evolution of the gastritis. In the first stage the quantity of secretion and the duration of gastric digestion are normal. Supersecretion and prolonged digestion characterize the second period. And during the third or terminal period the quantity of gastric mucus is diminished and the duration of gastric digestion is shorter than in health. In order to determine the condition of the stomach the employment of the Ewald-Boas test

breakfast, consisting of a French bread roll and one and a half glasses of water (seventy grams of bread and three hundred and fifty cubic centimeters of water) is practically the most convenient and exact method. One hour after this has been eaten the contents are withdrawn and analyzed. The bread is found to be in a fine state of subdivision, the odor is normal; mucus is found to be present in excessive quantity. The free hydrochloric acid is more than twenty and may run up to seventy or eighty (Toepfer's method.) The total acidity is more than sixty and may reach one hundred and ten or one hundred and twenty. The ferments are abundant. The salivary digestion is deficient. The microscopical findings are ordinarily uninteresting, unless there is found a portion of the mucosa, in which case evidence of gastritis, with proliferation of the glands, may be found. A trace of blood (chemical tests) is often present in the contents. The physical signs are not characteristic. Sometimes there is general gastric tenderness. Frequently there is evidence of excessive gas in the stomach and bowels.

Prognosis.—The prognosis in the earlier stages of the disease is good, provided the patient will obey orders. This affection is one which tends to become more serious, and unless the patient is willing to faithfully follow instructions it is useless to undertake his cure.

Treatment.—With present methods of treatment a complete cure can not be expected in less than two or three years. It is well to tell the patient that the disease will get worse and that the possibility of ulcer of the stomach is not remote in case he continues to neglect himself. It is most important that the causes of the trouble should be removed. The "cocktail" and "highball" must give way to pure water. Strong coffee and tea must be eschewed. All drinks which are too hot or ice cold are to be avoided.

It is scarcely possible to over-emphasize the need of keeping the nervous system continuously in a reposeful state. Whenever feasible the overwrought broker or the nervously exhausted prize-winning student should be induced to be less strenuous and to learn to work with less nerve-racking friction. If one of these patients can be sent off for a short vacation in th country the symptoms often disappear marked degree, only to return when h resumes his customary duties. In so fa as practicable we should insist upon li in the open air. The patient should tak his meals at regular intervals, five hou apart. He should endeavor to be reste when he eats and allow a half hour elapse after eating before resuming h usual occupation. He should, when po sible, exercise systematically in the ope air, but should never fatigue himself such a degree as not to feel rested afte lying down for fifteen or twenty minute He should sleep eight or nine hours ever night. He should partake freely of wate an hour or two before meal-time, and n take more than one glass with each mea being careful always to drink when th mouth is empty.

It is essential that all irritants, wheth in food or in drink, be removed from th dietary. Mustard, pepper, Worcestershi sauce, ginger, strong acids, and seed fruits or vegetables, such as strawberri and tomatoes, must be wholly forbidden

The cardinal indication is sedatio The food should be bland and nourishin Ordinarily a small amount of beef, mu ton or lamb, roasted or broiled, may b allowed once a day. At other mea chicken, turkey, partridge, quail, swe breads, calf brains, fish with tender whi fibre and not rich in oil, soft cooked eg and raw oysters may be eaten. Fat ten to reduce the acidity and it can ordinari be given to best advantage in the form butter and cream. Remembering that th rich acid is apt to prematurely arrest th action of the saliva, thorough masticatio of all starchy foods should be insiste upon. To accomplish this the breadstuf should be made up of the crust of wel baked French bread or rolls, pulled brea zwieback, or stale bread. Of the cereals ric cooked one and one-half hours, the fin preparations of wheat and hominy cook four to six hours, until thoroughly we done, are most desirable. Potatoes, eaten should be twice cooked, mashe and then baked. The vegetables co monly best borne are purée of spinac tender string beans, tender young pea stewed celery, summer squash, Hubba squash and young carrots. Of the frui

well to allow only the juice of an ge, the inside of three or four stewed es, the inside of a well-baked apple, h should not be tart, a ripe peach, or e Bartlett or Seckel pear.

cases where there is but little fer- tation and gas in the stomach or ls, there is no objection to the simple ts, such as vanilla ice cream, which ld always be eaten very slowly; rice ing, tapioca pudding, custard, sponge , etc.

e best drink is water. In suitable cocoa, cereal coffee and milk are to llowed.

the use of medicines it is important to t the supersecretion and to neutralize excess of acid when present. One- th to one-twenty-fifth of a grain of extract of belladonna, or one or two ms of the tincture with each meal, often of value. Some form of alkali een meals is usually desirable. For nple:

Bismuthi subnitratis.....2 drachms.
Sodii bicarb.....2 drachms.
Magnesiæ carb. levis.....2 drachms.
et. div. in chart No. XXIV. Sig.: One pow- with a drink of water two hours after each Repeat dose if necessary.

Bismuthi subcarb.....1 drachm.
Sodii bicarb.....2 drachms.
Magnesiæ carb. levis.....2 drachms.
et. div. in chart No. XX. Sig.: One or two a drink of water from one to three hours each meal.

rium oxalate, two to four grains, may dded to each powder if nausea is pres-

casionally one grain of chloral hy- e, in a drachm of chloroform water, n with each meal, is useful. Ichthyol, e to five minims, with an equal unt of olive oil in elastic capsule, may iven two or three times daily with fit; or, the following prescription be used:

Ichthyol.....1 drachm.
Carbonis ligni } a. a..... q. s.
Pulv. altheæ }
et. div. caps. gelat. No. XX. Sig.: One a drink of water at eleven, five and bedtime.

ccasionally one-fourth of a grain of ate of silver in a half ounce of water, n undiluted on awakening, for a week en days, proves of great assistance.

here the digestion is much prolonged he mucus is in marked excess, lavage he stomach may be desirable. Plain water, one per cent solution of ichthyol, or one in two thousand solution of nitrate of silver may be employed. The latter may be left in the stomach for one or two minutes, after which it should be washed out with plain water. Where the nervous element is an important factor it is desirable to give for a time strontium bromide five to twenty grains daily.

In controlling the constipation remedies should be employed which do not stimulate the gastric secretion.

Briefly summarized the essentials of treatment are:

1. Removing all irritants from the bill of fare.
2. Securing, continually, repose for the nervous system.
3. Employing lavage when indicated.
4. Using sedative medication.

[Written for the MEDICAL BRIEF.]

Stricture of the Urethra.

BY LOUIS GROSS, M. D.,
Clinical Lecturer of Genito-Urinary Diseases, College of Physicians and Surgeons, San Francisco, Cal.

Although there is no particular method of treatment suitable to all cases of stricture of the urethra, yet the different and numerous procedures are not opposed to each other; each has indications and a useful sphere of its own; yet, in my experience, I find dilatation, either interrupted or continuous, the method of choice, and one that should not be abandoned until we find it unsuited to the individual case. In many chronic cases, some of which have had an external urethrotomy previously performed, have I been able, by combining continuous with interrupted dilatation, to enlarge and maintain the caliber of the urethra. Another advantage of this method is that it does not interfere with operative procedures, should the case subsequently demand it. I would never advise the performance of an external urethrotomy without a guide, unless absolutely compelled to do so, much preferring to wait until a filiform can be passed through the narrow opening.

In this treatise I shall deal particularly with strictures of very small caliber—ones almost impermeable. Undoubtedly there are many of these cases where physicians have made unsuccessful attempts in passing the instrument and have complicated the case with numerous false passages, but if one possesses ordinary skill and the necessary patience, there are very few strictures which will not permit the introduction of an instrument.

Case 1.—One particular case in my clientele is that of an Englishman who had a gonorrhea many years ago, and through the use of some caustic remedy his stricture originated. While in Hong Kong, about two years ago, he consulted his physician, who made futile attempts in passing the stricture, after which he informed the patient his urethra was normal, and the best plan was to discontinue treatment altogether. He consulted me about a year ago with the following symptoms: Slight, gleety discharge, stream of urine small, and the act of micturition consuming considerable time and demanding much straining. With some difficulty I was able to introduce a tapering bulbous bougie, No. 5, French scale, and by gradual dilatation was eventually able to pass a No. 28. The discharge disappeared entirely and the stream is quite free.

The next two cases illustrate how much can be accomplished by dilatation in extremely tight strictures, recurring many years after an external urethrotomy.

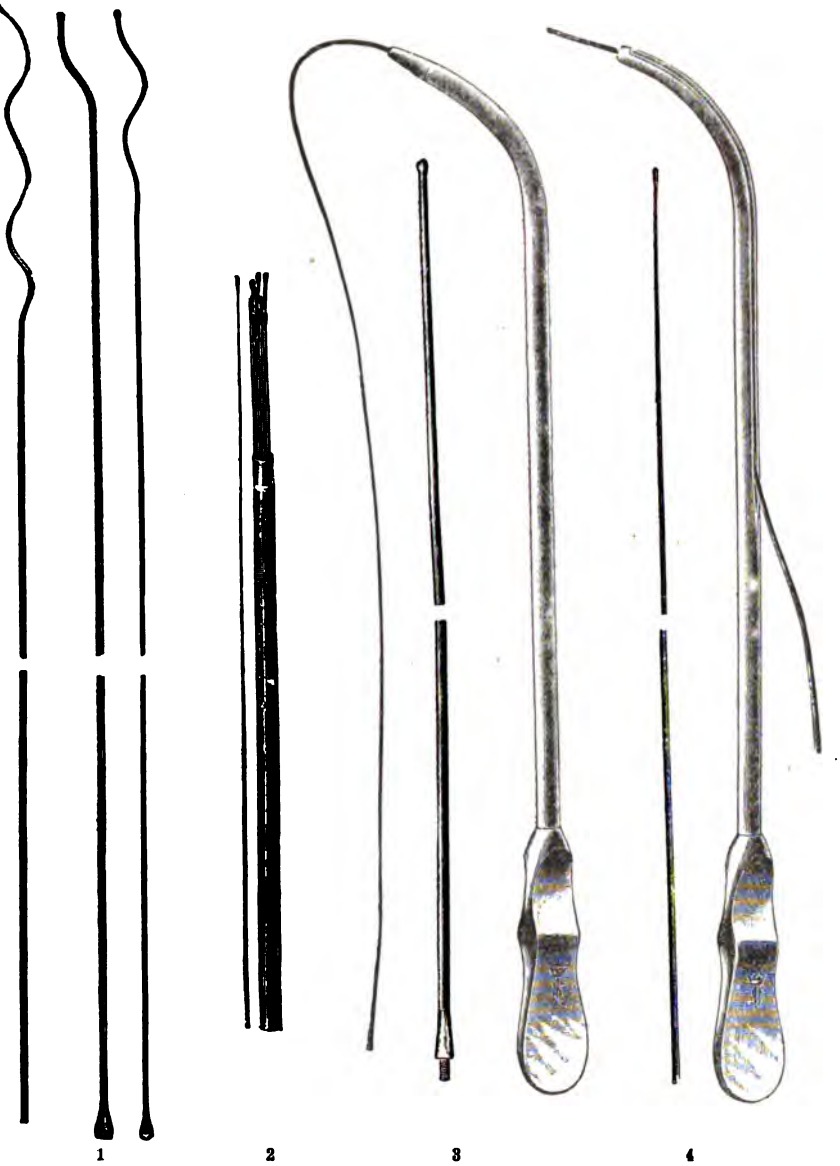
Case 2.—L. C., age forty, laborer, recommended by Dr. H. D'Arcy Power, November, 1902. Eleven years ago suffered from attack of gonorrhea, and a year or two afterward noticed that the stream of urine was becoming smaller and smaller, until one day (six years ago) had complete retention. Operated upon by external urethrotomy, which relieved him for a few years, when the same lessening in the size of the stream was again noticed. Having had an exernal urethrotomy performed, I decided upon continuous dilatation, after having passed a filiform. The instrument used was a Le Fort sound, which was screwed to the filiform. The stricture dilated rapidly, and at the end of a week and a half the patient was around. I was able to gradually increase the size by interrupted dilatation. The last sound passed was a No. 28, Frenc scale. The patient left the city and r turned in February, 1904, when his ur thra readily passed a No. 23, which wa increased to a No. 28.

Case 3.—A. L., widower, forty years seen at the City and County Hospital i September, 1904. Had gonorrhea abou fifteen years ago, which became chroni and was treated for many years. Abou six or seven years ago had complete r tention of urine, after relief of which h was operated upon by external urethro omy. He was instructed by the a tending physician to pass sounds at state intervals, but neglected this advice alt gether. Upon examination, found that h was passing urine in drops only. I a temped to pass a tapering bougie, bu without success. I then had recourse t the filiform, and after failing to pas same, patient was instructed to hold th filiform tightly against the strictur After a rest of about an hour, one passe through, which was tied in. Next day Gouley's tunnelled sound was passed ove the filiform, when Nos. 10, .12 and 1 sounds (French scale) passed throug At the present writing the patient's stri ture admits a No. 26 sound (Frenc scale) without difficulty, but some car must be exercised on account of a fals passage on the right side of the bulbou urethra. This can be avoided by passin the sound from the left side, that th beak of the instrument may avoid it. Pa tient had no instrumentation from No vember 8, 1904, until May 18, 1905, whe No. 18 sound passed stricture. Only r maining five days in the city I quickly d lated it to No. 28, French scale.

Case 4.—Dr. W. J., physician, thirty seven, married, first gonorrhea ninetee years ago, four subsequent gonorrheal in fections in the following seven years. I 1891 noticed a gradual diminution in th size of his urinary stream, considerabl straining, frequent attacks of cystiti tenesmus. Complete retention of urin for twenty-four hours, which was relieve by a full hot bath; four subsequent a tacks of retention within the followin two months. During the year 1894 an ex ternal urethrotomy was performed. Afte the operation the urethra admitted a No 30 sound (French scale), which size wa

nued weekly for a period of six hs, after which time they were ed monthly. At the end of the month e would be a recontraction to No. 22,

In our treatment of these tight strictures we should always begin with as large a tapering bougie as the stricture will admit, gradually reducing the size



No. 1. Whalebone filiforms, spiral ends.
No. 2. Whalebone bougies, straight.
No. 3. LeFort's sound, with filiform attached.
No. 4. Gouley's tunneled sound.

n would be eventually dilated up to 30. Sounds were passed regularly month until four months ago. At writing I was able to pass a No. 14 ing bougie.

should we fail to pass it. As the urethra is usually complicated by the presence of false passages, it is simpler to pass a bougie than a filiform. Should the smaller bougies not pass, then our only recourse

is to the filiforms. To facilitate the introduction of a filiform it is well to distend the urethral canal by injecting warm oil, holding the meatus tightly and passing the filiforms into the distended urethra. Undoubtedly the oil passes through the narrow opening of the stricture and enlarges and lubricates its lumen, facilitating the passing of the instrument. Introduce the filiform and with a rotary movement push it forward. This may engage in the orifice of the stricture. If not, introduce another, and so on until the urethra is filled with filiforms, trying one after another until one passes through. Should this plan not be successful, then rest the patient and instruct him to hold them tightly against the stricture, and within one or two hours we may follow the same manipulations as outlined above, which procedure is nearly always successful. The urethroscope has proved of little benefit in my hands, as the obturator prevents the tube from getting in close contact with the face of the stricture.

The instruments used are those of Le Fort and Gouley. The Le Fort instrument consists of a filiform bougie, to which a screw is attached, and after the filiform is passed, the sound, which contains a female screw, is attached to the end of the filiform and passed through the urethra into the bladder, the filiform curling up in the bladder. This sound can be removed and a sound of larger caliber can then be passed. With Gouley's instrument, the ordinary whalebone bougies are passed through the stricture, after which the tunnelled sound is passed over the filiform. In order to avoid losing the filiform in the urethra, I usually grasp the outer end with a pair of hemostatic forceps after Gouley's instrument is attached.

The question arises: Why should we subject an individual to an external urethrotomy, when there is so much danger of a recurrence, should the patient become negligent in his after-treatment? Does not continuous and gradual dilatation fulfil the same conditions? True enough, these tight strictures must be treated as long as the individual lives, yet do not the above cases demonstrate the fact that the same after-treatment must be continued after an external urethrotomy, or th will likewise recur.

In conclusion:

1. Dilatation is the preferable meth if the strictures will yield to this measu
2. There are very few strictures whi will not yield to dilatation.
3. After the performance of an ext nal urethrotomy, dilatation should alwa be insisted upon.
4. Dilatation is a successful meth in many cases, should the stricture rec after an external urethrotomy.
5. In very tight strictures, instead an external urethrotomy, a filiform shou be introduced, and the stricture dilat by continuous and then, later, interrupt dilatation.

"Remedies for Specific Conditions

BY PITTS EDWIN HOWES, M. D.,
Associate Editor "Eclectic Review,"
Boston, Mass.

Close investigation by critical obse ers have, in the past fifty years, elicit facts—which can be applied to the tre ment of disease—that were not dream of by our predecessors in the healing a

The search for specifics, that wou cure the various classified diseases whi are said to afflict mankind, has been d gently pursued by eager enthusiasts f many ages without success.

The trouble has been that the searc ers have been attempting too much. Th failed to realize that the departure fr normal health—which is termed disea —is of an exceeding complex charact That a great variety of causes may son times enter into a given disturban That what would relieve one attack pneumonia may be worse than useless another attack, even in the same pers That the various disturbances incident human life may be resolved into seve conditions, of which some are of mo importance than others.

When medical men began to gra these facts and investigate along the lines they learned that while specifi for diseases, as they are generally nam —such as pneumonia, bronchitis, chol

tum, dysentery, phthisis, etc., etc.—
ot to be found, yet the various con-
is which go to make up these ills—
ich human flesh is heir—can be spe-
lly treated, and treated with marked
ss.

rthermore, it was discovered that
the condition was determined in
any given remedy would produce
, it did not matter whether the pa-
was suffering from one disease or
er, the same effect was obtained.

m that time a rational system of
ine began to be evolved, and the
-rate commenced to decrease. The
cian who adopts this line of treat-
must become a skillful observer.
patient must be examined and
ed individually, if success is to be
ed.

m time immemorial the tongue has
a large factor in determining the
ment to be adopted. Yet it re-
ed for recent years to demonstrate
hat an extent this member of the
n body could be accepted as a guide
e successful restoration of normal
h.

ose who are constantly observing
ongue will easily notice two striking
itions. One where the tongue is of
p red color, and inclined to be nar-
and pointed. The other where it is
l and flabby, and covered with a
, whitish coating. The first of these
ate that the fluids of the body are
sely alkaline, and an acid is needed
store the equilibrium. When such
ndition is manifest the administra-
of lemonade, or a weak solution of
ochloric acid, as a beverage, will pro-
marked results. The other condi-
indicates just the opposite—that the
s are intensely acid, and a soda salt
eeded to restore the balance. Here
ddition of bicarbonate of soda to the
k will produce a happy effect. If,
ever, you should give an acid drink
e latter condition, or an alkaline one
he first, all the symptoms of the
dy from which your patient is suf-
ng, would be intensified.

any times the condition of the stom-
is such that your remedies are not
rbed, and thus fail to produce the
l which they otherwise would. Even
food is not properly digested and passes into the small intestine in such shape that putrefaction ensues, gas is generated and much pain and discomfort is produced.

Examination reveals a full, broad tongue, covered with a thick, dirty, white coating, which increases in thickness from before backward. Inquiry will reveal that there is a bad taste, especially in the morning. Also, that this bad taste is lessened to some extent by partaking of food. There is one remedy—and I believe *only one*—which will remove this condition, and that is sulphite of soda, given in doses of five to ten grains, from one to three times a day.

It is surprising to see how the tongue will clean under its use, and the general conditions of the patient improve.

If there is any one remedy which will prove the theory that there are specific remedies for specific conditions, sulphite of soda is that remedy. And the sign for its use is so simple that the most obtuse, in reading signs for remedies can not fail to see it.

The administering of this drug a few times, where it is indicated, will do much to convert any practitioner to the theory that there are remedies for specific conditions. As he watches his patients for this indication he will be surprised to see in what a variety of diseases it manifests itself. His surprise will fade into astonishment and joy as the administration of the drug works equally well in them all.

Children form a large part of the practice of many physicians. Those who come in contact with them to the greatest extent know that the large majority are extremely restless whenever they are attacked with any disease.

Combined with this peevishness you will almost invariably find that the cheeks are flushed, the eyes bright, and the entire body exhibits a picture of irritation.

When these conditions are plainly indicated, add ten drops of tincture of gelsemium—*made from the green root*—to four ounces of water, and give teaspoonful doses every hour. The effect is magical.

Just a word about the gelsemium. It is absolutely essential that the tincture

be made from the green root, otherwise it is useless. Many times a physician uses a preparation and does not get the effect which he has been led to expect, and thus condemns the drug. The fact is that he has not used the correct preparation of the plant, and the fault should be placed upon the maker, and not the remedy.

[Written for the MEDICAL BRIEF.]

Diabetes and Its Surgical Treatment.

BY ARTHUR C. BELL, A. M., M. D.,

Dean of the Faculty and Professor of the Principles and Practice of Medicine in the College of Physicians and Surgeons, Dallas, Texas; Ex-Professor Practice of Medicine, Materia Medica and Therapeutics, Ophthalmology, Dallas Medical College; Ex-Professor of Pathology, Histology and Physiology, University of Dallas. Dallas, Texas.

The name diabetes had its origin in a Greek verb, which means "to go through," to go through the kidneys. The word mellitus means honey. Diabetes mellitus means honey in the urine, sugar in the urine. Such urine smells sweet, and it is sweet to the taste. Sugar is then present in the blood and the other fluids of the animal economy. It escapes in the urine and may be detected by the Haines' test for sugar in the urine. No man, however grand and good, has ever fathomed the mysteries of this great disease. None can tell us its exact nature. No man has exactly explained its cause. Some great medical minds will direct us to the liver and tell us it is glycogenic perversion.

Others will point to the floor of the fourth ventricles, brain tumors, etc., in vain. Others tell us the pancreas is involved in fifty per cent of all cases. Some say it is a disturbance of metabolism, and how true this is.

The latest thought seems to indicate that the pancreas and the islands of Langerhans are involved in inflammation or, perhaps, degeneration.

It seems we can not yet agree upon any certain cause as to its etiology. It is certain we can find no pathological lesions characteristic of diabetes. We define it as a constitutional disease, a perverted nutrition, with a marked symptom, known as sugar in the urine. There are some curious facts to confront us in this ease.

1. The first curious fact is that urine, or other fluids, of a diabetic produce diabetes, glycosuria, if introdu into another patient or animal. This been proved by actual test many times

2. The second curious fact is that pancreas is changed by pathological sions in fifty per cent of all cases.

Going back to the first curious please note these points: Injection of urine of a diabetic patient into dogs produce glycosuria, diabetes even after sugar has been removed. Then you inject the contents of the intestine diabetic into the intestines of a dog you produce glycosuria in the dog. Ag introduce the contents of the intes under the skin of a rabbit and you duce glycosuria in the rabbit; just producing syphilis by injecting syphi virus.

I point out these facts to teach you diabetes is, in all probability, an in tious disease, and that it should be ta out of its present classification as a stitutional disease and be rated as an fectious disease, as syphilis, typhoid ver, measles, or scarlet fever.

This is a new thought, but I hope will ponder it well.

THE CLINICAL PICTURE.

Diabetes Mellitus.—The quantity urine is enormous, twenty to thirty pi The specific gravity is high, 1025 to 1 Sugar is abundant. The disease is tended with abnormal thirst and v cious appetite. There is feebleness of muscular system and progressive ema tion. It is usually chronic and fa Such is the clinical picture of diab mellitus.

Diabetes Insipidus.—Insipidus is Latin word for insipid; insipid u tasteless, not sweet, having no sugar. this case there is also enormous qua ties of urine passed, polyuria. It is watery and tasteless. But in this dis the urine is of low specific gravity, to 1005, and it contains no sugar. also attended with increased appetite abnormal thirst. Patients who have form of diabetes may realize no ser inconvenience, except the increased

of urine. They may live with the ase for forty years, and die with some rcurrent malady. However, it may lt in progressive wasting and prove l. Thus you have a clinical picture iabetes insipidus.

iabetes is more common in men than omen, and in the over-nourished than poor. It is not a disease of the kid-, because there are no certain patho-al lesions of the kidney. It is to be rded as a perversion of nutrition, d on a pathological pancreas, revealed bnormal metabolism of the carbohy-e foods. The only constant symptom he kidney is the abnormal flow of e. There may or may not be a diffuse ritis.

e Pancreas in Diabetes.—Total extir-on of the pancreas by a surgical oper-n is followed by diabetes in all cases in a few hours. The volume of urine mes enormous. Sugar appears in the e. Progressive wasting becomes es-ished. Thirst and appetite voracious, the disease proves fatal in about fif- days.

fter extirpation you may graft the creas back under the skin at any point if the graft proves successful your etes will speedily be cured. The urine be reduced in quantity, sugar disap-s, thirst and appetite return to nor-, wasting is checked, and recovery is plete.

emove ninety per cent of the pancreas ving ten per cent *in situ*) and you have no sugar in the urine, excepting n you eat the carbohydrate foods.

emove all of the pancreas and graft k ten per cent of it under the skin again you will have no sugar except ou take the carbohydrate foods.

wo striking thoughts present them-es to view:

a) That the pancreas has an office to form, an internal secretion, which pre-ts all mankind from having diabetes. at a sublime protection from the Ar-tect of the Skies!

b) The author suggests a surgical nsplantation of the pancreas of some nestic animal under the skin of the betic patient as a radical cure of dia-es. (See treatment.)

Foods enter largely into the management of the case. No carbohydrate food should be allowed. It is well to observe that the pancreas has a double function, an external secretion, a digestive ferment which enters the bowel through the canal of Wirsung; and an internal secretion, which is absorbed into the blood, and by some chemical action prevents the appearance of diabetes in the whole race. The authorities are agreed that atrophy of the pancreas is present in fifty per cent of all cases of diabetes. Atrophy of the pancreas destroys its function, the same as though it were removed, and diabetes must intervene. Inflammation of the pancreas, or tumors therein, will destroy its function and diabetes will appear. Microscopical changes in the cells of the pancreas may destroy its function, whereupon diabetes will appear. I believe that in no distant day the medical profession will recognize diabetes as a pancreatic disease, and that it will be recognized as an infectious disease and not a constitutional disease.

DIFFERENTIAL DIAGNOSIS.

DIABETES MELLITUS.	DIABETES INSIPIDUS
1. Begins from chill or injury.	1. Gradual injury or emotion.
2. Abnormal thirst and appetite.	2. Abnormal thirst, good appetite.
3. Urine pale, 5 to 30 pints.	3. Urine pale, 20 to 40 pints.
4. Specific gravity, 1025 to 1045.	4. 1001 to 1005.
5. Sugar, 5 to 10 per cent.	5. No sugar.
6. May be albumin and tube casts.	6. Rare.
7. Impotency.	7. May not.
8. Occurs at all ages.	8. Young most common.
9. Prognosis bad under 40.	9. Not often fatal.
10. May last 15 years.	10. May live 40 years.
11. Progressive emaciation.	11. Well nourished, may be.
12. Tongue dry, red and glazed.	12. Negative.
13. Saliva scanty.	13. Reduced.
14. Death usually in coma.	14. Usually other disease.

A low specific gravity and the absence of sugar are the striking features which distinguish diabetes insipidus from diabetes mellitus, but will remind you of chronic interstitial nephritis.

Treatment.—You should remember that the blood and other fluids of a diabetic are

saturated with sugar. It appears, therefore, in the urine as a waste product. The intelligent physician will, therefore, forbid the use of all sugars. Starches and other carbohydrates are readily converted into sugar and should, therefore, be forbidden. The carbohydrates are as follows: Sugars, syrups, candies, starches (potatoes, bread, etc.), fats, fat meats, vegetables and fruits. All these should be interdicted, because they are either sugar or readily converted into sugar. Bread and potatoes are examples of starchy carbohydrates. Wheat is composed of starch and gluten, a carbohydrate, and a proteid. The proteid is good, but the carbohydrate not. All carbohydrates must be avoided, as far as possible, but you must not starve your patient. Feed your patients on the proteid. The proteids are all lean meats, eggs, milk, cheese and gluten.

Medicinal treatment is not satisfactory. Opium or codeine are sedative to the glycogenic function. They will, therefore, frequently be of service. Strychnia and ergot are vasomotor tonics and may be indicated. Assafetida may be administered for the sinking sensations at the epigastrium. Diabetic coma is usually fatal. It rarely responds to treatment. The fluid extract of jambul is anti-diabetic and frequently reduces the sugar.

I usually advise students to feed their patients on pancreases obtained from the butcher, with the hope of supplying the pancreatic deficiency in the system.

The pancreatic extract may be administered to supply the same deficiency. However, this is not highly regarded by many physicians.

Original Surgical Treatment.—In the *Dallas Medical Journal* for July, the author said the following:

"I now come to my original surgical treatment. It consists in grafting under the skin of the diabetic patient a part of the pancreas of the ox, or other domestic animal. The animal should be instantly killed, and the patient properly prepared. The operation should be quickly and cleanly done. The pancreas should be transplanted subcutaneously, while still at the body temperature."

This pancreas, if the graft proves successful, will perform the function of the pancreas which has become diseased, a which, therefore, allows the patient have diabetes. Once the internal sec tion of this newly-grafted pancreas tak place, the diabetes is cured.

I quote again from my lecture:

"This treatment is based on the phys logical fact that total extirpation of t pancreas by the knife is followed in cases by diabetes; but afterwards, if t pancreas can be grafted successfully u der the skin, the disease disappears, a the patient is cured. I believe that t office of the pancreas, through its intern secretion, is to prevent all mankind fro having diabetes. If the pancreatic functi is destroyed, either by removal or by d ease, we may transplant the pancreas some animal to supply the internal sec tion. The studies of grafting the pa creas will justify my original and logic treatment."

There is another observation I wish make. It is a treatment directed towa overcoming the acidity of the blood. T blood of the diabetic patient is render too acid by the presence of diacetic ac and acetones. This acidity is called ace osis. The blood should normally be alk line, so that it can receive oxygen, a take up carbon dioxide from the tissu

This blood being too acid, as explain above, it can not take up the carbon di ide out of the tissues, therefore, he s fers from auto-poison.

Carbon dioxide has an affinity for t hemoglobin of the red blood corpusc in an alkaline blood only. Therefore, t acidity of the blood causes an interf ence of the physiological action of t blood. This acidity may, also, interf with the perfect oxidation of the blood the lungs. All these factors put your tient further and further down the sca

To correct this acidity I will suggest you to inject normal saline solution un the skin, with a large percentage of dium bicarbonate. This will render t blood alkaline, and permit the physiolo cal activities to proceed normally.

After reading several copies of t MEDICAL BRIEF carefully, I have been c vinced that I must have it.—E. D. Be M. D., Hardy, Neb.

[Written for the MEDICAL BRIEF.]

Notes On Nephritis

OTTO LERCH, A. M., M. D., PH. D.,
rofessor of Clinical Diagnosis, New Orleans Polyclinic.
New Orleans, La.

ht's disease is well defined by its matology. There are two char- tic symptoms—edema and al- uria, which are constantly found is disease of the kidneys. Though, nally, one or the other, or even ay be absent. When such is the e have to make our diagnosis from amnesis, general symptoms and s of the heart and vessels. We o differentiate between various the acute, the subacute and chronic besides, we have the amyloid de- tion of the kidneys, contracted kid- ed, granular kidney); and the con- kidney may be mentioned, as it the symptoms which characterize ease, though it is not a form of s disease.

urine contains, besides albumin, ment, which enables us in most make a differential diagnosis. The variety, as a rule, often accom- the infectious diseases, or follows wake, although a chilling of the , as a wetting, for instance, may it. This form is curable when y treated, and unless treatment is ed, and sometimes in spite of it, it ss into the chronic form. The pa- pale, anemic, the face is swollen find general anasarca. The urine entrated, dense, a large amount of n is present, epithelia cells and The general symptoms are those evere intoxication; headache, indi- , pains, etc. When this variety into the chronic form, it shows otomatology less pronounced. Usu- find a large quantity of albumen; bbules are always a symptom of hymatous degeneration.

e chronic form can be converted into erstitial form it may persist for years, but unless it can be so changed s to death in a year or two. It is fice of the physician to convert a c nephritis into the interstitial form. The large, white, sclerotic kidney is occasionally converted into the red granular kidney.

Often we find Bright's disease to start as a chronic disease. The amyloid degeneration of the kidney is due to pus in some part of the body, to old lues, malaria, to tuberculosis, and gives us a similar picture as the chronic variety, and with the amyloid degeneration of the liver, of the spleen, glands of the stomach and intestines, the etiology enables us to make a differential diagnosis. Although I live in a malarial country, I have never seen this form of kidney disease follow malaria. The red granular kidney, cirrhotic kidney and interstitial nephritis, kidney of gout, arterio-sclerosis, lead intoxication, malaria and lues, call our attention at once to the complications of this form of Bright's disease. One or the other of these may become the most prominent feature of the disease and may demand urgent relief. Endarteritis is never absent, and remembering that in every instance the primary cause of the disease is a toxic substance in the blood, we can well understand that such a relationship should exist. When its existence is established in the arterial system, the heart is bound to answer with hypertrophy to overcome peripheral resistance, and we find the tense pulse and the hypertrophied heart beating against the chest wall. Degeneration of the muscular tissue progresses and dilatation follows, marked by pronounced cyanosis, dyspnea, edema of the feet and ankles, and congestion of all the viscera. Murmurs are now heard over every valve, and the patient presents a picture of advanced heart disease. Endarteritis accompanies this disease in practically every case. Cerebral hemorrhages are frequent, due to rupture of milliary aneurysms. Liver cirrhosis is a common complication, and usually with the vast majority of cases we have to consider a chronic inflammation and fibrous tissue growth in every organ of the body. It is characteristic that in the majority of cases these chronic inflammatory changes may have seriously crippled the functional activity of every organ without interfering with the long life of the patient.

The patient feels well for months or even years, gradually or suddenly symptoms appear. As long as the kidneys do their work he will not be aware of any serious trouble. Failure of the kidneys to eliminate toxins finally causes those symptoms to appear with which every practitioner is familiar, headache, neuralgia, muscular pain, etc. Retinitis is often one of the first serious symptoms sometimes discovered by the oculist. Fainting spells are not rare, frequently indicating that the heart is unable to overcome the obstruction existing in the circulation. This may go on for many years, until a more careful examination discloses the real trouble.

If the disease is recognized in the early stages the trouble may be brought to a stop, but it will be well to understand that that portion of the functioning tissue destroyed, can not be remade.

The treatment must vary according to the form and the stage of the disease. As there is a similarity between the symptoms of all forms of this disease, so the treatment is similar. The acute form is best treated by absolute rest in bed and a milk diet. The milk is best skimmed, and a glassful taken every three or four hours day and night. More if desired. The milk is to be sipped or eaten with a spoon. Every portion of it must be well mixed with saliva. After the albumen has disappeared, fruit juice may be added to the diet, as well as fresh or dried fruits, and after the albumen has disappeared for months a more generous diet may be permitted.

In amyloid degeneration we must, of course, treat the cause of the disease. The interstitial variety is treated according to the various causes. Certain rules have to be observed in every instance, as, careful selection of clothing for protection against cold, to which all nephritic patients are subject; a non-stimulating diet, low blood pressure, and avoidance of irritation of the urinary apparatus; that is, to exclude from the diet all condiments, stimulating beverages, such as coffee and strong tea and alcoholics. An out-door life and exercise well proportioned with rest, especially rest before and after eating, and a change of climate is often found beneficial, the climate to be selected according to the idiosyncrasies of the patient.

In the more advanced cases the symptoms must be treated. The tense pu and the hypertrophied heart call for lief; the nitrates, nitro-glycerin, the dides and aconite are most relia remedies for this purpose. The dr must be given for the effect, that until the pulse has become soft. The tr ment of uremic symptoms has been m tioned, viz., the eradication of toxic s stances by a carefully chosen di second, to favor elimination by bow skin and kidneys. A combination of feine acts well with sodium benzoate an eliminant. Cardiac tonics are i cated when the heart has commenced fail. Digitalis must be combined w nitro-glycerin. Spartein for aged hea

In acute nephritis, if the albuminu appears during the fever of an infecti disease, a bath should be given wa and prolonged. For acute nephritis to chill of surface of the body, sw baths should be the first treatment. care of the skin is best attained by ord ing warm baths, and these are given tw or three times a week, duration one-h hour. Cold applications must be avoid The bath to be followed by one or hours' rest in bed. Attention must paid to the temperature of the bath-ro and the patient may be rubbed with cohol after the bath. The symptoms uremic poisoning, headache, weakn lack of appetite, are frequently relie by this method. Occasionally baths better when given in moderation. hot bath and sweat bath may be al nated and the patient directed to the third day. Edema due to nephritis well influenced by this form of treatme Winternitz advises the sweat bath of lower part of the body, with an ice over the heart when this organ is affect During the uremic attack the hot b and cold ablution have been highly be ficial. This is the only condition in wh cold applications are permissible. red granular kidney is best treated w prolonged warm baths every day or ev other day.

Bright's disease, in its acute form, curable. The chronic form may be c verted into the interstitial variety,

indurative process may be brought to
top. Unfortunately, chronic nephritis
rarely recognized in its early stages,
t frequently insidious, and the symp-
s that indicate its presence, headache,
ralgia, muscular pains, indigestion,
A tense pulse, an accentuated second
ic sound are not recognized in their
meaning and passed off lightly. Val-
e time is lost and the cause of the
ous troubles to come always leading
he exitus. Gout, lead intoxication,
nic lues, malaria, etc., goes on un-
ted till finally the symptoms make
r appearance that leave no doubt, in
y instances, too late for permanent
f. The destructive process has gone
far and, even if a halt could be called
his instance, the physiologic changes
ge, or some intercurrent disease find-
the resisting power of the organism
ken, will close the scene. It is, there-
, of the very greatest importance to
e an early diagnosis, and to consider
ptoms, no matter how little inconven-
e or trouble they may cause our pa-
ts and how quickly they may yield
reatment, as serious warnings of im-
ding danger of a progressive fatal dis-
, *unless properly treated.*

s soon as the diagnosis is made these
ents, if they are financially able, are
uently sent to springs that have ac-
ed a reputation for "curing Bright's
ase," with directions to take the wa-
which, as a rule they follow to the
r, consuming gallons of the liquid to
h the kidneys." Those that can not
e do the same at home. If we con-
r that interstitial nephritis is an in-
tive process, with frequently no sedi-
t in the urine and again a few
ine casts that can be detected only
r a most careful examination; urine
ight color, low specific gravity and
e quantities voided, we can readily
how *irrational* such a treatment is,
t realize the *danger* of such a course.
if we further remember that the
rt is the organ excessively taxed in
disease, that it always suffers, and
hypertrophy and myocarditis are
er absent in the advanced cases, we
h case must be studied and treated on
principles above mentioned.*

[Written for the MEDICAL BRIEF.]

Diagnosis and Treatment of Iritis.

BY L. G. WOODSON, M. D.,

Professor of Opthalmology and Otology in the Birmingham Medical College; Visiting Surgeon to the Hillman Hospital, etc., etc. Birmingham, Ala.

Iritis, an inflammation of the iris, is characterized by certain signs and symptoms, both objective and subjective.

The objective symptoms are discoloration of the iris; contracted and immobile pupil; posterior adhesions; ciliary congestion. The congestion is confined to a zone about one-fourth of an inch surrounding the periphery of the cornea. The subjective signs and symptoms are, pain —variable—lachrymation, photophobia, dimness of vision. Pain usually worse at night.

The disease is caused by syphilis (about sixty per cent of the cases), rheumatism (from twenty to thirty per cent), gonorrhea, gout, diabetes, infectious fevers and traumatism, making up the remaining percentage.

The disease is divided into three classes, serous, plastic and suppurative, the plastic being much more common and representing possibly about seventy-five per cent of the cases. Iritis is most common between the ages of twenty and forty-five years, though it is occasionally observed in children in the first few months of life, caused by inherited syphilis, and at a later period in connection with interstitial keratitis.

From the standpoint of the general practitioner I regard iritis as being one of the most important diseases of the eye, because it is exceedingly common, and unless recognized in its incipiency and properly treated, is certain to lead to a grave impairment of sight, or total blindness.

It is difficult to understand how it is possible for an intelligent practitioner to make a mistake in diagnosis of a disease in which the symptoms are so pronounced as in iritis. The condition is usually confounded with conjunctivitis, glaucoma, and cyclitis. The following points differentiate between these various diseases: In iritis, we have a contracted

pupil, discoloration of the iris, dimness of vision. In conjunctivitis the pupil and iris are normal. In iritis we have pain, ciliary congestion. In conjunctivitis there is no pain other than a gritty sensation in the eye, and vision is normal. In iritis there is no discharge. In conjunctivitis there is muco-purulent discharge. In conjunctivitis the inflammation is of a raw red, and the injection is confined to the blood vessels of the conjunctiva; while in iritis the congestion is confined to a circumcorneal zone about one-fourth of an inch wide, of a pink color, the vessels engaged lying beneath the conjunctiva.

Differential points between glaucoma and iritis: In iritis we have the symptoms already mentioned. In glaucoma we have a widely dilated pupil, shallow anterior chamber, tension of the eye-ball and severe pain. It is sometimes exceedingly difficult to differentiate between iritis and cystitis. In cystitis we have all the symptoms of iritis except the changes in the iris; pain, as a rule, is more severe; tenderness on pressure over the ciliary region, impairment of vision is greater than is found in iritis, though the differential diagnosis is of little importance between iritis and cyclitis, as they are usually due to the same causes and are amenable to the same general principles of treatment.

The treatment of iritis should be both local and constitutional. Local remedies consist first, last and all the time in the use of atropine to dilate the pupil and to prevent adhesions, or to break down those adhesions which have already formed before treatment is begun. Atropine not only dilates the pupil, but it paralyzes the ciliary muscle, relieves pain and places the eye in a state of physiological rest, which is most important in all inflammatory conditions. The strength of the atropine solution should be four grains to an ounce of water; one drop of this solution should be put into the eye every two or three hours during the acute stage of the disease, until the pupil is thoroughly dilated, then it should be used less often, as indicated. The eye should be protected from bright light by the use of smoked glasses, although if the photophobia be very severe, confi ment to a dark room for a few days m be necessary. Great relief may be tained by the use of hot applicatio cloths wrung out of hot water and plac over the closed eyelids for from fifte to twenty minutes at a time and repeat three or four times a day.

The abstraction of blood by artific or natural leeches may occasionally called for; my preference in these ca is for the artificial leech. Mercury a iodide of potassium should be given in cases. Mercury in some form when sy ilis is the cause, should be pushed to full physiological effect. In gout, rh matic and diabetic forms, salicylate soda, fifteen to twenty-five grains three four times a day, should be given. T bowels should be kept well open a moved regularly, and the patient's g eral health treated by tonics, such quinine, strychnine, iron, etc. The pr nosis in uncomplicated cases, as a ru is good where treatment is begun ea before adhesions have formed.

A Case of Early Appearance of B lateral Adductor Paralysis of the Vocal Cords, Due to a Mediastinal Growth (Carcinoma).

BY WILLIAM KELLY SIMPSON, M. D.,

Professor of Laryngology in the College of Ph cians and Surgeons, New York; Surg New York Eye and Ear Infirmary; Cons ing Laryngologist to Seton, N. Y., Foundl and St. John's (Yonkers) Hospitals; C sulting Otologist Presbyterian Hospi New York City; Fellow of the Academy Medicine, etc. New York City.

History.—W. B., male, age, forty-fou admitted April 4, 1902; died July 29, 19 Father died of cancer of the thro mother died of apoplexy; three broth still living, all nervous; father non-al holic, but very nervous; venereal, but specific history; has been moderately coholic, but of late years abstemio heavy smoker, excepting last th months; moderate coffee drinker; exc sive tea drinker. Measles in childho

ore eighteen had several attacks of us (?) fever. Fever twelve years (intermittent fever), and severe nervness at the same time. At that time physicians said he had some heart ble; he could not sleep at night without sitting propped up in a chair. There slight discomfort over the heart.

s been in this country ten years, and the last seven years has had attacks ragging down sensations, sleeplessness, sweatings, and has been very nervall the time. Last June he began to attacks of retching and discomfort he epigastrium; these persisted for e days, and then the voice began to weak; for two days it was completely The aphonia was not complete, as his present attack. It persisted for st a week, when the voice gradually rned.

esent Illness.—About eight weeks ago began to notice the voice getting ker again. It gradually became e so for fourteen days, when present state of aphonia was reached. eding this aphonia he had a bad h for four months, of severe paroxyscharacter, but with very slight expection. Once or twice the sputum was d tinged. He thinks that for a few and before the onset of the aphonia ad a slight pain in the right shoulder. e went to one hospital for three weeks, re a diagnosis of tubercular laryn was made. Then he came under my rvation at the Vanderbilt Clinic for first time, suffering from complete nia, which was practically the only ptom presented; the vocal cords shown a complete bilateral adductor paralythe cause of which for the moment d not be definitely made out, though as ascribed to a probable mediastinal sure, as there were indefinite physisigns pointing to such a conclusion. subsequently entered another promit hospital where, after careful watching ten days, he was discharged with a gnosis of hysterical aphonia. There been some sweating at night and a of eight pounds in four weeks. He n entered the Presbyterian Hospital at request, on April 4, 1902, at which e the above history was elicited, and n which date the remainder of the history is continued, being taken from the official records of the hospital.

Physical Examination.—Patient well-nourished. Does not appear anemic. Tongue moist, highly coated. Pharynx and tonsils congested, otherwise normal. No pharyngeal anesthesia. Voice almost completely lost, can only speak in a whisper. Pupils are equal and react to light, somewhat contracted, no corneal anesthesia. Slight enlargement of the superficial glands in right axillary and both inguinal regions.

Heart.—Apex impulse not visible, barely palpable in fifth space, four inches to right of midsternum, just inside of midclavicular line. Sounds are best heard at this point. Left limit of dullness one-quarter inch inside this line. Action is regular and slow. Sounds are distant, but clear and of good force. Basal sounds are normal in intensity. No murmurs could be made out. Pulse is regular, of good force; no increase in tension, the two radial pulses are of equal volume and force; also, synchronous.

Thorax.—Thorax is symmetrical, no pulsations or bulging made out.

Lungs.—Anteriorly slight, comparative dullness in first left space, for a distance of two and a half inches to left of sternal border. In first left space the breathing is high-pitched and somewhat tubular in quality. Over the whole of the left chest expiration is prolonged and higher pitched than on the right side. Posteriorly these signs obtain as low as spine of left scapula, but no dullness is present.

Liver.—Percusses from fifth space to free margin of ribs, the edge cannot be felt. Spleen does not percuss, large, edge can not be felt.

Abdomen.—Soft, not distended; no tenderness.

Extremities.—Upper are normal, excepting for tendency to clubbing of finger tips, and slight cyanosis. Lower extremities normal.

Special Senses.—There is no contraction of visual field, no loss of sensation to pain, touch, or temperature. There is some bilateral loss of taste. Patient can not taste salt placed on circumvallate papillæ; no anosmia.

Larynx.—Examination made by myself. Complete bilateral adductor paralysis of vocal cords, inability to make any expulsive cough; any attempt at coughing being with great effort, and with very weak sound (voiceless cough), with no motion of cords during the attempt, and great difficulty in dislodging any accumulation of mucus in the larynx.

The irritation from the accumulation of mucus in the trachea and larynx, and the desire to expel it, coupled with the inability, produced almost constant severe efforts at expulsion, which became more and more marked as the case progressed. The mucous membrane of the larynx was extremely pale in color, there being but little contrast between the vocal cords and the rest of the intra-laryngeal surface. There was no other intra-laryngeal lesion.

April 10. Dyspnea more marked; coughing spells more severe and frequent. Condition seems worse each day since admission.

April 13. Electric sparks were drawn from anterior aspect of neck last night.

April 23. Patient is coughing up large amounts of watery expectoration. Expiration at the apices posteriorly is markedly prolonged and higher pitched, an occasional subcrepitant râle heard. There has been a slight rise of temperature for three days. Cause not discovered.

April 25. Temperature rose from 99° to 104° F. during last night. This morning it is down to 100° F. Slight chilly sensations. Still no cause for rise of temperature ascertained.

April 29. Temperature continues irregular. Tubular breathing is more marked this morning, on left side it extends down as far as spine of scapula; no change in the percussion note or breathing sounds.

May 4. Laryngeal examination by myself reveals no change from former condition.

May 6. Patient is gradually losing ground.

May 15. This morning complains of pain shooting down right arm. Temperature 101.5° F. No change in physical signs observed.

Since May 15 several injections of toxines of streptococcus have been employed, with moderate reaction. Patient continues to lose weight; signs in the ch same.

June 14. Patient feels weaker; there some loss of power in both hands, es cially in the left; complains of consid able pain in back of neck. No appre ble change in thoracic symptoms. V little reaction from injections of Cole fluid.

July 3. Patient is losing strength s flesh, voice much weaker, some tubu breathing at apices posteriorly, sli bloody expectoration.

July 29. Patient has continued to l ground, had a bad attack of dyspn which lasted all night. Great difficulty breathing this morning. Became rapi worse and died at 9:10 P. M.

Autopsy made by Dr. Tuttle. Fra medium; adipose, scant; muscles, a phied.

Diaphragm.—Fourth rib left. Fou rib right.

Heart.—Pericardium contains 240 c of turbid serum. Valves normal. Mus appears a little atrophied; brownish.

Pleural Cavities.—Some slight ad sions around the bronchi. In lower p of upper lobe is an area of pneumon yellowish grey in color. There is a m of cancerous lymph nodes around bronchi, and the new growth rami along the bronchi throughout the lo lobe, and causes an uneven thickening the walls of the larger bronchi.

Right Lung.—A little adherent on ner surfaces to mediastinal growth. bronchial lymph nodes and the walls of large bronchi are cancerous. Remain of right lung normal.

Peritoneum.—There is a mass of re peritoneal lymph nodes moderately larged and cancerous, and a few scatte ones just down along the lumbar ve bræ.

In the superior mediastinum is a h irregular mass, extending from the s num in front to the vertebral column, from near the thyroid cartilage ab down behind the precordium, nearly the diaphragm. It surrounds the bifu tion of the trachea, and the large ves passing to both lungs, completely rounding the arch of the aorta and large ascending branches. In front flattened layer, about three-quarters of

nch thick, occupying the position of the hymus gland, and the remainder being nade up of cancerous lymph nodes.

On laying open the esophagus a portion lying behind this mass shows a number of whitish nodules projecting on the nner surface and without any ulceration, he mucous membrane apparently being ntact. The two large bronchi also show ancerous masses narrowing the lumen, ut without any apparent ulceration.

Abnormal Conditions.—Carcinoma of ediastinal glands. Carcinoma of left ung. Carcinoma of retro-peritoneal lands. Acute lobar pneumonia.

Microscopical Report.—Liver. Quite iffuse capillary dilatation. Small angioma; more or less injury to hepatic tisue in neighborhood.

Lungs.—Extensively invaded by cancerus growths. The cell groups of variable ize and shape. The cells themselves nostly medium, large and round. Much onnective tissue formation, with small roups of leucocytes and slight hemorhages have extensively obliterated structure of lung. Some small pneumonia reas. Some normal alveoli.

Mediastinal tissue also cancerous, but he connective tissue is more dense, and he cell pockets are larger.

During the patient's early stay in the ospital the radiograph was used and nowed to a certain extent the outline of he mediastina tumor.

In the recital of the history I have nitted the details of treatment, besides otes, and the various blood examinations hich have been strictly performed, but ear no special relation to the progress of he case.

The object of presenting the history of his case, from a laryngeal standpoint, is hree-fold:

1. To record an instance of complete, ermanent bilateral paralysis of the vocal rgans, which is the rarest form of laryneal paralysis.

2. To emphasize the early appearance f laryngeal paralysis, as an indication f intra-thoracic pressure, which is so ommonly observed in unilateral parlysis, and often, as in this instance, anedating any positive physical signs within he chest; and,

3. To note the difficulty of exactly defining the lesions, even when autopsy has proven it to be extensive, and as an additional reason, the diagnostic assistance rendered by an X-ray examination.

In using the term, complete bilateral adductor paralysis, in this case, I do so with due caution and appreciation of the term "cadaveric" position; which is, I think, but comparative, and according to Fein, a misnomer, he having found ten different positions in the cadaver. I made repeated examinations of the larynx and was much impressed with the completeness of the adduction, it having much more than the usual appearance of the so-called cadaveric position.

I wish to acknowledge the assistance of members of the medical house staff at the Presbyterian Hospital, and Dr. S. F. Jones, pathological interne, in presenting this report.

952 Lexington Avenue.

[Written for the MEDICAL BRIEF.]

Pneumonia.

BY T. J. DANIEL, M. D.,
President Arkansas Eclectic Medical Association.
Magazine, Ark.

Pneumonia is one of the most dreaded diseases we are called upon to treat, yet we read in medical journals where men have practiced medicine thirty-three years and never lost but "three cases" of this dread disease. When I read such startling statements and then find nothing new in the treatment, I am made to doubt the doctor's diagnosis. Calomel, aconite and carbonate of ammonia have been given in the treatment of pneumonia for years. Is it not strange that some can practice medicine for "thirty-three" years, use the above treatment and not lose but "three cases," while others lose about thirty-five per cent? There can be no routine or fixed treatment for pneumonia. You might have four cases at one house, and each require different treatment. It would depend upon the stage of the disease, and the conditions present.

I flatter myself that I have been as successful in the treatment of pneumonia as most physicians, but can not boast of

having only lost "three cases" in thirty-three years. If I am called to a case and find the tongue coated with a yellowish coating, or any other, tissues full, full abdomen, full veins, I give them the following:

℞ Podophyllin.....1 grain.
Leptandrin.....4 grains
Dioscorein.....4 grains.
M. ft. caps. No. 4. Sig.: One every two hours till bowels move.

If purse is full and bounding, or full and hard, I give:

℞ Spec. Tr. Veratrum.....30 drops.
Aquæ Puræ.....q. s. ad.....4 ounces.
M. Sig.: Teaspoonful every hour.

If there is pain in the side, or in right side of head, or flushed right cheek, or dusky skin, I add specific bryonia ten drops to the veratrum. I hold them on this, till the conditions change, or till the crisis comes. When the crisis comes and the temperature goes down, pulse becomes weak, I give small doses of strychnine, say a fiftieth or sixtieth of a grain, every three or four hours. And if the pulse becomes small and fast, showing a want of power of the heart to propel the blood, I give specific tincture of digitalis, about one or two drops every hour. But I *never* give it unless this condition is present. A man who would give digitalis with a full, bounding pulse, or a full, hard pulse, or with even a small pulse, hard or sharp, is not a good practitioner. As to local applications, I generally sprinkle the old emetic powder (com. powder of lobelia) upon a greasy flannel cloth, and apply over the diseased lung. The above is my treatment of pneumonia with the condition as described. But many times we have cases where the above condition is not present. Instead of the coated tongue, full tissues, full abdomen and full veins, we will find a small tongue, red tip and edges, pulse small and sharp, sometimes nausea. With this condition, I would move the bowels with sulphate of magnesia, or, possibly, give small doses of calomel, one-sixth grain every hour, until six doses are taken, then give the magnesia. At the same time I give:

℞ Spec. Tr. Aconite.....10 drops.
Spec. Tr. Ipecac.....10 or 20 drops.
Spec. Tr. Rhus. Tox.....10 drops.
Aquæ Puræ..... q. s. ad,..... 4 ounces.
M. Sig.: Teaspoonful every hour.

I hold them upon this till the condition changes, or the crisis comes. When the temperature falls, or if the heart's actio should become weak, I would give ca bonate of ammonia, if tongue was pale c had a white coat on it. But if not pal but rather red, I would give the muriat of ammonia. If the heart's action shoul become irregular, I would give specif tincture of cactus, from two to four dro every two hours. If, during the cours of the disease, the skin should becom purplish, or of a leaden color, or look lik one exposed to cold, I would give specif tincture baptisia. Add twenty or thirt drops to the aconite mixture, and give teaspoonful every hour. Should the co dition become such that I thought ant septics were indicated, I would give:

℞ Spec. Tr. Echafolta.....2 to 3 drachm
Spec. Tr. Baptisia..... .....½ drachi
Aquæ.....q. s. ad.....4 ounce
M. Sig.: Teaspoonful every two hours.

If the breath should become very o fensive, smell like a cadaver, or like woman with puerperal fever, I would pu one drachm of chlorate of potash to aqu four ounces, and give a teaspoonful ever two or three hours, instead of the ech folta and baptisia. There is not a rem edy in the *materia medica* that wi change the odor quicker than the chlora of potash. Try it and be convince Should the patient at any time during th attack become restless, with *flushed fac* I would give specific tincture gelsemiun Add one-half to one drachm to aquæ fou ounces, and give teaspoonful every hou Or, should he become restless, with *pa* face, specific passiflora; one-half drachi to one drachm every one or two hour will keep him quiet.

You have heard people say, "Passiflor is an uncertain remedy, sometimes it act well, but at other times it will not act a all." This is because it is given whe contra-indicated. Restlessness, with pale face, is the indication for it, and will seldom fail to act admiraby with thi condition. No remedy will act well whe not indicated. If the patient should b come dull, capillary circulation sluggish and patient inclined to sleep, I would giv belladonna, five drops to ten drops t aqua four ounces. Sig: teaspoonful ever hour.

If there is any symptom of effusion i the pleural cavity, bryonia is the remedy If there is a remedy in the *materia me*

ica that will promote absorption, bryonia will. In malarial regions, if there is periodicity, I give quinine.

Never give alcoholic stimulants, or any other stimulants in the first stages of pneumonia. Never give strychnine where the temperature is high, rigidity of the muscles, or nervous excitement. The condition calling for it is one of atony, with relaxation.

When the skin begins to get moist, asclepias tub. is one of our best remedies in the treatment of pneumonia, especially in children. When the pleuro is involved, have thought adhesive strips properly applied give relief. Much more could be said upon the treatment of pneumonia, and I would like to say more, but space forbids. A good rule is, to be sure and not give a remedy unless it is indicated. And, be sure you *know* when it is indicated. Study the action of your remedies, note carefully the condition of your patient, and be sure and not give anything that would injure him in the least. I have heard people say, "Well, if so and so does not do him any good, it will not do him any harm." A greater mistake was never made. Medicine is a force, and when taken into the system it expends that force upon it, and it is either for good or harm. An alkali given when an acid is indicated, does harm.

[Written for the MEDICAL BRIEF.]

Some Remarks Upon the Treatment of Acne Vulgaris.

BY J. WILLIAMS LORD, A. B., M. D.,

Clinical Professor of Dermatology in the Johns Hopkins Medical School; Dermatologist to the Johns Hopkins Hospital and Dispensary, etc., etc. Baltimore, Md.

Acne vulgaris, so well known as an inflammatory disease of the sebaceous glands, is rarely mistaken for any other condition, at least, in its early stages. It occurs most frequently in patients between the ages of fifteen and thirty, but is often found later in life.

The inflammation is usually confined to the face, but frequently eruptions appear upon the back and shoulders.

Subjective symptoms are few, and oftentimes are entirely wanting. Occasional pain, when the pustules are actively inflamed, is the only sensation complained of by the patient. There may be itching, slight or intense burning, and a feeling of discomfort.

The disease is always marked by the appearance of comedones (blackheads) and pustules.

Treatment.—Locally, press out the comedones (blackheads) by means of a comedo expressor; then open up the pustules with a Von Graefe cataract knife, which is particularly adapted to this purpose, by reason of its long and sharp blade. Follow this procedure by an application of Kummerfeld's lotion, composed of sulphur precipitate, four drachms; powdered camphor, ten grains; powdered tragacanth, twenty grains; aqua calcis and aqua rosæ, each two ounces.

This lotion is applied to the face, allowed to remain over night and washed off in the morning. After using it for about a week the face will often present a "dry" appearance, with scaling of the skin, although this condition is not always the case. When it does occur, however, limit the use of the lotion to three applications a week, and in the meantime apply cold cream to the face. An improvement will take place in the course of two or three weeks.

If there are many pustules upon the face a few applications of the X-ray will prove of decided benefit.

Diet.—The question of diet has always played an important part in the treatment of this annoying condition. However, I make it a point to forbid only such articles of food as are difficult of digestion, as, for instance, pork, sausage, pastries, candies, etc., etc. I do not advise a complete elimination of such articles as are known not to disagree with the patient under treatment. The patient's individual idiosyncrasy must be taken into consideration in this connection.

So far as internal medication is concerned, I use no drugs, unless there is some internal disturbance which needs correction. Constipation, a common condition in this disease, requires appropriate treatment, but my rule is to use as little medication as possible.

To sum up: My chief reliance in treatment is the local application of suitable

lotions to the face. A regulation of individual diet, and recommend as much exercise in the open air as possible, cold baths, and, lastly, the X-ray as a helpful remedial agent.

1011 North Charles Street.

[Written for the MEDICAL BRIEF.]

The Need of Pure Milk and the Difficulties Met With in Procuring It.

BY WM. H. PARK, M. D.,

Professor of Bacteriology and Hygiene in the New York University and Bellevue Hospital Medical College; Director of the Research Laboratory of the New York Health Department. New York City.

There is no difference of opinion among physicians and sanitarians as to the danger of pathogenic micro-organisms in milk. The chief varieties to be feared are the typhoid, dysentery, diphtheria, and tubercle bacilli and the unknown germs of scarlet fever.

At first glance it might seem very easy to prevent the infection of milk with these bacteria, or other micro-organisms, but when we remember that the consumer and, in fact, the dealer, living in large cities, knows almost nothing of the conditions on the farm, and that practically no health department has any close supervision of the farms from which this milk comes, we can see that it is rather a matter of luck, or good fortune, than through precautions that are taken, that the milk we drink is free from these organisms. The only adequate means now being used is through the co-operation of private societies with health departments, dealers and consumers. The largest co-operative work of this kind is carried on in New York City, where the County Medical Society has a commission, who act as a committee body between the consumer and the dealer, or farmer. The Health Department gives its laboratory for the bacteriological and chemical examination of the milk samples, sent from time to time. The commission has formulated a number of requirements for two varieties of milk, one of which is called "certified" milk, which must be produced under conditions as good as can be conceived; the other, which is called "inspected milk," must be produced under what we might call decent conditions; that is, the farms must be fairly clean, the cattle health the milkmen clean and free from diseas and the milk thoroughly cooled in tra sit.

Both varieties of milk are under co stant inspection by inspectors paid by th County Medical Society. The money fo this comes from the dealers whose mil is being inspected. At present six tho sand quarts of certified milk are so daily, and a somewhat less amount inspected milk.

When we come to the supply for th poor of the city it is at present impossib to guarantee a thoroughly wholeson milk. Milk which is really pure can n be retailed for less than eight cents quart, and the poor are, as yet, hardl ready to pay such a price.

Much can be done to improve the su ply, as, for instance, in New York Cit milk must be under 50° F. when it enter and if not, it is now being dumped in the gutter. As, perhaps, the greate harmless preservative of milk is cold, ju this one action has a great effect in pr venting deterioration of the milk. Th creameries and railroads are also bein regularly inspected. Notwithstanding tha much is being done it is still impossib to secure an absolutely pure milk supp for the poor, and we have been compelle to advise those not using certified milk purify it by heating, or pasteurizatio For the past four years a large numb of infants have been watched, one-ha getting pure, unheated milk, and the oth half exactly similar milk heated. The r sult has been very striking and great in favor of the heated milk. The childre fed on heated milk have flourished, whi among the others, in spite of every car there have been many deaths during th hot months.

It is understood, of course, that th babies are not actually put on raw mil but simply a certain proportion four taking it are not changed from th raw milk to the heated milk. was the unanimous opinion of th physicians looking after these ch dren that the care they received was of much importance as the kind of mil This covers clean bottles, willingness an ability to carry out directions as to met ods of feeding, quantities furnished, th

topping of milk at the first signs of seri-
us diarrhea, the proper care of the milk
self while in the house, and the meth-
ds of sterilizing; suitable clothing, and
eanliness of the child, and as much
resh air as possible—most of the physi-
ans stating that, leaving out the worst
ore milk, the good results were effected
ore through the difference in the care
the child. During the cool weather the
ind of milk did not seem to influence the
ortality to any great extent, but during
ie hot weather, when the resistance of
ie child was lowered, the kind of milk
ken, whether raw or heated, did influ-
ice the amount of illness, and the mor-
lity. Those who were given condensed
ilk and store milk did the worst, and
ose who received breast milk, pure bot-
e milk, and pasteurized milk, did the
st. The effect of bacterial contamina-
on was very marked, when milk was
ken without previous heating, but, un-
ss the contamination was very exces-
ve, the heating was sufficient to make it
irly wholesome.

Measurement of Eye Strain.

BY GEO. A. ROGERS, OPH. D.,

rincipal Chicago Post-Graduate Optical College.
Chicago, Ill.

Optometry reduces all principles per-
ining to the eyes to exact measure-
ents, the lineal unit of which is the
eter of practically forty English inches.
is difficult to comprehend how *eye*
rain, or fatigue of the eyes, can be re-
uced to exact measurement. It is not,
fact, but to relative values. But this
ves as perfect a basis of comparison as
the units were absolute.

If you take an ordinary rubber band,
ch as is used to hold a package of pa-
rs together, and loop it over the thumb
d finger, the elasticity of the band
olds the digits together. To separate
em one inch, two inches, three inches,
c., requires increasing muscular effort.
he first inch separation may be easy,
e second is much harder than the first,
e third may be very difficult. To sep-
rate them to the widest extent and con-
nue to hold them there is impossible.
is not the muscles that are put to the test, but the nervous force compelling them to act.

The above example illustrates the action of the ciliary muscles in accommodation, or adapting it to varying distances of the object. The limit is not far away, and the nearer the ciliary approaches the limit the harder the effort to obtain a required action. There are elastic forces in the eye that resist the effects produced by ciliary action, and such elastic forces are constant, because they are merely physical. Lifting a heavy stone may be possible, but how long can it be held, with gravity constantly drawing it toward the earth? How much harder it would be if the higher the stone was raised the heavier it would become.

To accommodate 1D., the normal amount for one meter, requires that a certain voltage of nervous force be sent to the ciliary. It may vary for different individuals, but that is neither here nor there. Designate the nerve force required to maintain such action one second a neuro-diopter. What nervous force would then be required to accommodate 2D., the normal amount for one-half meter? It is evident that the second diopter of action would, in itself, call for greater force, as in stretching the rubber band the second inch would be harder than the first. But in addition to this new demand for nervous energy, the previous force must, also, be maintained, which further adds to the demand.

It is evident that a simple physical law is operative in such cases. It corresponds to the law that "resistance increases as the square of the velocity," or to the law governing the law of falling bodies: The distance covered each second increases as the odd-numbers, 1, 3, 5, 7, etc., and the whole space "as the square of the number of seconds," based upon the distance fallen the first second. This would make the normal accommodation in diopters and the increase of nervous force required for each and all as follows:

Distance.	Acc.	N D.	Total.
Infinity	0	0	0
1 Meter	1 D	1 N D	1 N D
½ Meter	2 D	3 N D	4 N D
⅓ Meter	3 D	5 N D	9 N D
¼ Meter	4 D	7 N D	16 N D
1-5 Meter	5 D	9 N D	25 N D

This gives the key to the rapid exhaustion of the eyes that are, even when normal, *used excessively* for near work, or that are used for *excessively-near* work. But the normal eye is always within reach of the abatement of such condition. It can stop and rest by being turned to the distant object. Even the sign, "Quaker Oats," on a bill board across the street, is the "friend in need" that rescues it from over-strenuous labor and rapid tendency to exhaustion. A little rest, how good it is, for over-worked and imposed-upon eyes. They go back to their work like a pair of school boys, after fifteen minutes' relief from the tedium of the school room. But even for such normal arrangements of work and rest, they cannot be imposed upon with impunity.

But consider the case of the hypermetrope of, perhaps, 2D. For distance alone each eye requires 2D. of accommodation and 4ND. of nervous force. For the ordinary reading or working distance of 1-3 meter, each eye requires 3D. more accommodation, or 5D. in all. This represents 5_2=25N.D. of nervous force per second for each eye, or 25—9=16N.D. in excess of normal. While "Quaker Oats" may be a momentary comforter, cutting the rate of energy required down to 4N.D. for each eye, this is not rest, or it is the rest that the farmer gave his harvest employes at the noon hour. He lets them cut wood. Such eyes have but two modes of rest—sleep and death. Oh, yes, there is another. Nature seems to have a remedy for all things, save the proverbial "death and taxes." A pair of +2D. spheres carefully fitted in metal frames and put across the nose relieve the situation. They reduce the eyes to artificial normality. There are still nervous requirements, but only the normal amounts, and there is, oh blessed privilege, a chance to rest, if only for a moment at a time. For the bill-board across the way still holds out its sunny hand and says to tired eyes: "Come unto me all ye that labor and are heavy laden and I will give you rest." But come with your spectacles on, please. No remedy in the whole *materia medica* will be the equal of a dose of the above prescription for "Quaker Oats," or other bill-board specific.

The measure of eye stress is the *nor*
but *excessive* use of the accommodat
but the measure of *eye strain* is the m
ure of the *abnormal* expenditure of ne
force upon the eyes for a particular vi
point—the amount they need to use
corrected in excess of that which t
would require if reduced by lenses t
normal state of refraction. A 2D.
perope requires 25N.D. for ordinary re
ing in each eye. The normal amount
9N. D., making an excess of 16N.D.
both eyes the excess is 32N.D. per seco
1920N.D. per minute, 115,200N.D.
hour, or 1,152,000N.D. per working
of ten hours. And this is the accom
dative strain merely. There are ot
factors to be considered—those perta
ing to the extra-ocular muscle system

In the case of 2D. hyperopia the eyes
see distance distinctly, require 2D.
commodation each, or 4N.D. of nerv
force each. If the extrinsic m
cles, disregarding this influence, are i
condition of normal poise (orthophor
the hyperopia, by stimulating accom
dation, tends, also, to stimulate the c
verging muscles (the interni and also
superior and inferior recti), as these m
cles, operated by the third nerves, are i
mately associated in action with the
laries. And such stimulus tends to cr
the eyes and produce diplopia. To ov
come the latter effect the externals
called into action. But a slight tens
on the converging system requires,
neutralize it, a much greater innervat
of the externals. Granting that in
accommodative action, the internals wo
tend to converge one meter angle ea
about three times that force on the part
the externals would be required to n
tralize the tension, making 3_2=9N.D.
each of the externals, or 18N.D. per
ond, in addition to the 2N.D. on the c
verging muscles, or 20N.D. in all. T
more than doubles the nervous leaka
which is not increased, or reduced,
near vision.

Such a waste of nervous force up
these organs is undoubtedly responsi
for some of the most serious cases
nervous exhaustion, and the derangem
of the normal functional action of orga
remote from the eyes. The eyes are
most imperative of all the organs c

olled by reflex action. They demand d receive their supply whether there is undigested dinner in the stomach or t, and the organs concerned in the pro-sses of digestion have to take whatever ere may be left for them to use. It is t surprising, therefore, to find many ysicians awakening to the fact that to agnose some of the simpler organic de-ngements knowledge of refraction and e condition of the eyes is not to be ig-red.

Catarrhal Appendicitis.

BY S. L. BAYSINGER, M. D.,
Rolla, Mo.

The following will be found satisfactory the treatment of catarrhal appendicitis: hen satisfied of the diagnosis, give hy-dermic injections of morphine sulphate sufficient doses to control pain and miting. Cover the affected area with a rm and thick kaolin poultice, changing ery twelve hours for the first two days, en every twenty-four hours. Give one two teaspoonfuls, as needed, of liquid gnesia, to produce at least two or three e movements from the bowels every enty-four hours. Keep the patient quiet bed on a liquid diet.

me Hydrotherapeutic Methods of Treating Sciatica.

BY ALFRED W. GARDNER, M. D.,
fessor of Hydrotheraputics at the New York School of Clinical Medicine.
New York City.

During the past three or four years I ve seen many cases of sciatica, and m my own experience and that of ers the disease seems to be on the in-ase, and a question has arisen in my nd as to whether the disease is of rheu-tic origin or due to a general inflam-tion of the sheath of the nerve. In her case, however, the treatment of the dition is practically the same.

Many of my patients come to me with history of previous treatment by every own method, including medication of ery sort. Under those circumstances I e as few drugs as possible, and with excellent results. The treatment of sciatic patients by means of steam massage has given me, perhaps, the best and quickest results. This method of treatment, which is of German origin, consists in placing the patient upon a frame made of cane fitted over a bath tub, through which the steam could pass. This arrangement allows the patient to lie in a perfectly relaxed condition during the steam bath, which is not the case when the patient sits in a so-called steam cabinet. In the latter instance the patient, to retain the sitting position, must necessarily hold rigid the muscles, which are perfectly relaxed in the horizontal position. A cold towel is placed upon the head of the patient, and the body wrapped in blankets. The duration of the steam bath varies, according to conditions, but is not shorter than five minutes. The improvement following this treatment is as rapid as it is successful. A history of the case following may be of interest:

A patient, thirty-four years of age, female, presented herself, suffering with a very severe attack of sciatica; intense pain over the spinal cord and lumbar region. The pain in the lumbar region was more marked at night. She was unable to walk or stand in an erect position. She had been lying in a horizontal position for four weeks. I began treatment by giving her natural sulphur water douches over the sciatic nerve; temperature, 98° F. to about 115° F.; pressure, about ten pounds, and duration four to five minutes. Under this treatment she improved for four or five days. The pain left the spinal cord and she was able to stand for a few minutes. Then followed an afternoon and night of intense pain. The following day, instead of giving the douche I had her take what we call steam massage. The effect of this treatment was a marked improvement, and was continued for some days, alternating with continuous hot douche. The improvement continued until she was able to walk from her cottage to the hotel for her meals. During this time not only was her general condition much improved, but also her appetite, strength and general appearance. She returned home and was able to sleep for the first time since her attack without narcotics. I saw her since her

return home and she is suffering practically no pain, taking exercise daily, and general health continues to improve.

In every case I use as little medication as possible. I feel that the general nutrition is a very important factor in keeping the intestinal canal in proper condition. I treat my patients either with the continuous hot douche, or with the alternating hot and cold douche, and with steam massage. These I have found to be the three great factors in the treatment of sciatica.

Chemistry and Psychology—Chemistry of the Body as Effected by Adverse or Favorable Emotions—Psychology, Chemistry and Magnetism of Love, etc.

BY A. A. LINDSAY, M. D.,

Principal St. Louis College of Suggestion.
St. Louis, Mo.

The pathologist has collected much data demonstrating the chemical changes that take place in the human body through the darker emotions, such as anger, fear, jealousy, hate, and all the dark passions. He has learned that the secretions of the body that should be normally alkaline in their reaction become acid, and those acid alkaline, due to these untoward mental excitements. Various secretions of the body, such as the salivary, gastric, the perspiratory, and others of the excretions thereby, modified. And I think I am safe to say it is within the experience of the average physician to know of the mother's milk becoming poisonous to the child when the mother has had a shock, or been under the influence of the dark emotions.

Now, if a spasm, a wave of wrong emotion change the chemistry of the body and, therefore, the cell substance, it must take a powerful force to so react as to make the body take its equilibrium again, and be just as though no such wave had passed over it. Again, this is true, that giving way to an irritation once makes it so much easier to yield again that one shock after another is impressed upon the organism, and the vital force never ceeds in adjusting the body after paroxysm before another attack co and so we have chronic morbidness constant irritability (wrong emoti states), compelling tissue changes, a confirmed pathological state establi in the body through mental action. W ing diseases, of which tuberculosis is ical, may have their origin in fear, a jealousy, or any other inapposite ex ment, for these make their most profo impress upon the portion, organ, or ti whose standard of resistance is the est.

The science of all the above is something from the outside strikes mind (objective consciousness), infla it, and passes to the soul (subconsci ness) that presides over all the funct and forces of the body, and is controll by suggestion, an inflaming suggest and under that suggestion it acts, ch ing the chemistry to abnormal, becau is influenced in an unnatural way, as in anger, often causes violent re ance, with a much increased power, cause the soul brings the involuntary tems to its use. That is why one str with a blow so powerful and harder t he is conscious of, when he is mad. uses his voluntary, but his involun muscular system as well, and so it is do such marvelous physical feats u excitement.

If, under the impress of these unwl some emotions, such adverse chemistr produced, why do we not, when we disease and wrong chemistry appea the seat of the emotions, the soul, put there the most beautiful picture health, happiness, joy and peace, g expectancy of uplift, forgetting morbi and depression until the whole bein filled and thrilled with the glad emoti Talk to the soul, I say, and get the r expectancy there, for a man becomes i his head to his feet, from his skin to marrow, the expression of that which soul believes, and the thought he l will become expressed in the contour composition of his physical organism health is to abound it will be thro outward expression of an inward sciousness. Love, hope, faith, and all ful emotions must be enthroned, and

place left for the evil, and the chemistry of the body will stay normal.

Every passion has its characteristic chemistry. If it be a spiritual passion, that is, a passion that issues from within, there is health in it. If it be a darker passion that has its beginning in the sensual nature, there is disease in it.

In the discussion of chemistry and psychology there is no more striking illustration of how thought changes the chemistry and magnetism than in what passes for a love affair of the average sort.

A lady and gentleman meet, and when they look into each other's eyes, or clasp each other's hands, there is an exchange of some mysterious kind that is pleasurable and so noticeable that one or the other, or maybe both, observe the more than ordinary attraction between them. They get into each other's company and find, with ripening acquaintance, the growing intensity of attraction, and they begin to think and assert that they undoubtedly are intended for each other, and had been from creation and, therefore, would be for eternity. In this type I am now describing the attraction is purely magnetic, due to the affinity of positive and negative electricity, the same force that is present in all matter, whether it is in the human organism, animal, or mineral. Two men with such magnetic polarization falling into each other's arms in the dark, and each thinking the other to be a woman, would experience the same thrill of attraction as if opposite in sex. This takes much of the romance out of the usual love affair, so called, but we need to teach scientific truth to counteract the ruin that comes through the fiction which in its representation of love has its heroine and hero falling into each other's arms by some accident and discovering this eternal fitness for each other, because it was so pleasant to the senses, and our novel students grow up looking for that experience that will prove their infinite mating. Our lovers meet that way and experience an electric discharge, just like that which takes place when my patient sits under the head breeze of my static electric machine, when you see the spark jump from her head to the brass electrode and, no doubt, there is the same bright spark and a keen snap takes place when these lovers touch, as described, and I wonder if that is why love-making has been called "sparking," and was so named by an inspired individual, who spoke better than he knew? Anyway, the courtship is started, and the suggestion exchanged that they must have each other, for it is a fixed, divine decree that they must answer. They have emotions and so begin changing the chemistry of each other's bodies, placing in every cell of their bodies a chemistry that can only be answered by contact each with the other. The violent rushing together of hydrogen and oxygen is no comparison with the resistless demand that these respective chemicals make for satisfaction in each other. After all this wild physical attraction is awakened it is too late to consider anything as to their mental and spiritual fitness, or equality of birth, or heredity, in any of its possibilities. They have accepted the one suggestion that they were created for each other, and that fixes it all for them. They marry and under their more intimate and constant association the laws of chemistry and magnetism are satisfied, and, just as in putting a demagnetized piece of iron in touch with a magnet, the two pieces become of like magnetism, and they fall apart and are repelled by each other. Or, like the coming together of the hydrogen and oxygen, there is the production of the quiet, satisfied body of water. Now, the individuals knowing nothing of the basis of their union, and supposing they would always experience the same wild thrill as during courtship, find there is no such thing. They do not want to be like the calm body of water, that looks too dead, and they do not like to admit that they repel each other like the two magnets of like polarization, but one or the other will first suggest, "love is dead, or you love some one else, for your kisses do not thrill like they used to."

Of course, if they knew the basis of their union was physical and, therefore, due to magnetism and chemistry, and did they know that the two gases could be separated that comprise the water and they would want to rush together again, or that the metals that had been magnetized alike would again be demagnetized

so their polarity would attract again, and from that reasoning know that they could be in touch less, and soon feel the same attraction that bedimmed their reasons in courtship days, they would adopt that method rather than proceed at once to living disgruntled lives, or resort to divorce court.

Brother physicians, we should be teaching these things, for no one else knows how, but we should go beyond this physical matter, and be able to teach what the pulpit, nor the college professor is doing, that all such love affairs as the above, although constituting probably ninety-nine per cent, are abnormal, for the union is based upon an emotion that had its origin outside of the individual, or, at least, appealed to his sensual nature first. Teach that there is such a thing as love, but it has its nativity in the soul, and if persons are to be truly married this soul attraction must have precedence, and its promptings must be known before the sensual nature is aroused, and the wrong suggestion fastened upon the souls. The soul presides over the body and, therefore, a marriage based upon spiritual fitness will bring out all the possibilities of the physical in the most intense manner. Education that involves the instruction that there is a soul affinity from which all good will issue, but that there is a physical, or sensual, which, if it have the initiatory, will ruin every hope, is, as a preventive measure, as important.

It is the feeling that every couple has that no one but his or her particular mate could be so wildly attractive is the source of the most missteps. Teach the youth that there is no novelty in it, but that it is by law of the most common force in the world that they are attracted, and that even a cat enjoys being smoothed, and is attracted to him by the same law that he thinks makes him and his companion the exclusive affinities, and he will analyze his situation and may be will look out for that companionable one who appeals to his soul first, and may never effect his sensual nature at all, or if so, the soul will be master and sensuality and hence repulsion will not result from the union.

"The Psychology and Chemistry and Magnetism of Love" is a subject worthy of our careful attention. Psychology has a larger field than suggestive therapeutics and hypnotism. Let our capable men continue to write upon these matters.

The Pelvic Brain—The Cervico-Uterine Ganglion.

(Ganglion Cervicalis Uterina.)

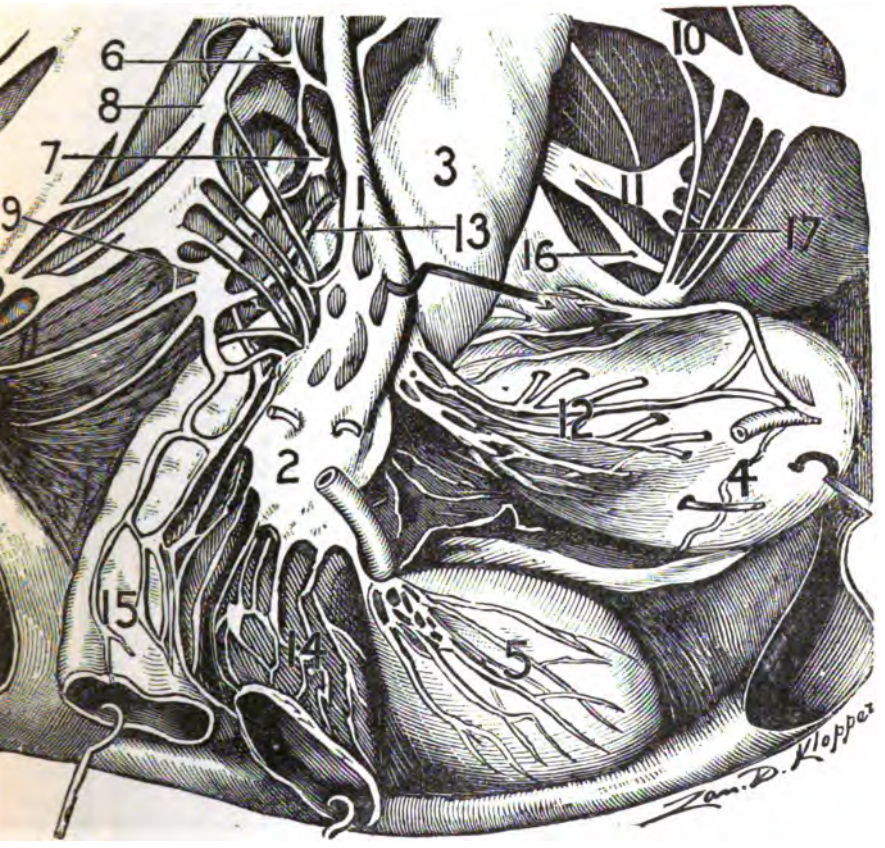
BY BYRON ROBINSON, B. S., M. D.,
Chicago, Ill.

I have termed the collections of nerve ganglia located closely adjacent to either side of the cervix and vagina—the cervico-uterine ganglion—the pelvic brain. What is a brain? A brain is an organ that receives sensation, reorganizes and emits emotion. A complete nervous system consists of a cell (ganglion a re-organizer), and conducting cord (nerve strand), and a peripheral apparatus (sense or collecting organs). The cervico-uterine ganglion consists of an aggregation of ganglion cells, and hence it is a brain. Since it is the largest collection of ganglion cells within the pelvis, it is the *pelvic brain.* The abdominal brain (ganglion celiacum) primarily dominates the tractus intestinalis. The pelvic brain primarily dominates the tractus genitalis. The genital tract, being located at the distal end of the body, at an extensive distance from the abdominal brain, requires an accompanying local, independent ruler—the pelvic brain. As it contains a less number of ganglion cells; therefore, the abdominal brain dominates the pelvic brain. In the same manner the automatic renal ganglia, having a less number of ganglion cells, is dominated by the abdominal brain, yet they rule like a State and govern their own territory. Likewise the abdominal brain dominates the tractus intestinalis, though the superior mesenteric ganglion is allowed to rule the rhythm of the enteron with the proximal half of the colon, and the inferior mesenteric ganglion is permitted to govern the rhythm of the fecal reservoir, or the distal half of the colon (one-half of the transverse colon, the left colon, sigmoid and rectum). Hence the abdominal brain is

e central potentate of visceral rhythm, ilsted by numerous subordinate, yet ctically independent rulers, stationed various distances.

n a certain sense the abdominal brain embles the pelvic brain, as the abdom- l brain is modified by the in- poration in it of a cranial nerve (the gus), while the pelvic brain has incor- flamed); the sympathetic should function- ate, perform its rhythm painless.

Scanzoni reports a woman paralyzed from the dorsal vertebræ distalward, who had a painless labor. Children may be expelled after the mother's death. The spinal nerves supplying the genitals trans- mit pain of the most acute and lancinat- ing character.



THE PELVIC BRAIN.

ig. 1 (By Byron Robinson). An illustration of the cervico-uterine ganglion or pelvic brain (1 and lt is composed of: (a) the hypogastric plexus (1), the lateral sacral ganglia (6 and 7), and many e strands from the II, III, and IV, sacral nerves. The pelvic brain was three-quarters of an inch , one-half inch wide, and one-sixth inch thick, in the subject from which it was dissected and rn; 3. rectum; 12, uterus; 5, bladder. It is a ganglion of giant power and majestic size.

ated in it the sacral (spinal) nerves. genitals are supplied with two kinds nerves, spinal (cervix, vagina and pu- dum) and sympathetic (corpus, fun- , oviduct and ovary). As regards the rus the spinal nerves supply the cer- and the sympathetic supply the cor- and fundus. The pain from the sym- hetic nerves is of a dull, aching, drag- g and sickening character (when in-

The spinal nerves supplying the geni- tals, in order of importance, are: (*a*) in- ternal pudic; (*b*), the third and fourth sacral; (*c*) pudendal; (*d*) ileo-inguinal; (*e*) genito-crural. The sympathetic nerve supplying the genitals, consists of (1) the great hypogastric plexus, which originates from the abdominal brain and the lateral lumbar chain. This great plexus passes from the abdominal brain along the aorta

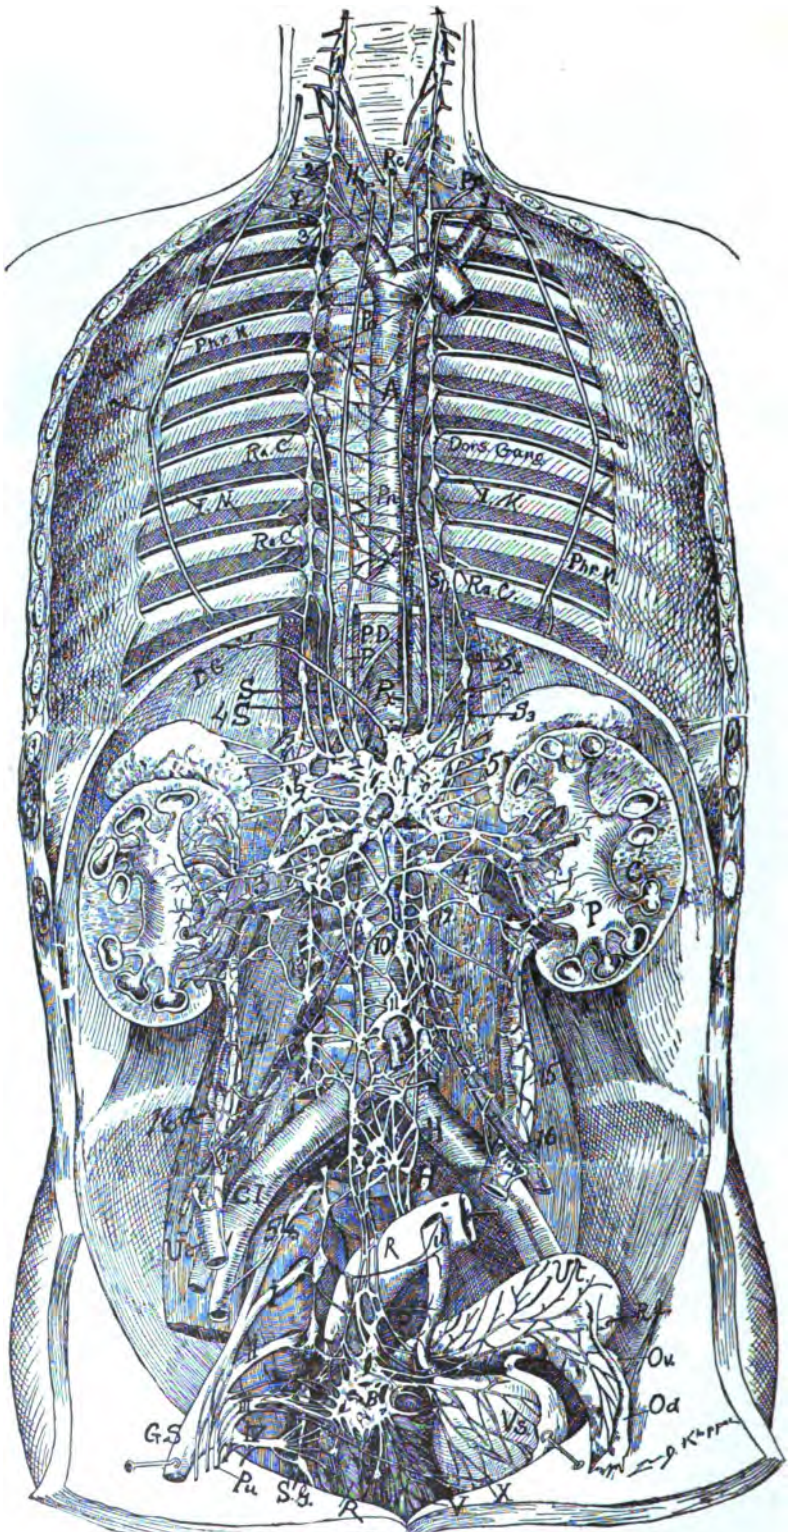


Fig. 2. An illustration of the sympathetic nerve with pelvic and abdominal brain. In this spe
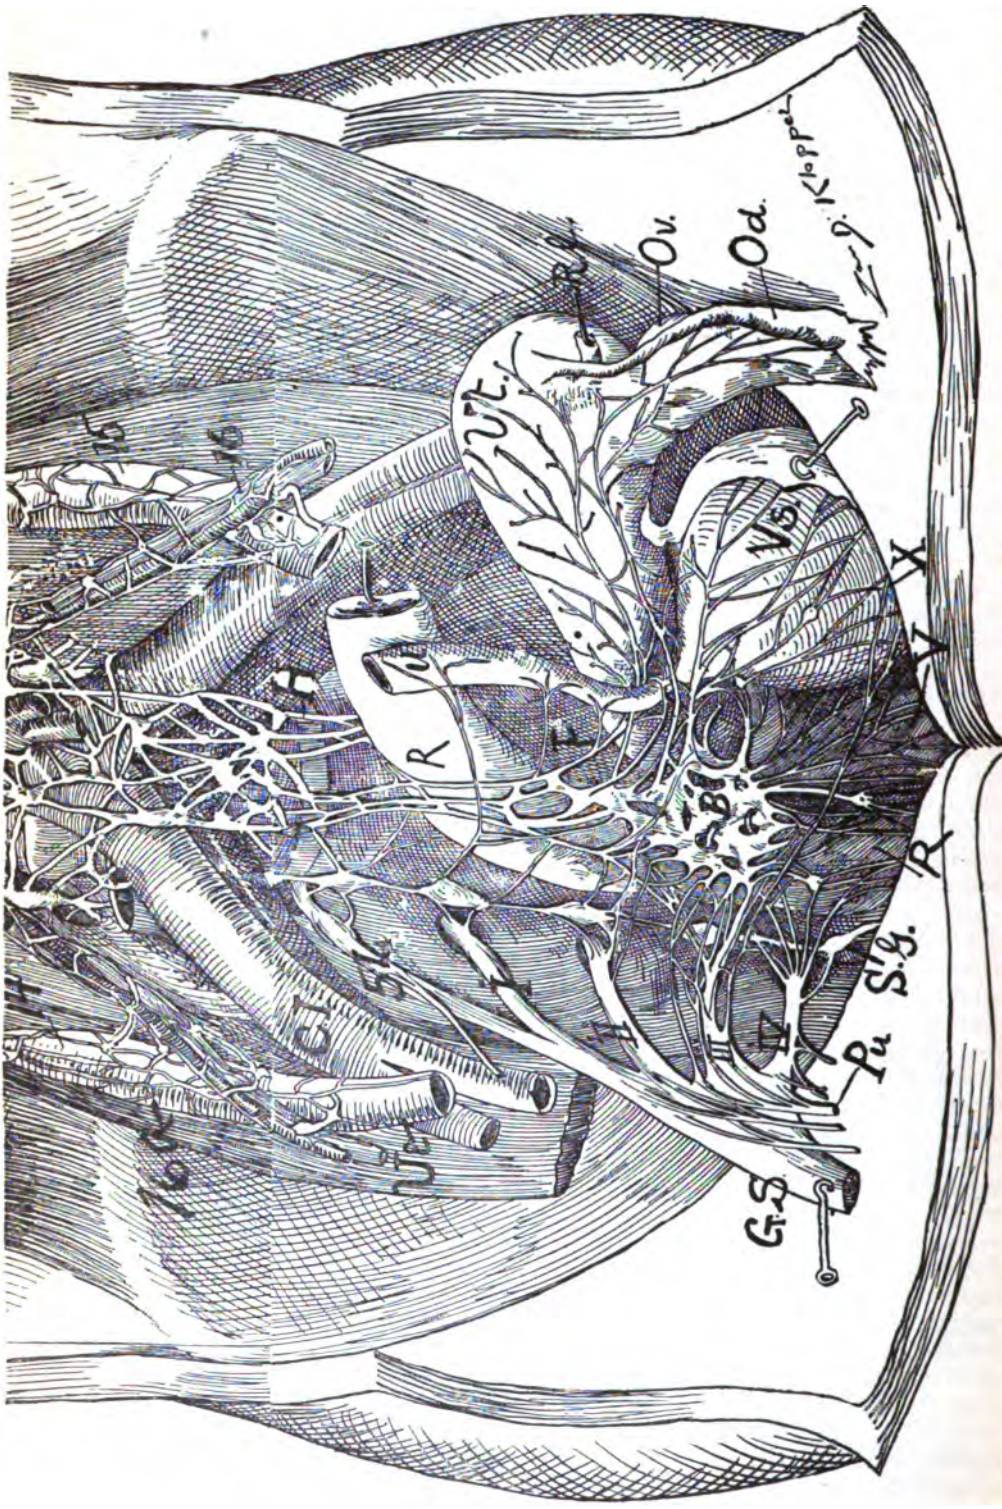
the ureters (calyces, pelvis and ureter proper) were dilated to the dimensions of an index finge
channel of the tractus urinarius presenting no sphincters intact. This subject possessed a t
abdominal brain (1) as well as a well-marked pelvic brain (B). The ganglion hypogastricum (H)
marked. This illustration presents fairly well the abdominal sympathetic with their varied s
moses. The great ganglionic masses of the abdomen (1) and pelvis (B) are evident.

(aorta plexus) to its bifurcation at the sacral promontory, whence it forms a coalescence, or a kind of nerve disc, the hypogastric ganglion, which originates the two great hypogastric plexuses. They then divide and pass along the lateral walls of the rectum and vagina, many of the strands traversing between the blades of the ligamentum latum, and along the lateral borders of the uterus, to supply its corpus and fundus (the nerves of the uterus are best observed, according to my experience, by dissecting a six month's fetus which has lain in alcohol for some months). The peritoneum of the fetus is transparent, and the nerve ganglia are reddish—hence visible. Spare cadavers are also successfully employed in exposing the hypogastric plexus. The hypogastric plexus is distributed in the ligamentum latum in the form of a fan, the periphery of the fan being the lateral borders of the uterus and the distal border of the oviduct. At the junction of the cervix and vagina one finds irregularly-shaped nervous ganglia (pelvic brain). Trauma, shock on the hypogastric plexus, will kill in a few hours. I performed an autopsy on a woman with her first child, who had ventral hysteropexy performed on her four years previously, and in whom immediately after labor the uterus invaginated, killing her in about two and one-half hours from shock.

(2). The ovarian plexus passes practically from the abdominal brain, however, actually from the ganglion ovaricum, to the ovary along the vasa ovarica. It consists of nerve strands and ganglia. The hypogastric plexus sends strands to meet the strands from the ovarian plexus to supply the oviduct. An enormous mass of nerve tissue is found in the ovary. It is apparent that the sympathetic nerves supply the corpus and fundus, while the cervix is well supplied by the spinal from the second, third, and fourth sacral. That the uterus is supplied by sympathetic nerves and the cervix by spinal nerves is significant in practice. For example, the uterus (corpus and fundus) is always ready for an abortion, because it is always in rhythm. The cervix is never ready for an abortion because it is not in rhythm, being dominated by spinal nerves. Abortion is worse than labor, from lack of drainage and consequent infection. The uterus being dominated by the sympathetic nerve is a rhythmical organ, and always ready to expel its contents. Any one can prove that the pregnant uterus is in a state of constant rhythm by placing the hand on the abdomen of a pregnant woman.

The cervix being dominated by spinal nerves, is not rhythmical, it is sober and quiet; a moderator, a guard, a sentinel, a breakwater against which dash the troublous waves of uterine, rhythmical, agitation. I have observed these uterine rhythmical waves gradually increase in violence until the cervix was compelled to yield, by sudden dilatation, which means cervical paralysis (and, perhaps, laceration of nerves). In this sudden paralysis (patulousness) and rapid recovery lies the fatal infection story of many an abortion. When the rhythmical waves of the uterus become violent, disordered, and force the fetal ball with unnatural vigor against the quiet cervix, the latter soon yields. However, the dilatation of the cervix is so violent and sudden that it becomes paralyzed and remains patent, patulous, after the fetal ball has been forced through the cervix. It will require two to four days for the paralyzed cervix to recover and close its canal, but during that time the patent cervix serves as an open door through which infectious germs pass into the uterine cavity. After the germs have entered, the cervix recovers from its paralysis, and closes its canal with its natural vigor, which prevents free drainage, and the multiplying germs pass through the oviducts into the peritoneum. Hence, drainage which is ample in labor, its lack is the essential element of danger in abortion.

With a comprehensive view of the kinds of nerves (sympathetic and spinal) supplying the uterus and their function (rhythmical and non-rhythmical), the physician is better capable of administering successful treatment. The genitals possess the largest nerve supply among viscera and, therefore, we may expect the greatest amount of neurosis from pathologic conditions arising from them. The essential pathology of the sympathetic nerve in health and disease is through reflex action. The reflex action from the



Ov.
Od.
Ut.
V5
X
R
Pu
S.G.
G.S.

genitals may disturb any one or all other viscera, as to function (peristalsis, absorption and secretion) or structure. The reflex action may compromise circulation (congestion or anemia), as regards the blood or lymph, and, consequently, assimilation.

When an adult female is suffering from reflex troubles the cause is generally found in the tractus genitalis. Reflex action travels on definite nerve tracts, and is reorganized in definite nerve ganglia (centers).

Nerve forces travel with most facility on lines of least resistance, which will be nerve plexuses containing the greatest number of nerve strands and ganglia; therefore, genital reflexes will pass first directly over the hypogastric plexus to the abdominal brain, whence reorganization will emit it next to the stomach, for the gastric plexus has a large number of nerve strands and ganglia. Consequently, women in reflex disturbances complain first of stomach troubles. The pelvic brain involves matters important to the science and practice of medicine. The dynamics of obstetrics is involved in the pelvic brain—the cervico-uterine ganglion. It must explain the normal and anomalous pains (peristalsis) of the uterus. The pelvic brain must explain the initiation and parturition (labor), its maintenance (continuous rhythm), and cessation. For the science of uterine peristalis, its beginning, continuing and ending, the pelvic brain (and the automatic menstrual ganglia) must be studied. It is time we realize that the genital circulation, in its different phases of pueritas (quiescent), pubertas (congestion), menstruation (engorgement), gestation (engorgement), climacterium (irregular congestion), and senescence (quiescence, anemia, atrophy).

By a more perfect understanding of the nervous system of the tractus genitalis more light may be shed on such diseases as eclampsia, mania and other diseases emanating from the genitals. A knowledge of the nervous system of the genital tract is not valuable for the science of obstetrics and gynecology alone, but it is important for successful practice. For long centuries though the stately, periodic, peristalsis "labor pains" had excited the wonder of all observers, yet until the last half century little of practical value had been established as to the nerves of the genitals. The work of Franz Kilan (1800-1863) on "The Nerves of the Uterus," issued in 1851, was the foundation of almost all subsequent labors. Kilan was an obstetrician and attempted, in a philosophical method, to solve the problem which nerves and from what source is the uterus influenced. From Kilan's well-known investigations modern books have copied, with and without acknowledgment.

Toward the end of gestation the cervix becomes more and more effaced. This anatomic fact exposes the pelvic brain to trauma (pressure) from the child, especially its head, which gradually excites, or irritates, the pelvic brain, arousing uterine peristalsis, which is finally increased to expulsion, or labor pains.

Coma and Delirium in Continued Fevers.

BY W. W. RICHMOND, M. D.,
Clinton, Ky.

For the relief of coma and delirium in continued fevers, nothing can equal cold applications to the head, which is always found extremely hot.

The ice cap, water coil or ice water douche should be freely used.

A convenient mode of using cold water on the head is by means of a towel tacked across the ends of two upright pieces six or eight inches wide, and same height of bed. The towel is stretched tightly by means of a central piece as a fulcrum, and bringing the distal ends together.

These ends are held by a strip tacked across them. This should be placed in a tub, and the patient turned across the bed, with the head placed upon the rack, and the bowl of ice water, or cold well water, placed on the central piece below the towel, and the nurse pours cold water on the head, which comes in contact with its entire surface, cooling all parts alike at the same time, to the great relief and comfort of the patient.

[Written for the MEDICAL BRIEF.]

"Active Air."

BY JAMES C. ROSS, M. D.,
Colorado Springs, Colorado.

Is consumption and tuberculosis one and the same thing? If not, what constitutes consumption and what tuberculosis? We have fallen into the habit of using the two terms synonymously, and, may be, recklessly.

The term consumption has been used for centuries to designate a particular form of wasting disease, but in recent years this term has been almost entirely abandoned by the profession, in favor of the term tuberculosis. Inasmuch as we almost invariably associate the term tuberculosis in our minds with germs, and inasmuch as germs may not be the important factor in the conditions which the profession has been trying so long to overcome, and in view of the further fact that the tubercle bacillus is beginning to hold a doubtful position in many scientific quarters, if called upon, I would cast my vote in favor of the old name, consumption.

I shall endeavor to show that the tubercle bacillus does not cause consumption, does not enter into it as a primary factor, and if a factor at any stage of consumption, it enters only as a complication that may or may not add anything to the dangerous consequence of the disease.

In supporting this theory, I shall present many of my arguments interrogatively, because many points are yet in doubt, and depend much upon circumstantial evidence rather than positive proof.

In showing preferences for the term consumption, my aim is not so much to draw fine distinctions of nomenclature as it is to question the significance of the tubercle bacillus and the basis for the bacillophobia that started two decades ago, and now has the world's people in a state of panic.

The tubercle bacillus is admittedly a vegetable organism and not a natural habitant of the normal animal, but in spite of this fact it has been condemned as an aggressor and death dealer mainly on circumstantial evidence, which ha been shown to be more or less unreliable It is true that it is generally found pres ent at some stage, in the course of con sumption, but is there any positive evi dence that it is in any way the cause The scientific world has labored for year to find positive proof of its guilt, but ha anyone been able to show that it is destroyer of living tissue, or contribute in any way towards the death of th consumptive?

Is it not true that much evidence i being developed in support of its inno cence; evidence to show that it is saprophytic organism, that it prefer dead tissue; in fact, cannot subsist o living tissue?

Is it not possible that the fact tha consumption is transmissible from ma to the guinea pig by inoculation, ha had much to do with the deep-rooted conviction that the tubercle bacillus i the primary cause of consumption, an is the all-important factor in the destruc tion of the life of the consumptive. I so, is the evidence reliable? Does Natur produce consumption in this way?

When the immortal Koch announced his discovery of the tubercle bacillus the world naturally jumped at the con clusion that the problem of consumption was more than half solved. That th germ being known, the antitoxin prin ciple that worked so well in other germ diseases would, when the same principl was applied, cure consumption. But di it? Has not this principle steadily an surely maintained when applied in othe germ diseases? Why, then, should it fai in this? If consumption is a germ disease does it not look as if Dr. Koch failed t isolate and identify the right germ?

The serum therapy proves up so satis factorily in many of the other germ diseases, why should it so ignominiously fail in this? If consumption is a germ disease, and the antitoxin principle fail when applied to the tubercle bacillus which it certainly does, then why no try it on some of the other germs tha are found to be associated with thi disease? If the right germ has not bee identified, why not extend our research Doubt cast upon Dr. Koch's deduction reflects no discredit upon the world'

enowned bacteriologist, whose success as been so phenomenal in germ diseases. e certainly deserves the undying grati-de of the world, even though he failed ascertain the cause of consumption. he profession, after trying to confirm s theory since 1882, has failed, and ow finds itself in a wilderness of un-rtainty. There is something wrong. ave we been following a delusion? ith all our knowledge of the tubercle cillus, the profession, as a whole, are t little better prepared to cope with nsumption than they were in the days Hippocrates and Esculapius.

Assuming that we are at the end of our sources in our efforts to fix the re-onsibility upon the tubercle bacillus as ing the cause of consumption, and ad-itting, as we must, that all efforts to re consumption by treating it as a rm disease due to the bacillus tuber-losis have been disappointing, and in ew of the further fact that consumption n exist and be real consumption with-t anyone being able to detect the esence of the tubercle bacillus, may we t wisely conclude that, owing to some asting process, the germs are attracted erely to feed upon the waste products, hich, wasting, may depend upon faulty trition, from a lack of air, or proper ment, or both. Would it not be more tional to treat the cause rather than e effect?

Your answer to this might be, that all ese conditions constitute a combination factors so closely associated that we nnot separate them and treat consump-n successfully. My reply would be at we are doing it. Actual experiments ove that consumption can be treated ccessfully without paying any of our spects to germs. Open air life for the nsumptive, combined with suitable ali-ent, when properly carried out, is at-nded with far greater success than any rmicidal methods, and this, too, right the midst of billions of germs, includ-g myriads of the dreaded tubercle cilli.

By the open air method of treating nsumption, we are taught an important sson. It indicates to us that the germ not the all-important factor which we ve been led to believe, if, indeed, it is a factor at all worthy of consideration in our efforts to suppress consumption. It, together with other things, teaches us that the cause precedes the germ in the consumptive by some pathological condition which we may properly call consumption. It is in my mind doubtful if consumption can at any stage of the disease be called tuberculosis, if tuberculosis must be ascribed to the destructive powers of the tubercle bacillus.

Your argument might be that the tubercle bacillus in itself may not be so destructive, but the well-known pyogenic germs so commonly associated with it, constituting mixed infection, are destructive to life.

My reply would be, the question, in what way is the tubercle bacillus responsible for the presence of the mixed infection? Is it not more than probable that the mixed infection comes also of their own accord to feed upon the waste products, and that they are not there by the invitation of the tubercle bacillus; that all come much as vultures are attracted to carrion?

I know that you are unprepared to share with me in my skepticism. It has been a part of your education and daily life to show your deference to the tubercle bacillus. I am myself loath to admit that my hobby is slowly but surely passing away. I regret to be forced to admit that I have been teaching false doctrines, because it is a beautiful theory. It seems so real, so plausible, but in view of these facts is it not about time that we should stop and ask ourselves the question, is the tubercle bacillus the deadly monster it has been represented to be? If it is, then can we free the atmosphere of it and prevent contamination, and thereby save our susceptible people from its ravages? I would say no, a thousand times no. Its presence has been shown to be broadcast throughout the land in all parts of the world, and it is so light when dry as to be carried upon the wind, which makes such undertaking as impossible as it would be to stop the wind. As long as vegetation grows and the winds blow, we shall be contaminated with this organism.

In my judgment, in studying the conditions which make consumption possible,

we must begin at the blood, inasmuch as the blood is the basis of soil conditions. The cells that go to make up the body are wholly concerned in the elements that compose the blood.

Our observations have taught us that conditions under which persons receive but little pure air are the most subject to consumption and that open air life affords the best chances of escape.

We are told by the tubercle bacillophobists that the tubercle bacillus must find suitable soil, that many persons possess natural resistance to it. What is suitable soil but another name for consumption? Some say that suitable soil consists in lowered vitality, depression of the system, malnutrition, dyscrasia, or anything that lowers the vital powers. It is admitted that thousands of people have lowered vitality, depression of the system, malnutrition, dyscrasia, and other things that lower the vital powers, who do not have tuberculosis. In fact, the great majority of them do not. Then, of what does suitable soil consist? Can one be starved into tuberculosis? This is lowered vitality. Can one be bled into tuberculosis? This is depression. Do dyspeptics always have tuberculosis? Here is malnutrition. Will loss of sleep cause tuberculosis? In this the vital powers are lowered. It is seen that the term suitable soil comprehends more than these.

Venous blood comes in contact with atmosphere in the lungs and is changed to arterial. It is here in the lungs that the respiratory organic impurities are exchanged for atmosphere, and the blood rendered pure for nourishing the body.

Again, to every student of physiology it is known that the food we eat is not transformed into blood corpuscles until it meets, in the lungs, the air we breathe; if, then, we do not take in enough air, or what we do take in is impure, the blood will be imperfect and in proportion unfit to nourish, strengthen and vivify the body.

Thus it is that faulty or imperfect elimination of the respiratory organic impurities produces an altered condition of the blood, altered in that venous blood is not properly changed to arterial; altered in that the food we eat is not properly transformed into blood puscles. This blood induces a cons tional weakness, which we call pretu cular or soil or consumption, and i prepared in no other way.

There are many reasons why such exchange does not or can not take p to the required degree. First, the breathed may be vitiated. Second, respiratory organs may be incapabl delivering the necessary amount of ai the blood, because of anatomical obst tions, either congenital or acquired. required obstructions may consist of lapsed air-cells from non-use or f mucus coating, or thickening from cat of the lining membranes, or from a v of knowledge of how to breathe prop All of which, and more, contribute to suspension of atmospheric influence.

It is not only important that the b be well aerated, but it is equally im tant that it be well distributed to parts of the body, that no part may allowed to fall into decay and in germs.

The mere turning of a consumptiv the consumptively inclined out into open air does not insure the neces amount of aeration. Greater ener must be employed towards assisting ture in its restorative efforts. If the sumptive is incapable of taking suffic air, even when the opportunity is forded, why not try to render him n capable? If by inheritance, habit disease, his lungs are obstructed and capable of admitting as much air as blood requires to keep it in normal dition, or restore it to a normal condi when diseased, then why not use m of removing the obstruction to resp tion. If air is good, and air is wha needed, why not give the consump more air? If the air is not active eno as it is in its natural state, to perf the requirements demanded of it by blood, then why not make the air n active? Air as provided by nature is doubtedly active enough to serve the pose under ordinary normal conditi but under abnormal conditions, woul not serve a better purpose if it v made more active?

I cannot do my subject justice wit touching upon some of the methods

loyed by me in the management of consumption, which have been instrumental n causing me to arrive at the foregoing onclusions.

It has been my constant aim to give ny consumptives the advantages of an bundance of fresh air and all the sunhine they could get, and remove obtructions to respiration, if possible. My xperience with "active air" has more fully emonstrated to me the importance of eration in the treatment of consumption. Vhen I say "active air," I mean air iat has been subjected to the action of high potential current of electricity and ien passed through volatile oils of the erpine group to relieve it of its irritatng effects. When such oils as eucalypis, pine needles and cajaput are treated ith air that has been rendered active y means of a silent discharge of elecicity, a combination is formed which a terpine peroxide compound wherein ie electrofied air is relieved of its drasc properties and the patient is enabled o inhale vast quantities without unward effects. This inhalant increases ie red corpuscles and hemaglobin of the od and renders oxidation more comete. It has a stimulating influence upon ie vaso-motor system, which, in turn, ouses all the organs of the body to a etter performance of their functions. he blood is better distributed; the apetite is increased; sleep is better and igestion and assimilation are markedly nproved.

Air rendered active in this way has a owerful influence over blood conditions, nd, consequently, over the consumption rocess. Active air not only increases ie red corpuscles, percentage of hemolobin and specific gravity of the blood, nt has a power even greater than that ossessed by an absolutely dry atmoshere, in that exhalation of organic imurities is made easier and the blood iade freer from these elements which, retained and reabsorbed by the tissues, ould contribute most extensively to hose constantly recurring unfavorable ymptoms of consumption.

I speak of the action of "active air" n the consumptive, for the reason that ny practice is largely confined to that roup of invalids, but its action in respiratory troubles is less positive than it is in certain forms of nervous troubles, many conditions of anemia, skin diseases, tetanus and syphilis. Its specific action in the latter is the most remarkable in its field of application. Not knowing the cause of syphilis I cannot well define its action, but I know to a positive certainty that it does cure it, and accomplishes the cure in the most satisfactory manner to both the physician and patient.

I am of the opinion that a careful study of hematology will disclose the fact that many widely different diseases primarily find their first divergence in disturbed blood conditions. This statement is not without justification, in view of the many phenomenal reports from the users of active air in reference to its action in scarlet fever, diphtheria, typhoid fever, malaria, etc.

If I were asked what I regard as the best course to pursue in the treatment of consumption, I would say, "Stop fighting germs" and give your patient a life in the open air; remove as far as possible obstructions to respiration, expand the lungs by calisthenics, exercise the muscles, or rest them according to the physical condition of the patient; give good and wholesome food rich in fat. I would use active air from the earliest possible moment after the patient comes under your direction. This treatment alone is an unquestioned and absolute specific in the first and second stages of consumption. In the advanced stage I would use in connection with active air the subcutaneous injection of oils in sufficient amount to cause the weighing scales to show each week an increase in weight, all of which go to serve the conditions best which we are called upon to meet.

[Written for the MEDICAL BRIEF.]

"Complications" of Influenza.

BY J. D. HARRIGAN, M. D.,
New York City.

No word, in the opinion of the author, tends more to complicate the study of the etiology of influenza and other epidemic diseases than the word "complications."

It throws one entirely off the scent.

We hear of influenza "complicated" by congestion of the lungs, congestion of the kidneys, liver, spleen, brain, spinal cord, etc.

These conditions have no right to be regarded as complications, since they are part and parcel of the process transpiring, known to us as influenza.

The "congestion of the lungs," the "pleurisies," the "pneumonias," the "meningitis," and other so-called phenomena, are simply manifestations of the many and complex chemical and electro-chemical processes transpiring, and, grouped together, are known to us as influenza.

We can speak correctly of complications only when an entirely distinct and different disease occurs contemporaneously with a prior complaint.

Thus, for instance, a patient suffering from influenza, with severe cerebral localization of the disease, might possibly get out of bed in his delirium and, falling on the floor, break a leg.

This certainly might be justly called a complication of his pre-existing ailment.

Similarly he might receive a burn or scald, or be wounded, and septicemia develop.

All of these would be complications.

But to speak of natural incidents of the disease as complications is erroneous and misleading.

It would be absurd to say of a great conflagration raging in New York, for instance, that the fire was complicated by the burning of the Metropolitan Opera House, or that particularly striking feature of the city known as the "Flatiron."

These would be only incidents of the general process going on.

Even if a particularly tremendous outburst of flame and smoke should suddenly attract our attention to some one place attacked by the flames, accompanied, possibly, by severe explosions, we would simply take for granted that a noteworthy incident of the conflagration was occurring, caused by the involvement of, perhaps, some great chemical warehouse.

A genuine complication of the fire would ensue if, for instance, the water supply should be suddenly cut off, owing, perchance, to the bursting of the water main.

So we might cite many instances genuine complications as opposed to t that are really only apparent ones.

How can a clear, correct and thoro knowledge of the etiology of disease had if we are unable to read aright visible, outward manifestations of s disease and, not only that, but also t connections with each other and, wise, the peculiar significance that n attach to them when viewed separat together, and from various sides.

Is it not perfectly apparent that i patient suffering, for instance, from s ilis, we would expect to find syphi lesions in many parts of the body?

Hence we would expect to speak syphilitic iritis, syphilitic laryng syphilitic periostitis, etc.

We would not say that the patient syphilis complicated by pericstitis, o laryngitis, iritis, etc.

And yet this is exactly what is with regard to influenza and other demic diseases.

We can cite instances almost wit number of this misconception of the significance of the various manifestat of these diseases.

As an example might be mentioned following, taken from Prof. Zuelzer's on influenza in Ziemsen's Cyclope *"Uncomplicated* Forms of Influenza dom Lead to Death.

"As essentially belonging to the dis we find only a more or less consider hyperemia and catarrhal swelling of Schneiderian membrane, as well as of mucous membranes of the phar larynx, trachea, and bronchi. The cat is often limited to the larger bronchi, in other cases it extends even into t finest ramifications, which sometimes be filled with clear, thin, frothy mu and sometimes with thick, viscid, op masses. Catarrhal and croupous p monias, or pseudo-membraneous capi bronchitis, etc., are included in the *plications* which generally bring abo fatal result. In the stomach, too, more rarely in the intestinal mu membrane, we find more or less exte hyperemia."

According to this statement one w be led to consider influenza as a m local affection, involving the Schneide

nembrane, pharynx, larynx, trachea, and ronchi.

Involvement of any other organs or tructures must be regarded as an onset f new diseases—for that is exactly what he word "complications" would indicate —if we were to take this statement liter- lly. Local affections would supervene pon local affections. But is this the ase? We know that it is not.

Zuelzer himself in a paragraph imme- iately preceding the above, shows that t is not.

He says: "The influenza is, as Biermer as properly described it, the sum of a eries of catarrhal manifestations which ave developed under common epidemic nfluences.

"* * * the sudden onset and the ften critical termination of the disease, ts general seizure, the severe nervous ymptoms, as well as the decided disposi- ion to cough which invades the organs f respiration, with a proportionately light increase of the secretion of the nucous membrane, all these are in favor f a general agent which rapidly affects he organism at large."

If this is the case, as all certainly must cknowledge is surely the case, judging rom the history of the disease and its ymptoms, then why detract from its ex- raordinary significance and "complicate" natters by terming any of its manifesta- ions "complications?"

No one surely would term any of the nanifestations of syphilis "complications" f that disease.

We speak of these localizations of this ffection as, *e. g.*, syphilitic iritis, syphil- tic periostitis, etc., as mentioned before.

Similarly, therefore, we should, to be trictly accurate, speak of influenzic pneu- nonia, influenzic gastritis, influenzic men- ngitis, etc.

Otherwise we would be influenced to hink that we were dealing with several listinct, separate diseases, and not with ne general disease, with innumerable ocal manifestations.

If we are dealing with one disease hav- ng "one general agent affecting the or- ganism-at-large," the task of locating and naming this agent becomes easier by con- sidering this one disease as one disease with various localizations, than it would be by considering a confusing array of "complications."

This, naturally, would bring up the question as to what way this general agent was distributed to the various parts of the body, and inevitably compel us to seek in the two grand trunk systems of supply to the tissues of the body, *viz.*, the nervous system and the circulatory system, for its place of development.

To either of these great systems, or to both of them, must we look for this "general agent," as mentioned by Zuelzer.

It might be said, in passing, that the extraordinary neglect of the nervous system as an important factor in the causation of diseases of an epidemic nature, has caused no end of surprise to the author.

How any one can see the various wonderful operations in electro-chemistry going on at all times around us in Nature's laboratory, with a reduplication to a very limited extent of some of these operations by man—more particularly in electro-chemical crystallizations—and not realize most deeply, and with far more than a passing interest, how intimately associated with all the functions and operations of the human body electro-chemical action is, is a matter for wonder.

It would seem only necessary to recall to mind some of the phenomena of the neuroses that have had as a result of their potency a complete change of anatomical structure in some one or other part of the body, to appreciate the fact that these results can be reduplicated to an incredible extent and to, if you might be so pleased to call it, an exaggerated extent.

Thus, we know that a sudden shock to the nervous system has had the effect of blanching a person's hair in a single night; a sudden fit of anger in a child has produced a crop of "shingles;" the sudden shock to the nervous system, caused by some passing emotion of pleasure, of anger, etc., has caused the face to become suffused, a flush, or blush, being the result; in other words, a congestion has resulted.

Dozens of instances might be cited similar to these, but they are unnecessary.

The above suffice to serve as an example. Where these so-called phenomena are possible, other phenomena on a much

more extensive and grander scale would seem to me to suggest themselves. Particularly would this be the case if, besides taking into consideration the nervous system, with its electro-chemical possibilities, as a factor in the matter, we should conjoin with it other chemical and electro-chemical possibilities in the shape of the food and fuel supply furnished by the circulatory sytsem.

The processes of peripheral congestions (as likewise of central ones) would simply be multiplied and remultiplied and extended, not only as regards area and locality, but likewise as regards intensity, and we would have as but steps from the congestions resulting inflammations, exudations—pseudo-membraneous and membraneous—disturbances of function of many parts of the body, with their greatest intensity localized at the point of least resistance; this intensity being modified in turn by several causes, not the least of which would be the quantity as well as the nature also, of the chemical constituents making up the disturbing factors in the matter.

By eliminating from our minds the idea that the "pneumonias," the "pleurisies," the "cerebro-spinal meningitises," the "nephritic," "hepatic," "enteric," "splenic," "cardiac," etc., manifestations are "complications," and simply considering them at their proper valuation as part and parcel of the disease we should certainly be able to clear the way for a much better understanding of the intricate operations, having their bases of chemical and electro-chemical activity in the nerve and blood supply in the animal economy, and which act as factors in bringing about that condition of the body which is a departure from what is known as "health," and has been known from time immemorial as "disease."

If influenza is, as Biermer says, "the sum of a series of catarrhal manifestations * * * due," as Zuelzer states it, "to a general agent which rapidly affects the organism at large," who is there who will place a boundary line for these manifestations?

Is it simply influenza when the Schneiderian membrane, as likewise the mucous membranes of the pharynx, larynx, trachea and bronchi are affected, a
some other disease when the "gene
agent," mentioned above, escapes the
limits and wanders up and down, and
and out through the rest of the system?

Is it simply influenza when the patie
gets better, and some other disease wh
the patient dies?

Has the "quantity" of influenzic ma
rial—the "general agent" mention
above—nothing to do with the extensi
as likewise with the intensity of the
tarrhal manifestations, with nothing
prevent the latter from proceedi
through all gradations of inflammation

Shorn of its hydra-headed, mystifyi
"complications," influenza is not such
difficult matter to comprehend.

Due to a "general agent which rapid
affects the organism at large," affecti
primarily, the blood and nerve supply,
ing wherever these go, modified in ma
ways by peculiarities of the individu
(chemical and electro-chemical), as, al
by peculiarities of chemical surroundin
generally termed hygienic, or sanitary,
culiarities of food and drink; also che
ical peculiarities of climate, chemical a
electro-chemical once more, it goes wi
out saying, almost, that it must be diff
ent under different conditions, must
different in different parts of the wor
must be different in different individua
etc.

Add to this its possibility of locali
tion of greatest intensity in any one,
several parts of the body, and it mu
certainly strike one with a force irresi
ible that certain of the epidemic diseas
that go hand in hand with influenza, a
that devastate the earth at various tim
posing under various titles of disea
having as their basis a ridiculous a
misleading arbitrariness of classificati
totally unjustified, are simply manifes
tions of the influenzic principle, or pr
ciples, at work.

Is this not possible?

Is it not, by all manner of means,
more scientific to claim a gradation
diseases, basing our deductions on t
known gradations in symptoms in diff
ent individuals, in different epidemics,
different localities, in different surrou
ings, etc., than to lay down a strict li
of demarcation between them, labeli

hem green, red, blue, yellow, or black, as he case might be?

In support of the gradation theory of isease it should certainly strike us very orcibly that never in the whole history f epidemics has one distinct type of dis-ase appeared alone to afflict the globe.

The epidemics have been one long ser-s of "dissolving views" of various shades nd intensities of disease.

Delegate the so-called "complications" o their proper, subordinate positions in he economy, and bring into greater prom-nence this all-pervading "general agent hich rapidly affects the organism at rge," and whose limitations no one can y are definitely fixed, and how easy ecomes the solutions of the coincidental ccurrences of epidemic diseases.

Consider, for a moment, that this "gen-ral agent," or what appears to the author ore probable, combination of "general gents," diffuses through the system with rapidity and an intensity far greater an the "general agent" of syphilis, and, ot unlike the latter disease, locating it-elf here, there and everywhere, and we an very readily see where the so-called complications" belong.

Then would the terms appear more ap-ropriate as, for example, "influenza with leurisy predominating," "influenza with neumonia predominating;" or, better till, might be "pleuritic influenza," or pneumonic influenza," or "hepatic-ic-eric-choleraic influenza," as the various anifestations would predominate.

It would be easy enough to devise a roper nomenclature for the varying hases of the disease.

The main principle involved is to keep orever foremost in our minds the influ-nzic agent of the trouble, and, just as we now that the syphilitic lesions, under hatsoever guise they may appear, are rst, last and all the time syphilis, so must ve appreciate the fact that the influenzic esions are first, last and all the time in-luenza.

And just as sure as the influenzic prin-iple is given its proper position of prom-nence, and the train of influenzic lesions roperly relegated to less prominent posi-ions than they now hold as "complica-ions" will, I have no doubt, the list of nystifying companions to the dread afflic-tion be suddenly shortened. I would state that in the MEDICAL BRIEF for February, 1904, under the title of "The Etiology of Influenza," to which I would respectfully refer the reader, has been set forth the outline of a theory that to my mind explains not only the origin of this disease, but elucidates also the mysteries of its "complications."

668 Lexington Avenue.

The Treatment of a Common Head Cold.

BY F. P. ATKINSON, M. D.,
Bexhill-on-Sea, England.

A cold in the head is generally considered such a very trifling affair that little or no attention is paid to it, but every now and then it is clearly shown "how great a matter a little fire kindleth," more especially amongst the very young and old. In both these stages of life it is not so very uncommon to see an extension of mischief, and a development of either bronchitis or pneumonia, and yet if the head cold be properly and expeditiously dealt with it may be completely stopped in the course of a few hours. Thirty drops of sweet spirits of nitre and thirty drops of sal volatile in an ounce of water, repeated in two hours, and then every four hours, will rarely fail to accomplish the object in view, in about six or eight hours. When the discharge becomes thick, a snuff composed of one grain of cocaine, two grams of menthol and one hundred grams of boric acid is particularly useful.

When the cold has already run down into the trachea, as shown by the tickling of the throat whenever a deep breath is taken, then the spirits of nitre and sal volatile are utterly useless, but a mixture consisting of two drachms of the solution of acetate of ammonia and ten drops of sweet spirits of nitre in an ounce of water will rapidly give the required relief.

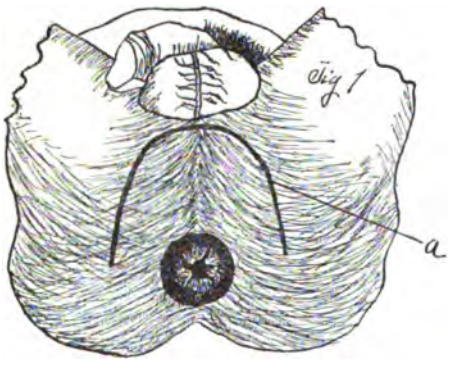
Enclosed find one dollar for renewal to MEDICAL BRIEF for 1905. It is well worth the money. We like 'em.—F. A. BOSWELL, M. D., Elmore, Ala.

[Written for the MEDICAL BRIEF.]

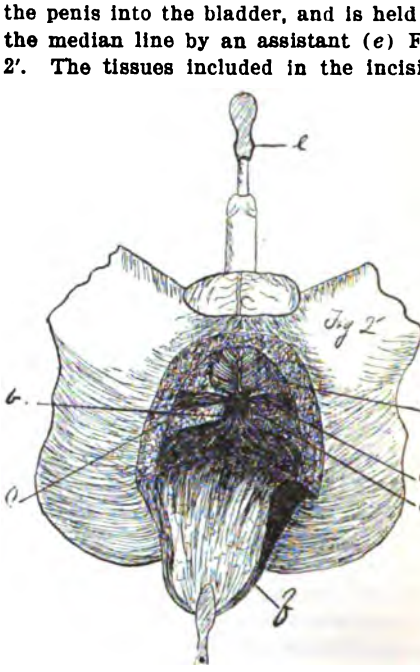
Technic of Perineal Prostatectomy as Used in Thirty Cases.

BY M. R. BARKER, M. S., M. D.,
Chicago, Ill.

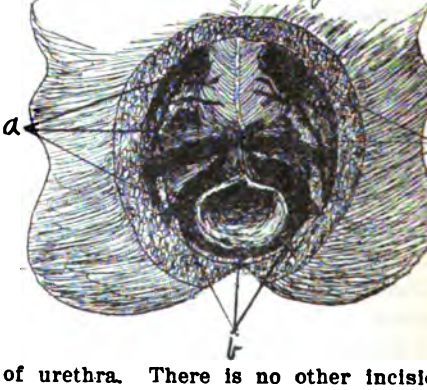
Perhaps there is no other operation wherein the surgeon is so generally solicitous of maintaining the vital forces of his patients, during the operation, as in prostatectomy. The reason for this is obvious: These patients have all passed the zenith of their physical endurance and, many of them, by reason of great age, combined with feebleness, due to their disability, are hazardous subjects, to say the least, for major surgical work. Hence, different surgeons follow different methods for doing the work, all of which are similar, and yet all different in detail, each surgeon using the method which, in his experience, best meets the demands of the operation.



My experience has taught me that there are three essentials to be attained in each operation, if we would conserve, to the uttermost, our patient's stock of vitality: Short operation, minimum loss of blood, and least possible traumatism. I have been able to accomplish these best by the use of the inverted U incision. This incision, or some modification of it, has been used for different perineal operations for more than a thousand years, and its usefulness should be pretty well established. The incision commences about one-third of the way from the tuberosity of the ischium to the margin of the anus, and is carried up over the bulb of the urethra, and around to a corresponding point to that of starting. Fig. 1 (*a*). It includes the integument, superficial fascia, and t perineal fat. Before the incision is ma however, a grooved staff is passed throu the penis into the bladder, and is held the median line by an assistant (*e*) F 2′. The tissues included in the incisi

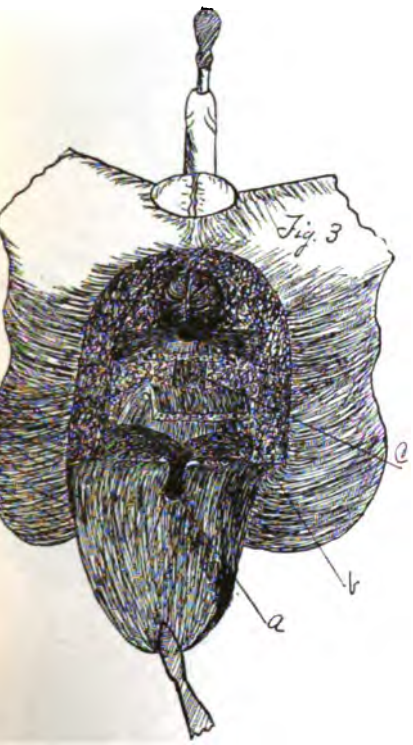


are now carefully reflected, (*f*) Fig. which reveals the following structure (*a*) Fig. 2′, central tendon of the pe neum; (*b*) Fig. 2′, anterior fibers of ext nal sphincter ani; (*c c*) Fig. 2′, tra versus perinei muscles; (*d*) Fig. 2′, bu

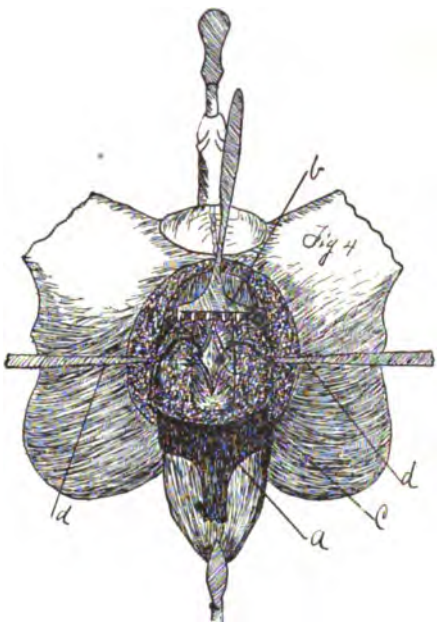


of urethra. There is no other incisi which brings the tissues, with which must deal, so plainly into view, and whi reveals every step of the operation so we If we deviate from the median line, a cut one of the transverse perinei muscl

e will also cut one of the main branches
f the internal pudic artery, the course
f which lies along this muscle. Hence,
hile we must advance our work and get
rough these tissues, it is best to avoid
ie hemorrhage which the above course
ould entail. We, therefore, avoid the
teral incision. The blood and nerve
pply of the external sphincter ani enter
at the side of the rectum, hence this
hincter can be cut, close to its insertion
to the central tendon, without hemor-
age or injury to the blood and nerve
pply of the sphincter. This, then, is

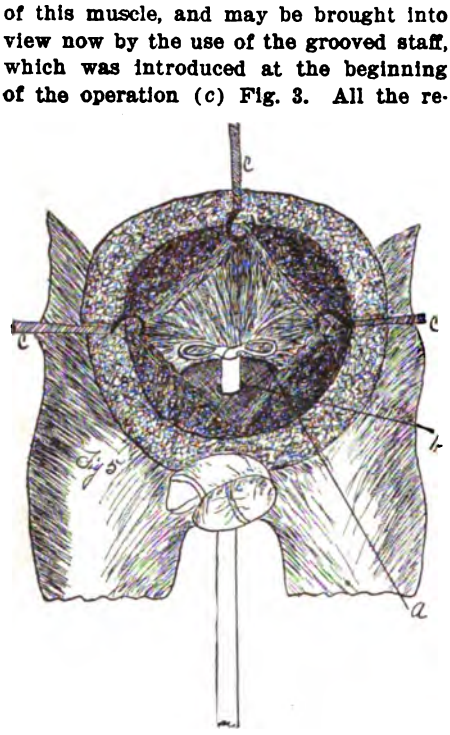


ne, and the muscle reflected (*a*) Fig. 3,
t by so doing the sphincter is rendered.
a time, inefficient, unless restored,
nce the last step in the operation, just
fore putting in the drainage: This
hincter is brought back and stitched to
e central tendon. Cutting this sphinc-
allows the rectum to recede, increas-
g the room for operating and diminish-
g the danger of injury to the rectum.
Fig. 2″, shows the incision carried back
yond the end of the rectum, demon-
rating the external sphincter ani. This
hincter originates at the coccyx. Its
fibers separate and pass on each side of the rectum (*b*), Fig. 2″, and are inserted into the central tendon of the perineum. This anatomical arrangement shows what would result from cutting this muscle, without restoring it. This cut also shows the relation of the rectum to the operative field, and the location of the internal pudic arteries (*a a*), Fig. 2″, the principal blood supply of the perineum, and the arteries with which we are most concerned in this operation. The incision in Fig. 2″ is never used as the operative incision, but is used here to illustrate more fully the relation of the structures with which we must deal in doing this work.

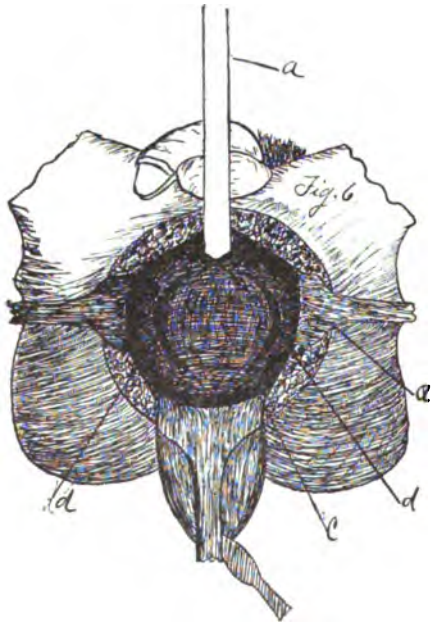


After reflecting the cut fibers of the sphincter ani, and continuing our advance by blunt dissection, we come to the anterior fibers of the levator ani muscle, which passes from the posterior portion of the prostate, obliquely forward, to be inserted into the central tendon. The rectum is attached to this muscle for a short distance anterior to the prostate. This muscle is sometimes known as the recto-urethralis, and again as the levator prostate. The finger is hooked behind this muscle, its fibers drawn forward, cut and reflected (*b*) Fig. 3. This allows the rectum to recede still further, and increases still more the room for operating.

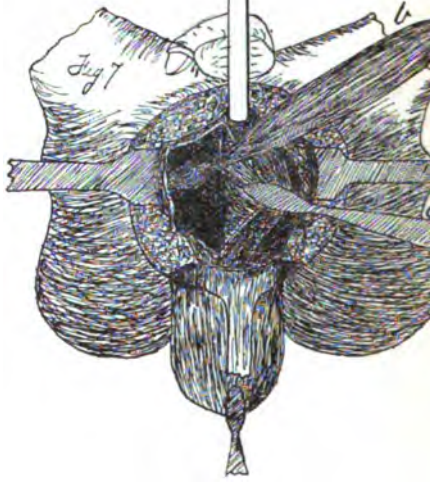
The membranous urethra lies just back of this muscle, and may be brought into view now by the use of the grooved staff, which was introduced at the beginning of the operation (*c*) Fig. 3. All the re-



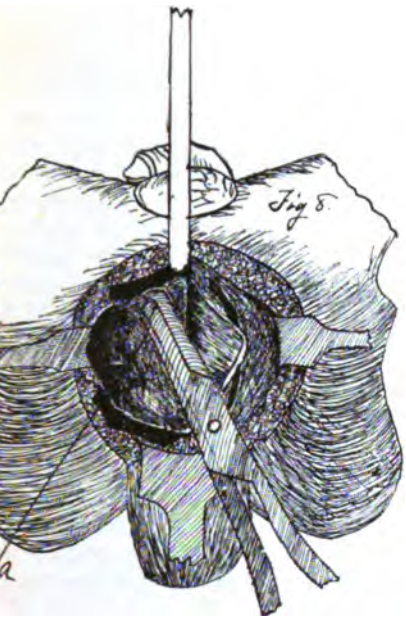
flected structures are now retracted, posteriorly (*a*) Fig. 4. The tissues attached to the central tendon are drawn forward by means of a sharp retractor (*b*) Fig. 4, bringing the membranous urethra into



the operative field. This is now incise on the grooved staff, exactly in the m dian line, and its edges separated hooks (*d d*), Fig. 4. The grooved staff now withdrawn, leaving the opening urethra (*c*), Fig. 4. Through this ope ing our tractor is passed into the bladd closed. The tractor is now opened (*a* Fig. 5, and lies above the prostate (*b* Fig. 5. (The bladder wall is shown this cut incised, and its cut edges hook apart (*c c c*), showing the position of t tractor in it. It does not illustrate a st in the operation). The sharp edges of t blades of the tractor, shown in Fig. 5, a in contact with the bladder wall, whi intervenes between the tractor and t prostate; hence, traction is not mad with the instrument in this position,



the diseased bladder wall would be i jured, many times, if this were done. T tractor is now changed to a lever by e vating its end and bringing its sha against the pubes (*a*), Fig. 6, which b comes the fulcrum of the lever, and t prostate the body to be moved. Th maneuver brings the broad surfaces the blades of the tractor in contact wi the bladder wall, minimizing the dang of injury to the bladder, removes the ha dle of the tractor from the operator's wa and brings the prostate plainly into t operative field (*c*), Fig. 6, for enucle tion. A semilunar incision is now ma

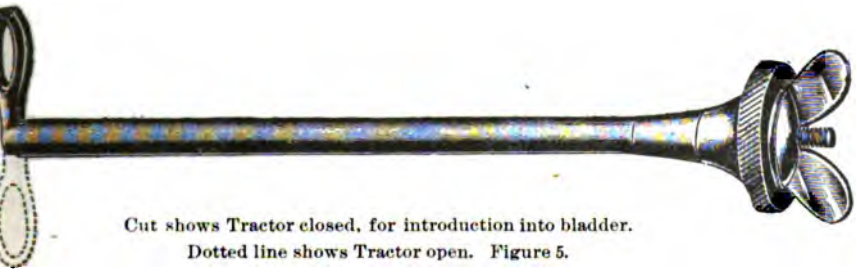


ugh the capsul of each lateral lobe
'), Fig. 6. The curve of these inci-
s is made as pronounced as possible,
affording the most room possible for
cleation. The cut edge of the capsul

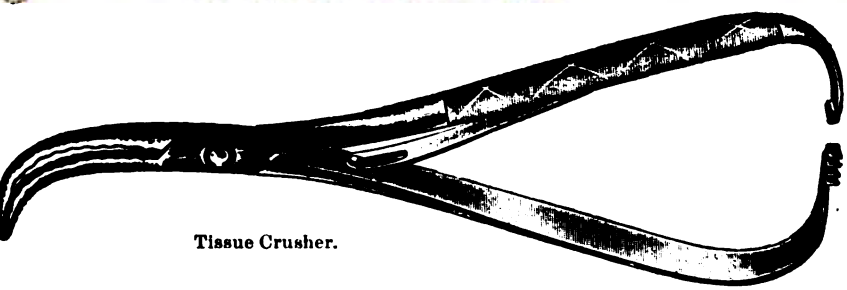
these bands are very tenacious and hard to break up by digital dissection. They are then isolated and our tissue crusher closed upon them (*a*), Fig. 8, which so nearly crushes them asunder that they are easily broken up, thus preventing hemorrhage and lessening traumatism. When the gland is released from these bands, it is easily removed. Both lateral lobes being removed in this manner, the middle lobe is pushed either to one or the other side, and removed through one of the lateral lobe incisions.

The wound is dressed and after-treatment carried out, as indicated in a previous paper.

Our tractor is very simple, easily understood and manipulated by any surgeon. It is introduced into the bladder closed, and is opened (*a*), Fig. 5, by turning thumb-screw five or six times to the left. The large nut is then slipped back on its shaft to the thumb-screw. The large nut is now held by the right hand, while the thumb and finger of the left hand turns shaft of instrument until the groove on the big nut is in line with the groove on the shaft of the instrument. The large



Cut shows Tractor closed, for introduction into bladder.
Dotted line shows Tractor open. Figure 5.



Tissue Crusher.

one side is caught by forceps (*a*),
7, and reflected. The enucleation is
commenced with a blunt dissector
Fig. 7, and continued until the finger
be introduced between the capsul and
gland. The finger is then swept around
l stopped by bands of tissue uniting
gland with its capsul. Sometimes

nut is then shoved back to its place, and the thumb-screw fastened. The instrument is now open and locked. The reverse of this closes the instrument for removal from the bladder. When operating, the groove on the nut and shaft must be in line, and must face the perineum. This is important. The advan-

tages of this tractor are: When in use the broad surfaces of its blades are in contact with the bladder wall. It is very simple, can not get out of repair, and is easily understood and used by any surgeon. The tractor is taken apart for cleaning by simply removing the thumbscrew.

The tissue crusher shortens the operation, and lessens the traumatism and hemorrhage.

Cerebro-Spinal Meningitis.

BY GEO. W. BOWEN, M. D.,
Fort Wayne, Ind.

Possibly, I may be able to contribute something in regard to a disease that is now making its second appearance in this country.

Thirty-five or forty years ago (I can not look up the exact date) I was requested by a physician in Plymouth, Ind., to come and help him with some cases, as I had often done before. This time it was the spotted fever, and many were dying with it.

Knowing nothing about the disease, I went to help him, if I could, and to learn something about this new disease. Many had died after a short attack of it. Three physicians had also been called from Chicago. I stayed three days and found the disease affected the brain first and the upper part of the spine next, generally the second day. All had severe headache and generally a slight chill, to be followed by fever.

The distress in the head was always severe and remained until the patient got well or died. Some died in less than six hours.

We found that those that lived and got well had weals, or red blotches, come out on the back or shoulders, generally the third or fourth day, but if they did not appear the patient died, and then the blotches came out blue. These spots varied in size from that of a dime to a dollar. When the patient lived the spots faded to a brown or yellow, and disappeared in about a week's time.

The doctor and I decided that one cal plan would be to relieve the from the congested and accumulated and help hasten the appearance of blotches that seemed like hives, but elevated. Our methodical plan en us to cure many cases, and we concl that the cases could be treated simil those of suppressed measles, or ery las, that had been forced back fro natural location on the surface. It a local affair, like that of zona, or gles.

From Plymouth the disease nex peared at Richmond, Ind., and a few later, in my city. It was then I ha opportunity to treat nearly thirty by the plan we had discovered, and none. Many died here, and the do and friends, in five or six cases, coul tell why I had them turn over the child, or person, but upon seeing the or blue spots on the upper part of spine they then knew the cause of d

The spotted fever, or spinal-menin was not seen again by me until last ruary, when a patient of mine, a he farmer, complained of a severe pa his head, which came on suddenly. cause could be found for it, so I sent some medicine, thinking it might be raigia.

Next day he was much worse and, making a careful examination, I f he had a slight chill, and the pain gotten down into the spine; also, a that made him nervous. Hesitatin say so, but I assured him and his that he had the spotted fever, and i would look on his back in forty- hours she would find red spots. She f them at the end of that time and we all much relieved. The headache less slowly, but did not leave und week's time. The patient was r weak, or dull, for about two weeks

My next case occurred about the 1 April, and it was a violent attack young, healthy girl, aged twenty-five, urged by her mother to retire at o'clock, for the next night she woul up late. She was rather nervous a time, but went to sleep early. At e o'clock she awoke with a severe pa her head, and screamed for her mo Her mother, unable to do anything

called me, and arriving shortly before
ve, I found her still screaming and
ng. I found her head, neck and arms
cold and with a very feeble pulse.
alized it was severe congestion or,
ibly, a ruptured blood vessel in the
n. The pressure there had to be re-
d, whatever the cause. She was bet-
t three o'clock and went to sleep.
ne next morning it was apparent that
attack was not simply that of menin-
, but one of spino-cerebrolis, as the
went to her spine, while the head
still involved. She recovered fairly

eningitis, but the principal complaint
been headache and weakness.

reatment.—My plan of treatment, since
study of it at Plymouth, has been to
ve the congestion and aid in the ap-
ance of the weals, or blotches, on the
.

am a homeopath and have practiced
icine more than fifty years, and have
ned that violent or acute cases need
immediate and prompt treatment, and that the brain and heart must be more carefully treated than any other organs of the body; the brain is easier and the most succeptible to medicine of all.

Never give more than one-tenth of a drop of medicine for a dose and generally only one hundredth of a drop. In violent cases the doses must be put closer together and only allowing reasonable time for its assimilation or absorption.

Two remedies have been found to be needed in securing the pathologic changes, using them as they are desired. These are belladonna and bryonia. I give them in pills, of course, and am certain that if they are taken morning and night for one or two weeks the spinal-meningitis can not be contracted by any one, for what will cure a disease will prevent it.

Put three or four drops, not more, of belladonna tincture in a glass of water and prepare the same amount of bryonia tincture in same manner, and then give in teaspoonful doses, one hour apart, alternating for first day, two hours apart the second day, and after that three hours apart. Place cotton batting between the shoulders, or soft flannel, as nothing else is required for you to do. Let the bowels remain torpid for a week, if it is necessary, until the brain has recovered from the assault of the disease.

Thus, feeling the responsibility of giving this advice I can not help believing that if this treatment is followed it will save some who are near and dear to others.

I do not believe this disease is either contagious or infectious, or that there are germs that lay latent in the system to come into sudden activity and produce this disease. It can have no relation or connection with any other one unless it be meningitis, for it appears to be a separate and a distinct disease.

With cerebro-spinal meningitis the brain is the first to be involved, then it goes to the neck and spine, and, later, the spots or blotches may appear that are not caused by meningitis.. Whether the arachnoid or the dura mater is congested or not, I do not know, for all I cared for was to learn what would cure it, or prevent its development.

Some Interesting Points Relating to the Psychic Powers of Man, Hypno-Telepathically Demonstrated.

BY C. EDWIN GOODELL, M. D., M. E., PH. D.,
Newark, N. J.

There are undiscovered potentialities in every human mind which only await the magic word of a positive command to be awakened from a state of lethargy to the realization of supremacy and power. I may say, furthermore, that there is nothing within the range of possibility which can not be accomplished by the one who recognizes the unlimited power of the mind and directs it with irresistible energy toward the thing desired.

Many of us encounter, and others read of instances of wonderful psychic abilities, but even so, do not imagine that it made its debut without considerable effort. This may be more fully realized when we take into consideration the extended time required for the development of the eastern adepts, of which I will speak later. One of the most wonderful exhibitions of psychical skill that I have had the pleasure of witnessing away from my native soil was while touring India, some twenty years ago, in company with a well-known American magician, who was in search of mystic material to add to his already extensive repertoire. Not being engrossed in the subject of psychology at that time, but familiar with American magic, was considerably astonished and, I may say, amazed, at the sight we beheld at an open-air seance given by one of those Oriental wonders, the yogi, or Indian fakir.

The occasion, if I remember rightly, was the Viceroy's natal day, a day of general festivities. Upon approaching the vast audience assembled our attention was particularly attracted to one of these fakirs, a wiry little fellow, who, upon giving a shrill whistle, threw what we supposed to be a rope, in the air, which straightened itself out in its upward flight, instead of falling to the ground, as one would naturally suppose, and was left dangling, as if from the sky. Presently the fakir clapped his hands, gave another whistle, and out jumped a small boy f somewhere, no one being within ten fifteen feet of the fakir, and he b clothed in nothing but a small br clout. The boy, being in full view of audience, was picked up from the gro by the fakir and tossed into the towards the hanging rope. Catching of the rope the boy began to climb, r key-fashion, until he was lost to viev the clear sky. After a few moments went the fakir until he, too, was los view. All eyes at this time were riv in space, watching for their return; w lo, down came sections of the boy, h arms, legs and trunk, which fell wit dull thud upon the ground, and a upon looking toward the rope we saw fakir descending, at first looking lik mere speck in the heavens, but gradu becoming larger as he neared the gro Upon his reaching the ground the membered portions of the boy gath themselves together, ran towards fakir and instantly disappeared, lea the whole assembly in wonderment.

The next phenomena brought to view was the mysterious basket tric modified form of which may be seen u the stage at the present time. The f produces a small, fragile bamboo bas which may be examined by the specta After thoroughly inspecting same, wizard places it upon the ground in view of the audience, closes the lid, o it again, still showing it to be perf empty. The lid is again closed, but moment begins to raise and a young appears inside the basket. The fakir mediately approaches the basket, fo the girl down with the lid, and upon d ing a long, sharp-pointed sword pie the basket on all sides, thus causing girl to scream. Each time the swor withdrawn we could see the blood str ing from its blade. The groans of child and the sight of the blood sickening in the extreme. As the dying gasp of the child was heard, fakir opened the basket, showing it fectly empty, the child having di peared. Upon examining the basket more we found no evidence of blood where in the basket or upon the gro

We looked at one another in am ment. My companion said to me, "Ar

vake, or all we all asleep?" I could say othing; candidly speaking, I was dumb-unded.

The seance ended there, and I have ver witnessed anything like it since.

Other instances of these wonderful ex-bitions of skill have since been reported various travelers. The report of offi-rs of an English warship, in company th several English civil officials, is full d complete regarding these wonderful ychological manifestations. One officer ys: "The first time I saw one of these own fellows doing his tricks I'll tell u it opened my eyes as wide as saucers. e were lying in an East Indian port, veral miles out, when he came swim-ing through the surf and scrambled up e anchor's chain, as nimble as a mon-y. He wore no clothing except a nar-w cloth around his loins, and had noth-g else upon him but a red cloth about yard square. The first thing he did s to pick up from the deck a ball of ine which some sailors were using, and he unwound the string from the ball went straight up in the air, instead of lling to the deck in accordance with the w of gravitation. He next took from e hand of an officer a half cocoanut, and lding this aloft, caused twelve buckets water to flow from it. Mind you, this low came over the rail of the ship. He uld not have had a confederate or any eans of assistance on board, because we d just come to anchor after a voyage several thousand miles. Everything used in his tricks belonged to the offi-rs and other men on board. An audi-ce crowded close around him, and there s no possible chance for deception. The kir then took a large earthen dish, ured into it a gallon of water, and held in his left hand, the other being lifted his forehead. The vessel began to ninish in size and shrank until it en-ely disappeared. Suddenly, we saw a own object, no larger than a grain of nd, which grew larger and larger until e dish regained its original dimensions, ed with water, which he spilled upon e deck. His last performance left us amazed that I, for one, went into a itting headache from thinking about He held up for inspection the red cloth which he brought with him. In order to keep it from getting wet as he swam out, he had it tied to the back of his neck in a tight little bundle. He passed it along and every one examined it closely. There was, evidently, nothing unusual about it. It was a plain piece of goods of coarse texture. After spread-ing it out flat upon the deck he walked around it several times, muttering to himself and turning his eyes upwards. Something began to move beneath the cloth. It grew in size as we looked, and out hopped a monkey, chattering and grinning like a little savage. In another minute an ugly cobra poked its venomous head from under the edge of the cloth and wriggled out in plain view. A much larger object began to stir beneath the mysterious red cloth, and a girl about twelve or fourteen years old arose to her feet and stood smiling there among us.

The looks of amazement on the faces of the men in that group is something I shall never forget. Before any one could stir, the fakir clapped his hands, then his creatures vanished into air. Quickly fold-ing up his little cloth he leaped into the sea and swam away with the graceful, easy strokes of a strong swimmer.

"At another time my astonishment was even greater when I saw what is known as the mango tree. I was present at one of these extraordinary public occasions when an elderly member of the caste ap-peared, and with many thousands of peo-ple about him buried in the ground a mango. I occupied a vantage point and closely watched every movement for signs of collusion. This was impossible, be-cause the crowd approached to within a few feet of the fakir. Watching closely we began to see a shadowy something emerge from the ground, growing and spreading until it resolved itself into a mango tree fully fifty feet high, bearing leaves and fruit. It was perfectly rigid, not a leaf stirring in the breeze, and, fur-thermore, though the sun shone brightly, it cast no shadow. I changed my position and the vision became less distinct, but on going back to my former stand I saw it plainly again. I was impressed with the peculiar expression in the eye and on the countenance of the wizard. People of many races were present and from thou-

sands of voices one could hear expressions of amazement. We went forward and touched the leaves and trunk of the tree, and actually tasted the fruit from its branches."

The captain of an English passenger steamer relates the following. He says:

"Once when there was among my passengers an English lady and two little children, an old fakir with a young girl came aboard. Everyone gathered around them and all very soon were much interested, especially the English lady, who was peculiarly and painfully impressed with the expression of the old man's face and eyes. With several others of the party she sat in a circle about him. After a few insignificant performances, he and the girl stood perfectly still; finally the girl began to raise from the deck and float across the space between the lady and a hammock, in which her baby and little girl were resting. To her horror she saw the fakir's girl stoop over and take up the baby. Holding the child she rose from the deck, higher and higher, until she was lost in the clouds, the mother, in the meanwhile, being unable to cry out or move, as if she was in a sort of waking nightmare. Suddenly, as she watched she saw a small spot in the clouds, and as it grew larger it took the form of her baby in the arms of the girl, who gradually descended to the deck and laid the child carefully beside its sister. Just then the mother had the power to break away from the circle, and, rushing to the side of the hammock, she eagerly snatched up the child, only to find it asleep and unhurt. 'How could you let that strange woman take your little brother away?' she screamed to her astonished little daughter. The child replied, 'Why mamma, brother has been asleep here by me all the time; no one has touched him.'"

In looking through Jacollicot's "Occult Science in India," we find the narrative of an educated gentleman occupying a high judicial position for fifteen years, a resident of India, and a close student of its people, its customs and peculiarities. He relates one instance of the yogi's power to move inanimate objects. An immense bronze vase, full of water, stood in Jacollicot's room. The yogi stood several feet away and extended his hands towa
the vase. Within five minutes it co
menced to rock to and fro upon its b
and gently approached the yogi with
regular motion. Metallic sounds issu
from it led him to think that some
had struck it with a steel rod. The blo
at times were quick in succession, and
numerous that it resembled hailsto
falling upon a metal roof; sometim
measured and slow, and again continuo
like the roll of a drum. The yogi
asked if directions could be given rega
ing the movements of the vase, and c
sent being given the vase moved ba
ward and forward, according to the co
mand given, the blows changing in th
intervals, in response to requests, fr
slow strokes to a continuous roar.
another seance, taking a small wood
table, he placed it on the terrace in
open air, and asked the fakir if he co
fix it there so that it could not be mov
The fakir at once went towards the sta
and, placing both hands on the top of
stood motionless for ten or fifteen m
utes; then with the operator's permissi
Jacollicot approached the stand, but fou
it immovable, as if fastened to
ground. Violent efforts were made, w
the result that the top came off in
hands, but the legs and cross-braces
mained standing and still refused
move. Requesting the fakir to rem
to the farther end of the terrace, Jaco
cot was able to handle the stand with
difficulty.

In order to judge concerning the p
formances of the yojis, Indian fakir, e
it is needful to bear in mind that th
people possess the power of produci
hallucinations in the minds of other p
sons, simply by forming pictures in th
own minds, which they mentally impr
upon the minds of the spectators;
upon *one* only, but upon hundreds a
thousands at once, making what is kno
as a collective hallucination. The ba
upon which all exhibitions of this ma
cal power rests is a knowledge of the
lations that exist between objective a
subjective states of existence. If we c
ceive in our mind of a picture of a thi
we have seen before, an objective form
that thing comes into existence wit
our own mind, and is composed of

bstance of our own mind. If, by con-ual practice, we gain sufficient power hold on to that image and prevent it m being driven away and dispersed by er thoughts, it will become compara-ely dense, and be projected upon the ntal sphere of others, so that the latter y actually believe to see objectively t which exists merely as an image hin our own mind; but if we can not d on to that one thought—a mental ture—and control it at will, we can not duce its reflection upon the minds of ers and, therefore, such psychological periments as the moving of ponderable ects, levitation, rope and basket mys-ies, spirit materialization, etc., etc., en fail, not on account of any absolute possibility to perform them, but on ac-nt of the weakness of those who desire experiment, but have not the power to centrate and control their own ughts, and render them sufficiently id for transmission. A novel way of nonstration is to hypnotize a person l silently formulate in our mind a fic-ous scene representing a burning build-and a mother with her child in her ns appearing at an upper window; or, may mentally picture the murder of subject's wife, mother or child. The ject, standing several feet away, with face to the wall, perceives the scene h vividness which we have formulated l projected mentally, with all the emo-n that such scenes would naturally ex-e.

Here we witness a psychical manifes-ion, a phenomena, a transferrence of as from operator to subject, thus pro-cing what may be termed a telepathic lucination.

An operator who has gained the power concentrate and hold on to a thought, y—as I have said—project it upon other, and the process will be facili-ed if the subject is in a passive state, pnosis, or somnambulism. The subject merely acts upon the suggested ught of the operator, but having no l of his own—it being inhibited for time being—becomes a hopeless in-ument, through which the thoughts of rator are executed upon the subjective objective mind of the subject.

There can be no doubt of these yogi performances being illusions, because an attempt to photograph any of them reveals nothing but an empty plate. You are simply made to see things which do not really exist.

You will naturally ask, what are the qualifications necessary for the yogi? I will answer by saying that the yogis, the Gurus, the Chelas, the Swamis, the Adepts, the Gnanis, and the Mahatmas, both of India and Thibet, belong to a separate class of individuals, who, during a period of many years, undergo a course of psychic training which has for its object the modifying of their organization so as to greatly increase the production of that subtile emanation from the body which they call *agasa*, the force of the subjective mentality; in other words, psychic force.

They begin by going through a period of development, or probation. First they crucify the self. They strip themselves of all former raiment and clothe themselves in rags, they give away their possessions to the poor, they hunger and thirst, they bear physical pain and injuries without complaint, without even indignation; they sever all ties of blood and relationship. While undergoing this development the meanest beggar is their equal and friend, they are content with nothing less than the most absolute equality; envy, hatred, pride, vanity, even self-respect, is blotted out.

They will not take the life of the meanest insect. In their philosophy the insect is one of them. They repair themselves into a jungle to meditate, and there remain until fully developed. They have auto-hypnosis, first of all. That is to say, a condition of subjectivity developed by continued concentration. They find that a sitting, or a recumbent position, is best to secure physical tranquility, and in this position they gaze either at their navel, or at a point or small object, keeping the eyes there for a period sufficient to insure a state of subjectivity, perfectly oblivious to the surrounding world. They do not develop this power in a few hours, or a few days, as many suppose. Every spirit medium will tell you that her period of development covered months of daily sittings in the silence, waiting for what was

to come. After her period of probation she begins to get phenomena.

Never mind what hypothesis you accept as to the origin of these phenomena; the important thing is that the phenomena are produced, and that the fakir and medium get them and produce them because they followed the necessary rules for producing them.

In conclusion, I would say that these observations have a direct bearing upon telepathy. They show that the observer must forget self and concentrate his mind upon the operator or the process in hand; he would, in this case, naturally be expectant. The operator, in turn, has his whole mind concentrated upon the scene to be enacted.

By carefully observing the incidents of this kind and keeping a careful record of them I have gathered considerable evidence of the influence of one mind over another.

These phenomena, therefore, may be accounted for upon the theory of telepathic suggestion. There are, permit me to add, many occurrences which seem to support the hypothesis that the exercise of the will-power of an individual being for the control of his own functions, induces a like impulse in the brain or nerve centers of another, the more powerful the concentration of the will-power of the one and the less the effort of the other to resist its effects, the greater the induced impression will be. The physical and psychical phenomena of Hindoism and Spiritualism, therefore, may be explained by telepathy, magic, or muscular automatism and illusion, or unconscious misrepresentation telepathically projected. The Hindoos, owing to that intent love for solitary meditation, which has been one of their most pronounced characteristics as far back as 580 B. C., have developed the subjective mental faculties to such an extent that Western civilization look on in wonderment. Hypnotism is, therefore, the key that unlocks the secret cabinets of this science, and robs it of its further mysteries. A man who can hypnotize any part of his own anatomy, cause his heart to stop visible pulsation, his external surface to grow cold, his eye to become
and his breath to depart, has, indee
wonderful power, and is endowed wi
full complement of concentrative abil

The Keynote to Strength.

BY AXEL EMIL GIBSON, M. D.,
Los Angeles, Cal.

Every vital process has its cause
sustaining basis in thought. The
order of growth must, therefore, pro
from within outwardly, from though
act. Hence, while it is possible to en
der action and apparent strength wit
the proceeding processes of mental
spiritual realization, the fact still rem
that any advancement arising from
order of life is of a mere passing cha
ter. For growth, in order to be true,
arise from an harmonious order of e
ence. And, furthermore, as harmon
the tenor of an existence inter-rel
with other existences to the extent o
conception of solidarity and univ
usefulness, it follows that only
method of physical development whi
based on a motive of usefulness is of
true and enduring value to the indivi
For usefulness is the price which
form or expression of life has to pa
Nature for its growth. Hence an
devoted to the service of Mother Na
in cultivating the soil, or in training
plants and flowers, results in more
benefit to the individual than many t
the amount of time and energy spen
swinging dumb-bells, kicking footbal
in the indulgence of any indoor ath
sport. And if this usefulness consti
the legal tender, decreed by Nature a
only standard of measure in the acq
ment of physical health, it is evident
any effort aiming at these possess
through some other means or me
than that of usefulness, is equivale
theft.

In the practices of breathing, the
ple, natural rhythm of the animal br
must always remain the reassuring
infallible gauge to reach the evolutio
benefits aimed at, as the physical pe
tion which obtains in the animal kin

bears irrefragable testimony to the fact hat the animal holds in its possession he secret of true breathing. Yet this eritage was not attained by the animal ucking in, or expelling, the breath so many times per minute by the clock while squatted on a tripod with feet planted in certain angle, and eyes and mind fixed n some brass button on the wall at a neasured distance from the nose. Nor is he plastic curves, graceful movements nd verile powers of the free animal at- ained by the antics of chamber calis- henics, but rather by living in parallel- sm with the laws of its being, which is nother word for usefulness. The strain- ng for health, strength and beauty for he mere sake of personal enjoyment, in- olves all too small and puny a motive o insure survival value. Human life, in rder to yield eternal results, must be eld at a higher price, and conducted on roader lines of growth. Detached from he chain of universal solidarity, any ractice of breathing or muscular exercise olates the individual from an inner vital elation with the source and center of all fe. Hence the selfish attempts of an in- ividual to leave Nature behind him by rcing her to yield undue and unmerited owers, will ultimately recoil on the surper, and leave him helplessly behind the march of a resistlessly advancing, olitary nature. No power, physical or yper-physical, if merited by adherence the law and principles governing life, an be held away from its due claimant. Seek first after the Kingdom of Heaven, nd all the rest shall be given unto you," nd what is the "Kingdom" but the "will the Father," or the living up to the upreme laws of duty and conscience.

It is a mistake to believe that the qual- y of life is dependent upon the quantity volved in its sustenance. Gross ath- tic sports and strenuous gymnastics, enerally considered health and strength roducing, on the contrary, rather tend shorten than to lengthen life. For very strain means a shock to the organ- m, which again involves a break of the ythm of vital processes, followed by the bsequent disrupture in the rhythm of e involved functional processes. Not e crude, athletic feats of mechanical aining, but rather soft, gentle rhythmic movements, generate physical strength and beauty. Thus, the soft, rhythmic movement of the arm of the violin player in guiding his bow in accord with the harmonic unfoldment of the music, is found to develop a power and endurance in the biceps almost incredible, and the writer of this article once knew a famous pianist whose fingers, through practice on the keyboard, had developed such strength that a mere tap of the index finger on a china plate would shatter the latter into fragments.

More than physical action, however, is mental and moral action, the generator of true strength. Strong, purposive, concentrated thought applied to the work engaged in, charges every muscle-fibre with throbbing energy. Firm, determined aim in life, purity and massive strength in motive, and a realization of the dignity and responsibility of individual existence, engender a deep tonic effect upon every vital center of the organism.

August Comte, the father of positivism, while constructing his staggering system of philosophy, felt a dissevering of the frontal structures of his cranium, from the enlargement of the brain volume, as a result of the creative thought processes at work in his mind. On the other hand, it was Ludwig Feuerbach, of Leipzig, who made the observation that the sanity of the mind is maintained only by continued, purposive action.

The practice of our present time in straining every issue and circumstance, however unimportant from a vital point of view, to yield its utmost power to the advantage of any separate individual, regardless of merit, or approval of conscience, has given rise to an ominous ascendancy of exclusively material interests. Our entire commercialism, with its various crafts of art and construction, seems largely to be wielded by one single motive—the physical comforts of its patrons. Scarcely a single appeal is made to the lofty and sublime in human nature. Chastity and simplicity of design and conscientiousness in execution are quite exceptional in our general constructive work. Beauty and ideality are forced to the wall, while the right of way is given to luxury and sensual comforts; and in place of the individual extending efforts

to be useful to his commonwealth, does his best to make the commonwealth useful to him.

Indeed, there are but few expressions of our modern time which have escaped the taint of this passion for personal gratification. So, for instance, in matters of diet, the interest is so engrossed in the question of taste and palate, that it either forgets or ignores the question of digestion. The bill of fare is not intended to form an index to the healthy needs of the body, but rather to the morbid cravings of an hypertrophied and insane appetite.

And this sacrifice of spiritual interests to the triumph of the flesh is not limited to the world of industry and commerce, but forms a no less important factor in matters of public education—a circumstance which probably accounts for the failure of the school and church to successfully cope with the ever-swelling flood of immorality and crime, which, after all, are mere forms of egotism—self-seeking. Taught to be ethical, rather than moral, and to strain for reputation and public recognition rather than for character and self-respect, the individual, in his attitude to the vital issues confronting him, will exert his best powers only where he sees in view the attainment of some purely personal ends. The course of evolution, which in nature spells from within outward, from the ideal to actual, from seed to plant, from species to variety, etc., is largely reversed in the movements of human society, where, through an artificial pressure, nature is coerced to proceed from without inwardly, from the reactions of social environments, to the fashioning of conventional judgments and convictions, and finally by a plunge into the deeps of sensation and personal gratifications propose to attain a vision of spiritual attitudes. In place of the body being used as an instrument in the service of the soul, the individual, in devising schemes for sensual gratifications, places his soul-nature in a most degrading servitude to the body. Thus, in place of being the means by which to ascend the imperishable heights of immortal life, the body has become the worst obstacle possible in the way of such a career.

Can we reasonably conceive of nature or culture, in all their diversified expressions in the fields of physical and m growth, to aim at any other ultimate sult than to make men good and t But if this be so, should it not ther the self-written duty of every man to fellowmen to extend his approval and ronage only to those efforts of talents genius which aim at the improvemen character, and the elevation of moral ethical ideals of the people?

That the logical consequence of such attitude would be the extermination some ninety per cent of the books general literary publications of the wo and the abandoning of the great bul our inventions, does not lessen strength nor the urgency of the princ back of it, if the moral vigor and ir rity, which alone make true r hood and citizenhood possible, is be more worth considering than support of devitalizing and de alizing crafts and institutions. fulness should be the inspiring motiv every effort; a usefulness, however, based upon luxury, comfort and ima ary needs, but springing out from evolutionary vital necessities. When t necessities meet us on the moral and r tal plane we enlist the service of art their fulfillment. Hence art, not less talent, genius not less than mecha skill, should be gauged by vital needs necessities, whether the latter be fel the moral or physical plane. For any not based on inner vital necessity is generating into luxury and ceases to true means of culture.

Hence art degenerates into luxury moment it ceases to be an expressio vital needs. Luxury is art lost in seeking; art turned into a financial l ruled by desire and ambition in plac inner, vital needs. Art is universal impersonal, hence unselfish, and of g est usefulness for the moral upliftin humanity; while luxury is selfish circumscribed, aiming at personal and by appealing to and stimulating sensual elements in the human natu not only ceases to be useful, but bec a positive barrier in the field of hu progress. Consequently, any expre of talent or genius, in art or mecha craft, however startling and epochal application to industry or culture, i

directly or principally concerned in the moral betterment of man—of man as soul and immortal being—is a dissolving, deterrent element in universal evolution.

After all, the criterion given by Immanuel Kent almost two centuries ago, on the moral legitimacy of an act, still holds good as an infallible guide for human conduct: "Refuse support to any principle which is not morally applicable to any order of universal life."

It is the application of this principle of universal usefulness to daily vicissitudes of an individual's life that gradually but surely will put into his conscious possession the keynote to true and enduring strength.

[Written for the MEDICAL BRIEF.]

Echinacea Angustifolia.

BY J. M. FRENCH, M. D.,
Milford. Mass.

Echinacea angustifolia (common names, black sampson, nigger head, purple cone flower) is a perennial herb, belonging to the natural order compositæ, growing to the height of two or three feet, abounding in prairies and marshes, and on elevated tablelands, throughout the Central and Western portions of the United States. That which grows on the prairie lands of Nebraska is said to have the most active medicinal properties. It has a stout, erect stem, with thick, black roots, having a pungent taste. It flowers from May to July. The part used in medicine is the root.

This now famous drug was first introduced to the notice of the medical profession some time in the early '70s, by Dr. H. C. F. Meyer, of Pawnee City, Neb., in the form of "Meyer's Blood Purifier," a remedy for depraved conditions of the blood, and especially recommended as a cure for snake bites. It is said to have long been known to the Indians as a remedy for snake poison, and it is probable that Dr. Meyer got his first suggestions as to its use from them. He did not for a long time know the name of the plant which he used in making his "blood purifier," but he had such confidence in its virtues that he wrote repeatedly to the medical press in its advocacy, and finally sent a whole plant to Professors King and Lloyd, of Cincinnati, who analyzed it and pronounced it to be echinacea angustifolia. Professor J. U. Lloyd became interested in the claims which were made for it, and set about investigating them, with the result that he soon gave it the stamp of his approval, and in 1887 introduced it to the eclectic branch of the profession in the form of specific echinacea. It has been used quite largely by the eclectics, and to a considerable extent by the homeopaths, but only recently has it been studied, or used, except in a few instances by the so-called regular branch of the profession.

The principal preparations in use are the fluid extract, of which the dose ranges from fifteen to thirty minims; the specific tincture, which is the official electic preparation, the dose ranging from five to thirty drops. The dose of any of the preparations may be repeated every two to four hours, or, when the larger doses are used, three or four times a day. There is also a homeopathic tincture, made by macerating the entire plant in twice its weight of alcohol. This should be but half the strength of the specific tincture.

The tincture produces a feeling of pungent warmth when taken into the mouth, which increases to a tingling sensation after a time, and remains for half an hour, or more. This feeling resembles, to some extent, the tingling produced by aconite, and still more that of xanthoxylum. If swallowed undiluted, it causes a constriction of the throat, with great irritation. It promotes the flow of saliva, causes diaphoresis, and increases the activity of the kidneys. The glandular organs, almost without exeception, are stimulated by its use. It tones up the appetite and increases the power of digestion, encourages absorption and assimilation, and stimulates nutrition. It encourages secretion and excretion, and stimulates tissue waste more powerfully than any other known remedy. It does not appear to have any toxic effect.

It is primarily a remedy for depraved conditions of the blood, especially for those conditions included under the name

of blood-poisoning. It divides with calcium sulphide the honor of being a most efficient systemic antiseptic, non-toxic when taken in sufficient doses to accomplish the desired result. It is also an intestinal antiseptic. Its general properties may be included under the terms antiseptic, antifermentative, and antizymotic.

It may be used in every case where there is a tendency to sepsis and malignancy, or "bad blood," as in gangrene, sloughing ulcers, boils and carbuncles, and various forms of septicemia, and all suppurative diseases; puerperal, typhoid, and all septic fevers; tonsillitis, and ulcerated sore throat, diphtheria, stomatitis, catarrhal sore mouth, appendicitis, spinal meningitis, erysipelas, mammary cancer, fever sores, old ulcers, syphilis, snake bites, hydrophobia, and hemorrhoids. Ellingwood, in his Materia Medica and Therapeutics, relates several instances in his own practice where it has produced remarkable results in septic conditions. Meyer gives the history of six hundred and thirteen cases of rattlesnake bite in men and animals, all successfully treated with echinacea. Gregory Smith recommends it as a remedy in hemorrhoids, and says that twenty-five drops of the pure tincture injected into the rectum three times a day promptly effects a cure. Tyson, Adolphus, and others, report good results with its use in small-pox. It has, also, been used with success in scarlet fever. As a remedy it occupies, to a certain extent, the same field as baptisia, which is, however, comparatively limited in its applications.

While it is not probable that careful investigations and continued experience will sustain the wonderful and probably exaggerated claims which have been made by many enthusiasts in favor of this drug, yet in view of all that has been written—which contains so much that is favorable, and so little in opposition to its claims—it seems reasonable to believe that we have in echinacea a drug of great value to the general practitioner, and one well worthy of more extended investigation.

This drug is one of the most important ingredients in Ecthol made by Battle & Co.—Ed.

The Treatment of Pneumonia.

BY W. T. DAVIS, M. D.,
Harrodsburg, Ky.

Pneumonia is a self-limited disease. the majority of the cases we may look the crisis between the fifth and the e enth day. It is obviously our duty no interfere too zealously in natural cesses and by injudicious handling vent a favorable termination, for we h no specific remedy. The constitutic tendencies, and the surrounding circ stances should receive careful attentio deciding on a plan of treatment. A orous, healthy person will require m vigorous handling than a broken-d alcoholic. If seen during the stage of gestion much may be accomplished b full dose of quinia and morphia (qu ten grains, morphia one-quarter gra with small doses of the tincture of aco root (one or two drops, every two or t hours).

The feet and legs, up to the kn should be immersed in water as warn it could be borne, impregnated with verized mustard, for ten or fifteen utes. Mustard cataplasms should alsc applied to the chest, over the seat of p An active purgative should be admi tered after the quinia and morphia h been absorbed. The purgative serves the quinia and morphia to diminish abnormal blood pressure. Some ag which has the power to lessen the vis ity and coagulation of the secretion p ing out in the bronchioles and air s should be employed—liquor potassa ci tis is excellent, ammonia sometimes swers a good purpose. The solution the carbonate of ammonia in liquor monii acetas (one-half ounce, five grai every three or four hours. The ammc solution should be continued up to crisis. Arterial sedatives of every k should be discontinued as soon as cons dation of the lung is accomplished. If subject is robust the tincture of verati viride may be given with good effect ing the congestive stage, but when hepatization has resulted it ceases to useful, as does also the tincture of aco

for then arterial ischemia and over-distension of the veins exist, which certainly would be increased by the administration of cardiac sedatives. During this stage the temperature is very high, hence the necessity for employing other measures to restrain it. Under the existing circumstances we must rely upon the use of antipyretics. We should place our patient in a warm bath for five or ten minutes, the bath should be pleasantly warm (I give warm baths in pneumonia for fear of a shock with cold baths). When removed from bath tub the patient should remain lightly wrapped up, until chilly sensations commence, then apply more wrappings, to suit the demands. A warm bath will cool down the fever of a pneumonia patient equal to a cold bath, if lightly covered for a few minutes after taken out of the bath-tub; then there is no danger of our patient's having shorter and quicker respirations while in the bath tub, like they frequently do if placed in a cold bath. If any good has resulted from the bath it should be kept up as long as it does good and as often as the nature of the case demands it. If the means for a warm bath are absent, the patient should have the benefit of sponging with warm water.

The next best remedy to the warm bath and warm sponging is quinia. It is very useful for reducing the fever, but to accomplish the desired effect it must be given in ten-grain doses every three hours until the temperature falls sufficiently to suspend its use until the fever again demands it, which more than likely it will do in twenty-four or thirty-six hours. As long as there is fever in any case of pneumonia, the antipyretics should be continued; unless there is too much depression, which might be the case during the stage of red hepatization; if there is, quinia should be given in stimulating doses of two or three grains every three hours, and such stimulants as spirits frumenti and spirits vini gallici, but cautiously given in half ounce, or ounce doses, as the case may demand, every three hours.

The utmost circumspection is absolutely necessary as the period of crisis approaches, for some exhausting discharge, or some other grave phenomenon, may tax the vital powers too severely. Under those circumstances the careful administration of appropriate stimulants and suitable aliment may be the means of saving life. During the stage of exudation and of the exudates, coagulation, cardiac sedatives such as digitalis, aconite, veratrum viride, and others that could be mentioned, can, if given, only add to the burden of the heart, already laboring in consequence of the lack of blood on the arterial side, and of its stasis on the venus side.

Bromide of potassium (in twenty-grain doses, every four hours) in my hands has proven itself to be worthy of trial in such cases. It aids in relieving the stasis of blood on the venous side, it will retain the fluidity of the blood, it will prevent further clotting, it will give the absorbents an opportunity to do their part in relieving the lung of the stasis of blood that already exists. A continued high temperature contributes to bring about paralysis of the heart. The administration of quinia and tepid baths will, in a large majority of cases, obviate all tendencies of that nature. While arterial and cardiac sedatives should be avoided at the stage of red hepatization, it is also necessary to avoid the immoderate use of alcoholic stimulants, but at the same time alcoholic stimulants are needed in full doses in inebriates at the crisis, and also when the stage of purulent transformation is reached. Then the pulse is weak and rapid, the skin is clammy and relaxed, with more or less delirium; symptoms which positively call for alcoholic stimulants in broken-down alcoholics, and in full doses. Protracted wakefulness with delirium demands very careful management, owing to the condition of the pulmonary circulation, the collateral hyperemia and edema; opium or morphia should be avoided. Chloral hydrate will answer a better purpose; it has a good effect on the exudation, quiets delirium and procures sleep, but at the same time great caution should be used in the administration of the hydrate of chloral; fifteen grains at bed time and ten more grains in two or three hours, if the first dose was not sufficient, is all that is required. Frequently repeated doses, or doses too large, may cause paralysis of the heart. Without waiting for depres-

sion to come on, aliment should be given; it may be carefully given from the beginning. Chicken or mutton broth, beef juice, milk and egg flip, with a little wine, aids wonderfully when our patient is greatly exhausted under the debilitating powers of such a dreadful disease as pneumonia. In very weak or exhausted subjects, wine may be given from the beginning. The inebriate with penumonia should have alcoholic stimulants from the very first symptoms of the disease, for the delirium that always accompanies pneumonia in inebriates is largely due to the sudden withdrawal of the usual supply. Fly blisters are undoubtedly of great service when the crisis occurs. I have tried them in pneumonia for fifty years; they have acted well for me, but at the same time they should be closely guarded. If there is prune juice, expectoration relaxed and sweating skin, with weak pulse, small doses of turpentine or eucalyptus may be given.

[Written for the MEDICAL BRIEF.]

Enuresis.

BY L. HERBERT LANIER, M. D.,
Martinsburg, Mo.

Incontinence of urine is a symptom which depends upon insufficiency of the sphincter vesicæ muscle in the greater per cent of cases, yet I am pleased to quote Carpenter, who says:

"Enuresis may be caused by debility of the neck of the bladder, and of the internal sphincter; insufficient innervation from disease of the spinal cord and of the nerve centers; reflex irritation; masturbation; over-distention of the bladder with urine, and changes in the constitution of the urine."

And to the above list of etiological factors figuring in the production of this troublesome malady, I shall add a few, the potency of which are confirmed by extensive observation of these particular cases.

Partial anesthesia of the sensory nerves of the bladder, due to congenital anatomical defects, the nerves become accustomed to this constant pressure, and can not respond to stimuli.

The anomalous condition of the bla der referred to is an abnormally sma bladder, with thickened walls, due t chronic inflammation of the vesical mu cosa.

Incontinence, in many cases, is due t hyperacidity of the urine, cystitis, or a adherent prepuce, either of the glan penis or the clitoris; pyelitis, nephriti vesical calculi, masturbation, and recta irritation.

Prognosis.—Favorable where the caus is discovered and removed.

Treatment.—The treatment must b empirical unless the cause be discovere and its removal effected, as is true i treating all other diseases.

Outdoor exercise should be encouraged As to diet, coffee and tea, as well as heav meats and deserts, should be prohibited Elevate the foot of the bed three inches and have the patient sleep with head low give a hot foot bath before retiring, an cold sponge bath in morning.

Ferruginous preparations are indicate in anemic cases, the syrup of the iodid of iron is readily taken by children. Fo adults give tincture nux vomica in a cending doses, where due to weakness o sphincter, salol in six or eight-grai doses where due to abnormal condition o the urine. The following prescriptio will prove efficacious in treating all cases

℞ Santonin.....1 drachm
Bromidi Potassi.....2 drachm
Extractum Valerianæ Fluidum...3 ounces.
Aquæ Dest.....q. s. ad.....4 ounces.
M. et. Sig.: Cochleare parvum three time a day, post cibum.

Where the bladder is abnormally sma and inflamed, dilatation by vesical irrig tion with solution of permanganate o potassium, one-three thousandth, is esp cially indicated.

In young women this procedure is a ways necessary, and frequently you ca not accomplish a cure until nitrate of si ver, in weak solution, has been applied t the urethra and bladder.

While it is true that you have to ind vidualize your cases and direct you strongest therapeutic agents against th predominating element in the malad yet you can, by close observation o your patient, discover the weak point an you will find among the remedies I hav here suggested something that will sure

influence the case toward a favorable termination, if the proper relationship exist between the adaptability of the drug to the disease.

Hence, there is no excuse for a physician to tell anxious mothers that the child will outgrow its present trouble, which will probably prove to be untrue in half the cases, as is proven by the many young men and women who apply to every physician for treatment for this dread malady, stating that they were unable to retain the urine in the bladder in daytime, thus depriving them of education by keeping them at home; depriving them of social and business relations with the world at large, and which by its psychological influence on the sufferers caused them to seek solitude, where they could pine away in secret anguish for the want of relief from their affliction.

But just here I wish to suggest that dietetic and hygienic precautions suffice until the patient is three and one-half years of age.

I have never failed to accomplish a cure in these cases and I sincerely hope that every physician may soon be able to make similar assertion.

[Written for the MEDICAL BRIEF.]

Necessary Abortion.

BY ANDREW J. MANN, M. D.,
Evermay, Ga.

Sometimes it is very necessary to produce an abortion. Nothing indicates an inevitable abortion more than profuse hemorrhage, and this, without the prompt expulsion of the fetus and secundines, is where the trouble and danger comes in. It is owing to the rigidity of the os that prompt measures are not secured with the ordinary oxytocics; but, happily, this may be overcome by thorough packing with the gauze tampon, absorbent cotton saturated in the iron alum solutions. Every practitioner should be provided with uterine dilators. Do not borrow from your neighbor; have some of your own, and you will not then be disappointed with ergot or dangerous delays. Dilate the os when the temperature runs high, at least, with the dilators, and prompt contractions will follow, with the expulsion of all the contents, saving much time, and avoiding the great dangers of further hemorrhage and puerperal sepsis.

A dead fetus gives rise to a high temperature and danger to sepsis. The dilators are my anchors.

Examination Questions of the Indiana State Board of Medical Registration and Examination. Indianapolis, Ind.

M. S. CANFIELD, M. D., President.
W. T. GOTT, M. D., Secretary.

(Submitted by J. C. Webster, May 2, 1905.)

MATERIA MEDICA AND THERAPEUTICS. (REGULAR.)

1. Give derivation, medicinal dose and therapy of suprarenal extract (1:1000 sol.).
2. Give derivation, medicinal dose and therapy of hyoscine hydrobromate.
3. Give derivation, medicinal dose and therapy of pilocarpine hydrochlorate.
4. Name a medicinal agent which increases the renal function by its action on the cells of the tubules, and one which stimulates said function by increasing blood pressure.
5. Name some medicinal agents which are parasiticidal in their action.
6. Name some medicinal agents which are regarded as intestinal antiseptics.
7. Give technic of hypodermoclysis.
8. Give technic of the administration of (*a*) chloroform, and (*b*) sulphuric ether to surgical anesthesia.
9. Give antidote to carbolic acid.
10. Name antidote, and dose of same, to arsenic.

INTERNAL MEDICINE. (REGULAR.)

1. Give etiology, symptoms and treatment of cerebro-spinal meningitis.
2. Give etiology, symptoms and treatment of acute pleuritis.
3. Give etiology, diagnosis, remote pathologic results and treatment of mitral disease of the heart.
4. Give treatment of pulmonary hemorrhage.
5. Give etiology, symptoms and treatment of cirrhosis of the liver.
6. Give etiology, symptoms and treatment of gastro-intestinal catarrh of infancy and childhood.
7. Give etiology, symptoms and treatment of dysentery.
8. Give etiology, diagnosis and treatment of acute nephritis.
9. What symptoms would lead you to suspect cancer of the stomach?
10. Give symptoms and treatment of gastric ulcer.

ETIOLOGY AND HYGIENE.

1. Give etiology and hygienic measures for prevention and treatment of tuberculosis.
2. Give etiology and hygienic measures for prevention and treatment of acute gastro-intestinal catarrh of infancy and childhood.
3. Give etiology and hygienic measures for prevention and treatment of typhoid fever.
4. Give hygiene of sick room.
5. Describe personal hygiene.

ANATOMY.

1. Describe the quadriceps extensor femoris muscle.
2. Give a brief description of the solar plexus.
3. Give the names of the muscles that flex the leg upon the thigh.
4. Name the regions into which the abdomen is divided and give the structures in each region, by diagram.
5. Give the anatomy of the portal circulation.
6. Where, on the anterior chest wall, do you get the most distinct sounds of the cardiac valves, and why?
7. What are the anatomical reasons for pulmonary engorgement when the cardiac valves are incompetent?
8. Explain anatomically why inguinal glands are involved from septic infection at the foot.
9. Give the anatomy of the hip joint.
10. Give the origin, course and distribution of the phrenic nerve.

PHYSIOLOGY.

1. Give the names of the tissues which compose the body, and tell where each kind is found in the animal organism.
2. State the various facts to which are due the phenomenon of normal blood pressure.
3. What digestive changes take place in the small intestines?
4. Mention the principal excretory organs of the body and explain the difference between excretion and secretion.
5. Mention the facts and conditions that favor absorption and those that retard it.
6. How does the fetal circulation differ from the circulation after birth?
7. How is animal heat generated, maintained and lost?

PATHOLOGY AND BACTERIOLOGY.

1. Define degeneration and infiltration.
2. What is the pathology of enterolithiasis?
3. Describe all of the pathological conditions present in a heart where mitral stenosis has existed for several years.
4. Describe a lung affected by broncho-pneumonia.
5. Describe the pathological conditions present in each of the forms of goitre.
6. What is the pathology of spina-bifida?
7. Explain the difference between congestion and inflammation.
8. Name the different modes by which bacteria propagate.
9. How would you obtain a pure cultu the Klebs-Loeffler bacillus?
10. What bacteria may cause chole titis?

RHINOLOGY AND LARYNGOLOGY.

1. What is the most common cause o struction to the posterior nares?
2. Differentiate between tubercular syphilitic laryngitis.

NEUROLOGY.

1. What are the general diagnostic s toms of cerebral tumor?
2. What are the diagnostic symptom multiple sclerosis?
3. Give the location and functio Broac's convolution.
4. Give the etiology of multiple neuri

MEDICAL JURISPRUDENCE.

1. What are the diagnostic sympton morphine poisoning?
2. What are the characteristic *post-m* findings after drowning?

CHEMISTRY.

1. Give the formulæ of (*a*) cane sugar glycogen, (*c*) glucose.
2. How would you detect the presen indican in the urine?
3. What is the clinical significanc leucin and tyrosin in the urine?
4. What is the difference between the curous and the mercuric compounds? Gi example of each.
5. What is the difference, regarding bility, between alkaloids and their sal each of the following: (*a*) Water, (*b*) (*c*) alcohol, (*d*) benzene?

SURGERY.

(In questions concerning differential nosis use parallel columns.)

1. Differentiate between ulcers of th due to the following causes: (*a*) Syp (*b*) epithelioma, (*c*) varicose veins.
2. In what portion of the male urethr gonorrheal strictures most common?
3. Differentiate between the follo swellings in the inguinal region: (*a*) abscess, (*b*) irreducible hernia, (*c*) bubo
4. Tabulate the causes of mechanical
5. Give the etiology, most common si lesions, and diagnostic points of actin cosis.
6. Give etiology and classification of tric cancer.
7. Differentiate between acute arti rheumatism and gonorrheal arthritis.
8. Give the differential diagnosis classification of aneurysm of the pop artery.
9. Differentiate between a dorsal di tion of the hip and tubercular coxitis.
10. Give the pathology and diagn points of erysipelas.

(The questions of the eclectic, homeop physio-medical and osteopathic branches appear in the next issue.—ED.)

Editorial.

Theoretical vs Practical.

That period of American history which ceded the civil war is called the practical age of this country. The present day called by some writers the theoretical . It is remarkable for the prevalence fads and theories in politics, religion medicine.

n this connection we are reminded of old joke about the divinity student, home on a vacation, who accompanied father to church on Sunday to hear new minister's discourse. After the mon he called the clergyman aside said to him, "Sir, I have learned re from hearing you preach this morn- than I have from all my studies. preached to-day on Sodom and norrah. I am well informed on doc- al points, but up to this time I had posed that Sodom and Gomorrah were n and wife."

Evidently his time had been so taken with the consideration of theories that his practical knowledge of the Bible had been neglected.

Not long since a young medical graduate told the Editor he had acquired some valuable practical information during a recent attack of rheumatism, which was new to him.

It seems he had been given salicylate of soda. His stomach was already out of order, and the medicine did him no good. When he got home he called in the old family physician, who made the same prescription, but specified that the soda salt should be prepared from salicylic acid, obtained from oil of wintergreen. Much to his surprise, the last prescription not only acted nicely on the stomach but cured his rheumatism.

Thus he learned the practical fact that while salicylic acid made synthetically is chemically correct, it does not act on the system like that made from oil of wintergreen.

Facts of this nature, so useful and necessary in practice, ought to be taught in college. This young man was well-informed on bugs, knew the latest and most approved methods of staining and

mounting bacilli, making cultures, etc., but when it came to practical facts in clinical medicine, he was at a great disadvantage.

The trouble is that the character of the teaching in our medical schools has changed. Nowadays they hasten to adopt the fads, indulge in speculation, and inculcate pet theories instead of familiarizing the student with drugs, their indications and other practical agencies for curing disease.

The same tendency is seen in affairs of government. In antebellum days, men were instructed in the rights of the individual, how to secure and preserve them. In that early age, men were really equal before the law. No man was above it, not even an official. Nowadays, there has arisen in this country a force of arbitrary power, working through machines, which usurps the rights of individuals, and menaces our institutions. This force takes advantage of our fondness for theory to secure the passage of all kinds of fool laws, providing offices and salaries for the underlings of the machine. Corruption, bribery, graft, are the natural sequences.

Things have arrived at a pass when policemen, appointed to preserve peace and order, do not hesitate to break down doors and invade homes to secure evidence, they arrest men without warrants, and use every artifice known to craft to induce suspects to incriminate themselves. Indeed, in some parts of this country, the principles of free government have practically lapsed and are forgotten.

People must be aroused to a realization of the danger of these conditions to the individual. The police and other officials must be made to keep within the law as well as other people. Abuse of the law is the surest way to bring it into contempt.

No one but Americans should hold office, and no one should hold office who is not thoroughly imbued with the fundamental principles of our government as laid down in the constitution. His duties, powers and limitations should be carefully and clearly defined.

Doctor, you are a broad-minded man, a thinker, an influential man in your community, and interested in the cause of good government. You can do a good work by helping to disseminate cor ideas of government among the peo and at the same time gain their adm tion and respect.

It is Not Treason Now.

At one time it was considered trea by the Church, for a man to do any th ing for himself in religious matters. was impressed upon him that he had right to think except as the Chu taught. The same idea prevailed in State—the old monarchical idea that was a subject, and had no right to do independent thinking in politics. A senting opinion in matters of Church State was heresy and treason, entail the severest punishment.

To some extent the same idea is be promulgated in the medical professio this age of the world. The doctor being told that he has no right to th except as the profession thinks, and "the profession" is meant some half-do self-constituted leaders, who do the thi ing for the profession.

But, fortunately, it is rather late in day to promulgate such an idea succ fully.

Can any one tell us why the doc should not have the right to patent a gical instrument or anything else wh he may invent? The doctor who inve such an instrument, or any device, of to the sick, has just as much right patent it as has the man who invent new plow.

To ask the hardest-worked, poorest-p class of men in the world to forfeit such rights, and blindly follow the tates of a few, is too much. Why sho the doctor be the only man to rack brain and tax his body, lose sleep, storms, and finally go untimely to grave, leaving his family in dire p orty, to further a quixotic idea of ethi Such self-abnegation is heroic, subli Yes, and it is the rankest folly.

The Folly of Dissembling.

Some people have an idea that t must pretend to be something that t are not. Never was there a greater take. Hypocrisy is repugnant to ev

rmal mind, even if it be practiced in
e cause of so-called ethics. Just be
nest and sincere and the rest will take
re of itself. Accept yourself as you are,
d make the most of your opportunities.
A man need never be ashamed of his
als and mistakes. He scarcely realizes
w they interest and encourage people
o have suffered in the same way, never
specting that others shared in their
aknesses and errors. When a man finds
t that his own qualms and doubts are
e common lot of all, he is helped by the
ought that he may expect to find a way
t, just as others have.

Many people have an impression that, order to be popular, one must be in-cere, must profess what one does not l, say what one does not think. Few elligent persons can be imposed on in s way. Simplicity, sincerity and po'se ke more friends than meaningless flat-les or backboneless deference.

The man who means what he says, and s what he means, is the man who is pected and trusted. People know what expect from him, and where to find n. A man can not pose for long. He sure to be found out, and then he sinks the estimation of others to a greater oth than if he had not tried to elevate nself by false pretenses.

A master of diplomacy once said that most successful way to fool people s to tell them the truth. The late P. Barnum, of circus fame, took advan-e of this in advertising his summer ne for sale. He enumerated all its advantages in graphic terms, winding with the statement that mosquitoes re so bad no one could live there. eryone was amused, but no one be-ved him for a moment.

To be sincere, therefore, is to be strik-ly original, and that is always wel-ne where so much is hackneyed. *Sin-ity is like a cool hand on a fevered w, or like a cup of cold water to one irst.* It is soothing and grateful. It ms the mind and satisfies the heart.

There is a chord in every human being ich vibrates at the touch of sincerity. is sincerity which gives the thrill to quence. It is the note of sincerity ich moves the crowded audience to en-siastic response. Without sincerity a man may discourse learnedly, or make flights of oratory, but it will all fall flat.

To be sincere, a man must do his own thinking. His beliefs and acts must be based on conclusions which he has reached by his own mental processes. He must have courage to take his stand, and hold it until he gets more light. He must think well of his fellow men, and bear them good-will, for then it is easy and natural to be sincere.

Dissembling is always folly, however we look at it. In the first place, it never imposes on anyone for long, and then it hurts and hinders the upward development of the man who practises it. The experiences of life tend to raise a man if he will only keep his eyes open and learn to think. It is an anachronism and an irreparable mistake for a man to "play 'possum," to try to throw dust in people's eyes, or to pretend to be other than he is.

Fibroids of the Uterus in Pregnancy and Labor.

BY ROBERT A. MURRAY, M. D.,

Formerly Professor of Obstetrics in the New York School of Clinical Medicine; Late Surgeon to the City Hospital; Fellow of the Academy of Medicine, American Gynecological Society, etc.; Member of the County Society, Obstetrical Society, Alumni Bellevue Hospital, Northwestern Medical and Surgical Society, etc. New York City.

Of the three varieties of fibroids of the uterus, sub-peritoneal, interstitial, and sub-mucous, the sub-peritoneal has the least influence, and is least influenced by the condition of pregnancy; unless the sub-peritoneal fibroid be behind the uterus, low down, unable to be lifted up by the ascending developing uterus, labor, as a rule, is not impaired, nor is pregnancy interfered with.

During pregnancy, fibroids may undergo rapid growth, and by pressure symptoms cause pain, incarceration of the uterus in the pelvis, dysuria and vomiting, so as to necessitate interference. Particularly if the pressure be so long continued as to cause threatened abortion or necrosis of the tumor itself. As a general rule, however, where the fibroid is not low in the pelvis, neither pregnancy nor labor is interfered with.

A rapid-growing fibroid may be mistaken for a developing pregnant uterus, and, on the contrary, a developing uterus may be thought, when a fibroid is present, to be a rapidly growing fibroid.

Diagnosis.—Fibroids of the uterus are most frequent in primipara between thirty and forty years of age, are apt to cause displacements of the uterus by their weight, if situated posteriorly, or low down anteriorly, and also by their rapid development to give pressure symptoms on bladder and rectum. From the displacement a diagnosis of retroverted uterus is to be made. From the continued pressure, degenerative changes in the tumor result, causing sepsis and bloody discharges, possibly followed by abortion, and accompanied by profuse flowing, and sloughing of the fibroid, leave no doubt as to diagnosis.

Interstitial and also sub-peritoneal fibroids having long pedicles in the early months of pregnancy, may be confounded with ovarian cysts, displaced cystic ovaries, dermoid cysts, and other tumors. Pregnancy should never be diagnosed unless other symptoms and rapid growth of the symmetrical uterus be present.

Treatment.—Sub-peritoneal fibroids are little influenced by pregnancy unless the tumor be low in the pelvis, and prevented from rising, when operation may be demanded to prevent degenerative change from an interference with its nutrition, and to prevent abortion. The submucous and interstitial varieties are more prone to rapid growth, to less local degeneration, but may demand operation at time of labor from interference with delivery. The risk during pregnancy may be summed up as follows:

1. Rapid increase in the size of the tumor, causing severe pain and distress.
2. Incarceration of the tumor in the pelvis.
3. Serious pressure on the bladder.
4. Degeneration of the tumor through diminished nutrition.
5. Excessive rotation of the pregnant uterus.
6. Abortion or premature labor as a result of pressure or of sub-mucous development of the fibroid.

Abortion or labor might be complicated by (1) Obstruction of the natural passages; (2) by mal-presentation; (3) retention of the placenta or membran (4) by extrusion of the tumor dur labor.

During the puerperium, the presence uterine fibroids renders septic infect more likely, and whether to interf during pregnancy or not depends upon presence of the symptoms before the set.

The choice of operation will be det mined by the site of the tumor, amount of pressure symptoms, and period in the pregnancy. Abortion w this complication has had a large mor ity, and most authorities are agreed t it is bad practice. If no urgent sympto are present, the case may go on to te If the tumor can not be lifted out of pelvis, celiotomy followed by myon tomy or hysterectomy should be d early. If the tumor is interstitial, early myomectomy, before degenerat or sepsis, is indicated, and in a num of instances the pregnancy has c tinued. At labor, if obstruction occu Cesarian section, followed, if possible, a myomectomy, or Cesarian section, le ing the uterus to be dealt with after puerperium; or a Cesarian section w hysterectomy after the delivery of child, have all been performed succ fully as the case demanded. During after the puerperium, severe bleeding apt to occur, and instrumental inter ence is often necessary. Added to t the sloughing of the fibroid mass, sep as a frequent complication of fibroids hysterectomy may be demanded.

The use of the curette to clear out bris of placenta and membranes may o up a capsule of sub-mucous fibers, local sepsis may result from necro which may demand early hysterecto to prevent purulent infection. The c ette should seldom be used in a fibr uterus, for fear of infection, subsequ sloughing and sepsis.

[Written for the MEDICAL BRIEF.]

n the Group Classed as Rheumatoid Arthritis.

S. HERBERT PERRY, M. D. (LOND.), M. B., CH. B. (BIRM.), M. R. C. P. (LOND.),
sistant Physician and Medical Tutor to the eneral Hospital, Birmingham, and Physician for Out-Patients to the Birmingham and Midland Counties Hospital for Children.
London, England.

The title of this paper may be taken as ording some indication of the purpose the writer. It has become increasingly evident, of recent years, that we have been in the habit of classing a variety of arthritic conditions under the term rheumatoid arthritis, and that a revision of the nomenclature is urgently desirable, or, at least, one should admit the existence of various forms of rheumatoid arthritis. Until a comparatively recent date, the disease was known and written of in standard text-books as chronic rheumatoid arthritis, the existence of acute and sub-acute forms not being definitely recognized.

One of the main objects of this paper is to emphasize the existence of the acute form, and its marked distinctions from the most chronic form, *i. e.*, that form occurring typically in elderly people, for which the term osteo-arthritis is suitable, and to which this term should be restricted.

The typical osteo-arthritis is essentially a degenerative process, and has little in common with that rapidly progressive disease of young adults, which is accompanied by grave constitutional disturbance, and for which the term rheumatoid arthritis may well be retained. Bertram Abrahams in a recent article writes: "At the outset I would venture to say that I count myself amongst those who think that this name (*i. e.*, rheumatoid arthritis) should be discarded, as both barbarous and unscientific." I am, myself, not prepared to go to this extent, but I should propose to restrict the term to certain forms of arthritis.

Dr. A. E. Garrod, also, in opening a recent discussion on the relation of the rheumatoid arthritis and chronic rheumatism to acute infective rheumatism (the so-called rheumatic fever) pointed out that the contents of any modern text-book would bring home the fact that we were living in an age of transition with regard to the classification of disease. He further advanced the view that the terms "rheumatism" and "rheumatic" were more loosely used than any others in the vocabulary of medicine, and that it would be not too much to ask that in future the term rheumatism should be limited to acute rheumatism, and to conditions believed to be the products of the same morbid process or sequelæ of its activity. He added that there were few now who re-

fused to recognize acute rheumatism as an infective disease.

It is, however, more especially with regard to chronic rheumatic conditions that views have changed, and are changing, rapidly. There is small doubt that we have been, and still are, in the habit of classing a number of different chronic articular diseases under such a term as rheumatoid arthritis. Moreover, until recent years, it has been the custom to speak of rheumatoid arthritis as a chronic disease only. One of the chief objects of this paper, as above stated, is to emphasize the fact that the disease may have an acute onset, and may run a rapid course, and to point out that this acute and subacute condition has distinct clinical and pathological distinctions from the chronic rheumatoid arthritis of elderly people, the condition for which I should prefer to reserve the name osteo-arthritis. The term arthritis-deformans I should put aside as valueless, and entirely failing in definition, a multiplication of names for one type of disease already constituting a more than sufficient inconvenience to nomenclature.

Abrahams (*loc. cit.*) would include under the title of rheumatoid arthritis at least four different conditions, the relations of which to one another it is the purpose of this paper to analyze:

1. The children's disease described by Still.
2. The acute process occurring in young women.
3. The familiar multi-articular affection of middle-aged women.
4. The equally well-known malady of the aged.

Dr. Abrahams writes of Still's disease that "this is usually referred to as rheumatoid arthritis in children." This is a statement with which I can not possibly agree, and it is, therefore, interesting to note that he himself (Abrahams) continues that this reference is "a most unjustifiable attribution," since in his paper Dr. Still pointed out with the utmost care how the disease described by him differs from other arthritic diseases of childhood.

Still described this disease under the title of "a form of chronic joint-disease in children." He defined it as a "chronic progressive enlargement of joints, associated with general enlargement of glan and enlargement of spleen." The onset almost always before the second dentitio and is usually insidious, but may occ sionally be acute, with pyrexia, and po sibly rigors.

Finally, Still concludes that, under t head of rheumatoid arthritis in childre at least three conditions have been co fused, namely:

1. The joint disease described by hi self.
2. A disease identical with the rheum toid arthritis of adults.
3. A disease probably identical wi that described by Jaccoud as chron fibrous rheumatism.

I can not find grounds for Dr. Abr hams' statement that Still's disease commonly referred to as rheumatoid a thritis; it would seem to me to be f more probable that this disease, bearin in mind the glandular and spleenic e largements, has tubercular relationshi and might possibly be grouped with t condition recently described as tuberc lous rheumatism.

I shall myself describe the followi varieties of rheumatoid arthritis:

1. The rheumatoid arthritis of chil dren (*not* Still's disease, or chron fibrous rheumatism).
2. The rheumatoid arthritis of you adults (typically of women).
3. The rheumatoid arthritis of midd age.

The latter two types agree with I Abrahams' classification.

For that well-known arthritis of elder people, which is typically mon-articula which commences with bone chang (*i. e.*, fibrillation of cartilage and sub quent absorption at points of pressu and osteophytic outgrowth at points e ternal to pressure), I should wish to r serve the name of osteo-arthritis, reco nizing also that this condition is not e clusively confined to the aged, nor rhe matoid arthritis to the young and midd aged.

It will be convenient for the purpose my paper to describe here typical cases the forms of disease for which I reser the title of rheumatoid arthritis.

Acute Rheumatoid Arthritis.—Case A female, aged eighteen years. The ons

was at first gradual, but soon became rapid, affecting the joints of the hands and wrists, and later both knees. Three or four months after the onset the patient had an acute (febrile) attack involving other joints in addition to those already affected; this attack was called rheumatic fever. This acute attack subsided as regards temperature, but the articular condition only partially cleared up, and at the present time—only twelve months after the original onset of the disease—the patient is completely crippled and confined to bed. The joints chiefly affected are the knees and ankles, the elbows, and the articulations of the wrists and hands. There is great muscular articular wasting, and the patient presents the anemic and highly-debilitated appearance so characteristic of these acute cases. The quickened pulse and sweaty hands and feet are also present. The patient also presents the pigmentation of rheumatoid arthritis in a marked form, the whole of the skin having a dirty brownish tinge. The articulations affected present a fusiform thickening, which is evidently chiefly due to a pulpy synovial thickening. There is no evidence of osteophytic outgrowth, and but very slight and doubtful evidence of bone erosion. Both knee-joints contain a moderate amount of fluid. The heart is not affected.

This case may be taken as a typical example of acute rheumatoid arthritis, the patient becoming completely crippled within a few months of the onset. It is specially interesting in view of the fact that an acute exacerbation occurred some two months after the actual onset of the disease; this exacerbation was termed rheumatic fever, but on consideration of the future progress of the case it seems not unreasonable to hold the view that it was in reality an acute rheumatoid arthritis supervening upon a sub-acute condition.

In such cases as the above, we frequently get a history to the effect that the chronic state followed on an acute rheumatic attack. I wish to put forward the suggestion that in such cases the acute febrile attack is not acute rheumatism, but should be termed acute rheumatoid arthritis, the term chronic rheumatoid arthritis being reserved for those cases in which onset is definitely gradual. Rheumatic fever (acute infective rheumatism) is not usually followed by chronic arthritic troubles; typically, the synovitis of acute rheumatism absorbs without leaving more than a moderate amount of ligamentous stiffness, which is usually very amenable to massage and movements.

The history of the above case is very different, and points to a condition which may, I think, be properly termed acute rheumatoid arthritis. The patient's joints were affected from the first, and the arthritis never cleared up; there was no carditis of any form, and the patient had not the very typical sour sweating of rheumatism proper, though the sweaty palms and soles were well-marked. I do not, however, wish to imply that acute rheumatism is never followed by rheumatoid arthritis, but merely to point out that rheumatoid arthritis may often have an acute onset, and one should not fall to the conclusion, usually based on lay statements, that the original attack was rheumatic (here using the term rheumatic as being limited to acute infective rheumatism and its processes).

Sub-Acute Rheumatoid Arthritis.—Case 2. A female, now aged fifteen years. Some seven years ago she began to be affected with what were considered to be slight attacks of articular rheumatism. These attacks never entirely cleared up, leaving almost invariably a certain amount of articular swelling. This condition progressed steadily for the next few years, but there was no acute attack at any time. At the present time—seven years after the onset—the patient is still in fair health, but her articulations are considerably affected. Both knee-joints contain a fair amount of fluid, and the elbow and wrist joints, together with the digital joints, present the typical fusiform swelling. The heart is not affected. Under treatment, extending over two years, the disease has become reasonably quiescent, and the general health very fair.

This case is a good example of the steady progress of subacute rheumatoid arthritis in a child. Here, too, I should suggest that the slight exacerbations which marked the early period of the disease should be classed as mild attacks of

acute rheumatoid arthritis, and not as acute or sub-acute rheumatism.

In this case, definite bony grating can be felt in several joints, but the greater part of the fusiform joint swelling is due to synovial thickening and fluids. This case did very well under treatment with arsenic and iodide of iron. The condition was never very acute, the pulse not having marked rapidity, and the arthritic muscular wasting not being excessive.

The Chronic Rheumatoid Arthritis of Middle Age.—Case 2 exhibits fairly the condition occurring in children, and Case 1 the very severe type which typically affects young women. The condition as it affects middle-age is of a quieter character. It, also, usually affects women. In it, the pulse rates is usually quickened, and the palms and soles are sweaty, but the pigmentation is not severe, and the general constitutional effects are far less than the severe type of disease in young adults. Like the other forms of the disease, it is usually poly-articular, but may be mon-articular, in this respect forming clinically a half-way house to the disease of older life, which I call osteo-arthritis. This latter disease is typically mon-articular when affecting the large joints, such as the hip or knee; poly-articular as regards the small articulations. The primary pathological lesion appears to be a bony one, and commences with fibrillation of the cartilage, whereas in the condition which I term rheumatoid arthritis there is certainly considerable synovial thickening, though, undoubtedly, the bone is also later on affected, and the condition, if the patient survives, may run on to an arthritic appearance, not distinguishable from the chronic osteo-arthritis. Both of these conditions, that is to say, may lead in the end to a complete disorganization of the joint. But, in the early stages, there is a great and obvious distinction between the rapid progress with great constitutional disturbance, of the rheumatoid arthritis of young people, and the slowly progressive osteo-arthritis of the aged—a condition which is essentially degenerative, and more in line with the degenerative joint condition described by Charcot.

I draw the following conclusions:

1. That rheumatoid arthritis occu typically in children (as in Case 2); young adults (Case 1); and in mid age.

2. The essentially degenerative lesi which occurs in advanced age is bet known as osteo-arthritis, and this te should be reserved for such lesions.

3. That in cases, concerning whi one is given the history that the lesi was a sequela of acute rheumatism it w frequently be found on investigation th the febrile onset was in reality an acu rheumatoid arthritis.

In the space of a short paper it is n possible to enter fully into the numero relationships of rheumatoid arthritis. O may, however, briefly indicate some these.

Buzzard, in his article on tremor in t *Encyclopedia Medica*, states: "The fo diseases, neurasthenia, rheumatoid a thritis, paralysis agitans, and Grav disease, are purposely placed together, b cause they appear in more ways than o to be related, and to belong to a group which the pathology is still obscure."

The relationship of rheumatoid arth tis to Graves' disease has been well de with by Llewellyn Jones. The result his experience rather indicates that rhe matoid arthritis and Graves' disease fr quently co-exist than that there is a actual affinity. In cases noted by hi the thyroid swelling was usually of mo erate size, and certainly varied from tir to time. Tremor, in the complete typ was, as a rule, general, and often mo marked in the limbs affected with jo swellings. As regards ocular symptom —in addition to proptosis—the signs Stillwag, Von Graefe, and Moebius, t gether with slight ptosis and weakne of the external recti, were very mark in some cases; in others, less so.

He questions as to whether the rap cardiac action, which is a feature some early cases of rheumatoid arthrit is peculiar to this disease, or due to larval manifestation of Graves' diseas Llewellyn Jones also points out that it possibly significant that many of the s called secondary features of Graves' d case occur in the subjects of rheumato arthritis, and, moreover, in cases whe

ne of the cardinal symptoms of Graves' ease are present. Increased pigmen- ion is fairly common. Leucoderma d scleroderma are occasionally met th. Urticaria is also met with in both eases. Edemas, fixed, transient, and of egular distribution, are met with in h maladies. Disturbances of the di- stive system occur in both diseases, o menstrual troubles and leucorrhea. ilateral flushing, subjective feelings of at, excessive sweating and excessive aciation are also features common to h disorders.

Clinical research distinctly suggests ne obscure relationship between rheu- atism and rheumatoid arthritis, and es suggests that the following factors y determine this sequence in some es: (1) A fundamental element in the m of a neuropathic diathesis, in evi- ce of which he cites this co-existence h Graves' disease in some cases, and o the fact that in many other clinical tures it resembles diseases of nervous gin; (2) an accidental element in the sence of a possible source of toxemia or example, oral sepsis, chronic indi- tion, gastric ulcer, sometimes dilata- n of the stomach or chronic diarrhea, e throats, etc.

Chorea is another disease with which aves' disease enters into relationship, d the same may be said of rheumatoid hritis. The sequence is usually rheu- tism, chorea, rheumatoid arthritis, but author has known chorea to be fol- ed by rheumatoid arthritis without a vious history of rheumatism.

The question of the relationship of any to the involuntary spasms or mps met with in both rheumatoid ar- itis and Graves' disease is also dealt h, and it is noted that tetany has been orded by Maude in the latter disease. es has himself recently recorded the ilarity of the cramps of rheumatoid hritis to those obtaining in tetany, and ted that Chvostek's sign (increased chanical excitability of the nerves) is ily obtained in some cases. A general sideration seems to suggest the possi- ity of a cerebro-spinal toxemia under- ng rheumatoid arthritis, and one de- ed from many different disorders. sterior sclerosis was found by Tribou- let and James in a case of rheumatoid ar- thritis, and the same lesion occurs in er- gotism, a condition, according to some, closely allied to tetany.

Jones, in conclusion, in view of the fact that the part played by the thyroid gland in Graves' disease is still doubtful, and that this disease may precede, arise coincidently with, or possibly be engrafted upon, rheumatoid arthritis, suggests that these two diseases, when fused together, may be extensions of one and the same morbid process—that is, a toxemia.

The possibility of a toxemia underlying rheumatoid arthritis may certainly be considered, but recent bacteriological research has, in my opinion, established the respective origin of both rheumatoid arthritis and acute rheumatism. More- over, it is well, in endeavoring to form a correct picture of rheumatoid arthritis, to warn one's self against the danger of suggesting that the coincidence of multiple disease implies a relationship, *e. g.*, to base a relationship of rheumatoid arthri- tis to neurasthenia, Graves' disease, and paralysis agitans, on the occurrence of tremor as a marked feature in all these diseases.

Before concluding, a brief summary of the bacteriological researches with refer- ence to rheumatic and rheumatoid condi- tions is advisable; the more so in that the most important of these are as recent as 1902—that is, the work of Poynton and Paine.

In 1901, J. F. Poynton and Alexander Paine isolated a diplococcus from eigh- teen cases of rheumatic fever. They write as follows: "We have isolated the organism in these eighteen cases from various regions of the body—from the blood and urine of the living patient, and from the pericardial exudation, cerebro- spinal fluid, cardiac valves, the blood, the nodule, the pleural exudation, the lungs and urine, after death. * * * * We have grown it in the pericardial exuda- tion, and also in a medium of bouillon and milk slightly acidified with lactic acid, upon blood-agar, in ascitic bouillon, in milk rendered considerably alkaline with normal carbonate of soda, and in bouillon of high alkalescence. These lat- ter results, as we suspected, make it highly probable that the diplococcus de-

scribed by Wasserman, Westphal, and Malkoff, and isolated by them from a case of severe rheumatism, and the diplococcus described later by Meyer, are identical with ours.

"It has produced, on intra-venous inoculation into rabbits, pericarditis, valvulitis, pleuritis, pneumonia, and in one case also peritonitis, polyarthritis, bursitis, tenosynovitis, and in two cases nodules, chorea and weakness of the hind limbs, an acid urine loaded with urates, and infarcation, as well as fatty changes in the myocardium, liver and kidneys. The anatomical lesions in man and rabbits are identical. The organism is, as we have insisted before, a *minute diplococcus*, and will grow in a medium of slight acidity for long periods." (Trans. Pathological Soc. Lond. 1901.)

There is, therefore, definite evidence that rheumatic fever owes its origin to the above-mentioned diplococcus, and that it is best described as acute infective rheumatism.

Valuable work has also been accomplished with regard to rheumatoid arthritis. Some years since, Max Shuller described bacilli obtained from the fluid of the diseased joints. In 1896 Bannatyne, Wohlman and Blaxall, independently discovered in the blood and synovial fluid a short bacillus of dumb-bell shape, which Blaxall succeeded in cultivating.

More recently, Poynton and Paine have isolated a diplococcus, have cultivated it, and by injecting it into rabbits have produced arthritis. Their conclusions are worthy of summary:

1. A diplococcus was present in the synovial membrane of the knee-joint of a man aged sixty-seven, several of whose joints showed the chronic destructive changes recognized as occurring in one type of rheumatoid arthritis.

2. This diplococcus was isolated and cultivated in pure growth.

3. Upon two occasions, when injected into rabbits, it produced a severe arthritis, but no cardiac lesion.

4. The organism was isolated from the exudation produced in the joints of the rabbits.

5. In the second case a mon-arthritic resulted from the intra-venous inoculation.

6. This arthritis differed in type fr that previously produced (by the sa observers) with the diplococcus of rh matic fever.

It is, therefore, concluded that t diplococcus was the cause of the arthr in the case from which it was isolat and of the condition produced by exp ment in the rabbit. (Poynton and Pai Trans. Pathological Soc. London, 1902.

Of other observers, Chauffard and R mond in 1896, also isolated a diplobacil from the lymphatic glands and syno fluid, but did not obtain cultivatic Also, in 1898, Von Dungern and Schn der isolated a minute diplococcus fron case of rheumatoid arthritis, which l followed rheumatic fever. (This case c responds to the class for which I sho suggest the name of acute rheumatoid thritis.) This diplococcus when injec into the knee-joint of a rabbit, produ an arthritic condition, which the obser believed to be rheumatoid.

The evidence is that, both in ac rheumatism, and in rheumatoid arthri there is now direct evidence of infectiv —for which evidence we are chiefly debted to Dr. Poynton.

The organism, which may be cal the diplococcus rheumaticus, is a sm diplococcus, with a tendency to arran ment in streptococcal chains. It gro well in several media, not only in lac acid milk, as Dr. Poynton first thoug The discovery of an apparently simi organism, in rheumatism and in rheu toid arthritis, would lead one to expec very definite relationship. One of chief objects of this paper has been point out that such relationship is ev less definite than one had supposed. It probable that, shortly, one may expec differentiation of the organism of above diseases.

I have only been able to touch brie on a very wide subject. No mention been made of treatment, for the rea that a separate paper would be needed.

I have merely endeavored to write paper which, if failing in informati may possibly be found suggestive.

[Written for the MEDICAL BRIEF.]

The Therapeutics of the Iodides.

C. D. F. PHILLIPS, M. D., LL. D. (EDIN.); LL. D. (ABERD.) F. R. C. S. AND F. R. S. (EDIN.).

aminer in Materia Medica in the University of Aberdeen, late Examiner in the Universities of Glasgow and Edinburgh, and Lecturer on Materia Medica at the Westminster Hospital. London, England.

In this paper it will be my endeavor to ve an account derived from many years' actical experience of the medicinal uses the various salts of iodine, including a ief sketch of their pharmacological ac-ons.

Iodine and the iodides have a similar tion: the former is better adapted for odifying the general constitutional state in tuberculosis, whilst the alkaline io-des being more quickly passed out of e system, act better where some mor-d material needs elimination, *e. g.*, in philis, lead poisoning, or rheumatism. e potassium iodide is the salt most mmonly employed, but the depressing ects of the potassium, especially when ken for long periods, have led many to ploy the iodides of sodium, ammonium, strontium in preference.

Melsens found that mercurial com-unds were soluble in alkaline or neutral utions of iodide of potassium, and that rrosive sublimate, if fixed in a muscle tendon, could be dissolved out of the ganic tissue by soaking it in such a ution. He found that even metallic d was, to some extent, soluble in the ne medium, with the formation of a uble iodide of lead and potassium. He gued that in cases of mercurial or lead soning, with salivation, tremor, colic d palsy, iodides introduced into the od formed soluble compounds with the tal deposited in the tissues, and en-abled it to be taken up by the absorbents and passed out by the kidneys, salivary glands, the mucous membranes, and skin. Support has been given to this argument by the fact that an insoluble salt of mercury or lead may be administered to animals without evident effect until after the administration of an iodide, when symptoms of poisoning appear. We know, clinically, that in metallic cachexia, when active symptoms are no longer present, and the poison can not be detected in the secretions, if an iodide be given symptoms of acute mercurial or lead poisoning may be developed, and that foreign substances may be found in the urine. Chronic conditions of illness, such as palsy or cachexia, may be present when the use of the iodide is commenced, but in the course of a few days acute symptoms, such as colic or salivation, may be reproduced until elimination is complete.

The case of M. Faure, recorded by himself, is a good illustration of the value of iodides in cases of lead poisoning. Engaged in white lead manufacture, he suffered severely from symptoms of plumbism, and cured himself with iodide of potassium. He remarks that he could tolerate the drug better when he took it before, than with food, which he attributed to the "fasting stomach being coated with mucus."

I have had very good results with iodides in cases of plumbism, the best being obtained in conjunction with purgative treatment. The metallic iodide is excreted by the mucous membrane of the alimentary canal, and should be immediately removed to prevent its re-absorption; hence the necessity for counteracting the constipation which so frequently accompanies this condition. A good formula is:

℞ Magnesii Sulphatis.....30 grains.
Potassii Iodidi..... 5 grains.
Aquæ Chloroformi..... 1 ounce.
M. Sig: To be taken every four to six hours.

Iodide of iron is valuable in later stages.

It is probable that iodine acts in syphilis much as it does in metallic poisoning, by assisting the elimination of a morbid material. It has been maintained that its influence is best seen in cases which have been previously treated by mercury; but there can be no question that the drug has curative powers of its own, independ-

ent of mercurial action; they are evidenced in the later, or tertiary stages of constitutional syphilis, when either the mucous membranes are affected, as in deep ulceration of the fauces, or the bones are attacked with periostitis or nodes, or the skin is affected with rupial or lupoid eruption, or the meninges are thickened, or gummatous deposits are formed in the viscera. In such conditions it acts better than mercury, although this latter drug is preferable in iritis. In a certain proportion of undefined syphilitic cases, an iodide and mercury together will give better results than either medicine alone.

By causing the absorption of deposits and thickenings in various parts of the body, iodides relieve many resulting symptoms, such as those due to pressure on different portions of the nervous system, nocturnal pains, neuralgia, paralysis, dullness of sense or intellect, and convulsive paroxysms. The dose of iodide of potassium is a matter of much importance, and need be limited only by the susceptibility or idiosyncracy of the patient, and the progress of the disease; it may vary from one to two grains up to sixty grains two or three times daily, and the best results have sometimes been obtained from heroic doses, one-half to two ounces daily, when ordinary ones have failed. Personally, I am not in favor of the administration of large doses.

Graves was one of the first to point out the value of iodide of potassium in rheumatism, and it is now well established. I connect its efficient anti-rheumatic action mainly with an eliminant action through the kidneys, and to promote this, recommend it to be largely diluted and combined with bicarbonate of potassium. To lessen irritation of the stomach, the medicine may be given in an effervescent form. Sometimes if the patient is feeble, and the urine abundant and of low specific gravity, the iodide may be combined with hydrochloric acid and quinine, or given as hydriodic acid. In cases of chronic rheumatism, small doses of iodide, continued for a long time, act exceedingly well, but some patients are very sensitive to its physiological action, and need special care to secure its toleration. The use of iodide of potassium is now mostly limited to chron cases, or to those acute cases where dium salicylate can not be tolerated.

I have had several cases of meningi which derived much benefit from iodid given alone or in combination. A chi aged six years, who had been ill for eig days, and was insensible, with dilated pils, dysphagia, paralysis of one side, a convulsive twitching, and who had be getting worse under previous treatme began to improve soon after commenci potassium iodide, given in ten-grain dos every six hours, with five minims of ti ture of belladonna in the intervals. covery ultimately ensued, and the b has now reached adult age.

In another case, aged eight years, the was pain, vomiting, delirium, unc sciousness, convulsion, dilated pupils, t anic stiffness of the neck muscles, gri ing of teeth, difficult respiration, slo weak pulse, and every sign of fully-d veloped meningitis, yet recovery to place under potassium iodide and bel donna.

Leared recorded a case of recove under five-grain doses of iodide of pot sium when other remedies had been us without relief. He was satisfied as to t diagnosis of tuberculous meningit Trousseau and many physicians of ex rience deny that the tuberculous form curable under any circumstances, a certainly a large majority of such ca end fatally.

In the sub-acute and chronic stages bronchitis the iodides relieve by an alt ative action on the bronchial muc membrane, thinning and ultimately dim ishing the muco-purulent tough secreti and so rendering expectoration easi They may with advantage be combi with antispasmodics. Potassium iod should be given for this purpose in do of three grains; but in weakly subje the iodide of ammonium, in doses of fr five grains every four hours, acts bett When there is an increase of tempe ture, aconite should be given in doses five minims every two to four hours. an expectorant be required, tartar eme should be chosen; the dose should small and frequent, and care should taken to avoid emesis or undue depr sion.

I have known iodide of potassium to re-
eve many asthmatic patients, and it is
ie main ingredient in a secret and suc-
essful remedy for asthma. Trousseau
nd Jaccoud speak of its value, and Sée
as recorded valuable observations upon
venty-four cases watched for a long
me. Four of these were children, four
d people, the others adults; the daily
ose varied from twenty-two to forty-five
rains, being reduced as improvement
rogressed. If given some hours before
e usual attack this was often prevented;
given during it, respiration was ren-
ered free in one to two hours. Chronic
sthma with emphysema was also bene-
ted by the remedy; inhalations of iodide
ethyl, ten drops several times daily,
nd the occasional use of opium or chlo-
l were with advantage, conjoined with
e treatment. Hyde Salter observed ben-
it from iodide of potassium in full doses
fifteen to thirty grains—every two to
ur hours, in very diverse cases of
sthma. I think that such attacks as are
onnected with catarrh, and are relieved
free secretion, and in which the nerve
mptoms are reflex rather than primary,
ow the best results from this remedy.
have known it to be efficacious in
sthma connected with amenorrhea and
erine congestion, and also in the asthma
rheumatic and gouty subjects. In an
teresting case in a rheumatic patient,
e asthmatic attack was relieved by four-
ain doses of iodide, but severe pain in
e region of the kidney followed, with
cretions of scanty acid urine; this oc-
rred more than once, and was only re-
ved by producing free excretion of al-
line urine by appropriate remedies. In
is case the drug was supposed to cause
nal congestion by increasing the ab-
rption of waste nitrogenous material.

In cases of thoracic and abdominal
neurism, in which surgical treatment is
possible, the clinical results obtained
potassium iodide should not be ig-
red. Nélaton recorded marked relief of
e signs and symptoms of an innominate
neurism under the use of this remedy,
hich he gave empirically at the request
the patient, and Bouillaud, following
this clue, obtained good results in
neurisms of the carotid and thoracic ves-
ls. Chuckerbutty, in Calcutta, pub-
lished an account of three cases which were relieved; in one of these the aneurism was already projecting through the sternum when the drug was commenced.

It is to Dr. G. W. Balfour that we are most indebted for drawing attention to this subject. He summarizes fifteen cases, all of which, save one, were relieved, and in twelve the external tumor was actually lessened, and the sac partly consolidated. In one of his earliest patients the bulging, which was evident between the second and third ribs, disappeared after a few weeks' treatment with thirty-grain doses thrice daily, and this dose was continued for nine months "without any unpleasant symptoms," but with complete subsidence of aneurismal suffering. The same man had not improved under previous doses of twenty grains, and Balfour points out the importance of pressing the drug to saturation before considering it inert. It is quickly eliminated—large doses within two or three days—and many of his patients took thirty grains several times daily. In a few, coryza and headache were produced, but, as a rule, no worse symptoms were caused by large than by small doses. Suckling has contributed an additional series of twenty cases treated by potassium iodide in doses of ten grains, increasing to sixty grains, combined with Tufnell's diet; of these twelve were benefited, but he notes that in several the pulse rate increased, and the drug then disagreed. Referring to these cases, Balfour points out the necessity of regulating the dose by the effect on the circulation. After some days in bed the patient's normal pulse should be ascertained, and doses of ten grains commenced, and then later increased to fifteen grains if the pulse rate remain unaltered, the object being to lower blood pressure within certain limits. Although in his early writings on the subjects already quoted, Balfour was inclined to attribute to a sedative action on the nervous system the good effects of the drug, he has, for some time past, traced them rather to lowering of blood pressure, consequent on dilatation of the arterioles, and some depression of heart action; following this more resisting power develops in the sac, the coats of which tend to hypertrophy, and

so to cure; whilst if the nutrition be unduly lowered by starvation diet, or by excessive doses of iodide removing albuminates from the system, the hypertrophy is hindered; if the pulse quickens under iodide, he concludes that tension is unduly lowered, and the dose too large.

In contrast with these observations must be noticed a very careful series of experiments on the blood pressure in rabbits after intravenous injection of potassium iodide; also of records of pulse rate and tension on patient's taking full and large doses of the sodium and potassium salts by Drs. Stockman and Charteris, which lead them to the conclusion that " these salts when given to man by the stomach in ordinary doses have no direct depressing effect on the action of the heart, or on the blood pressure in the arteries" (*B. M. J.*, November, 1901). If sometimes weakening and quickening of the pulse follow their use, it is an indirect effect due to increase of, or change in, the iodine containing thyroid secretion. With regard to their clinical value in aneurism, whilst quoting Rosenbach, of Berlin, against it (Drs. Heart, 1893), they acknowledged that almost universal experience is in their favor; certainly mine is.

In cases of chronic endocarditis, and arterio-sclerosis, hypertrophy, and even fatty degeneration, relief may often be given, especially to the anginal attacks and dyspnea by a steady course of various iodides. Of course, as Charteris remarks, in long-standing cases dependent on factors continuous in action, their cure can not be reasonably expected and adjuvants of rest, diet, etc., must be secured, but under favorable conditions the drugs may be very valuable. Germain Sée, Laborde, and others, have recorded illustrations. Dr. J. B. Nichols (Washington) concludes that they arrest or retard the earlier symptoms, and ameliorate later by an alterative action, not only anti-syphilitic (International Clinics, 1904). Biering again recommends them in the sclerosis of gastric and intestinal vessels. Powell mentions it as valuable in angina pectoris "to reduce arterial pressure." Mott advises it as most useful when arterio-sclerosis is well marked. Sansom combines it with heart tonics, "to unlock the arterioles," *i. e.*, to lessen tension, and wherever there is thickening of arteri walls, gives a long course of iodides.

In a recent paper published in conjur tion with Dr. Charteris, Professor Ral Stockman shows that the action of t iodides on the circulation is not dire but is due to increased formation of t iodine containing thyroid secretion, whi exerts a powerful effect, both on the c culation and on metabolism.

The iodides are readily and rapid eliminated by the different secretion and may be detected in the saliva, t buccal and bronchial mucus, the tea the milk, the perspiration, the urine, a even the serum of joints. R. W. Tayl has reported evidence of elimination iodine by the skin in the case of a m with pityriasis, who took large doses the potassium salt whilst wearing starched shirt; he had profuse perspi tions, and a dark coloration, due to t formation of iodide of starch, appear on his back. In another case of a m taking ten-grain doses for syphilis, n only the linen, but the hair became c ored brown.

It is probable that almost all the iodi taken is excreted in the urine, for Sch lau recovered from that excretion thr hundred and forty-five centigrammes o of three hundred and fifty, and, accordi to Melsens, very little can be traced the feces, the iodine that is excreted in the intestine being absorbed again by t lining membrane before it reaches t rectum. Rabuteau found a small quanti in the feces, so long as it was present the secretions; if diarrhea occurred t quantity was notably increased. Ehle concluded that doses above twenty grai are not completely absorbed; of th quantity he found seventy-five per ce eliminated.

The rapidity of elimination varies wi the quantity taken, a large dose givi evidence of its passage very quick Ranke found traces in the urine thr and a half minutes after administrati and even sooner in the saliva. Nothnag also found it early, in ten minutes in t latter secretion. Richardson found it the urine within one minute of injecti tincture of iodine into an enlarged bur and three minutes after breathing iodi of ethyl iodine could be detected in t

ine. It is an important practical point at the elimination of this drug is completed sooner than that of many others. alfour noted that even if large doses of otassium iodide had been taken for any weeks, their elimination was complete within three or four days after ceasg to take them. Rabuteau, after fifteen ains, found traces in the urine for ree days; after one hundred and fifty ains, for ten days, not afterwards. The reater part was eliminated during the st day, little passed on the second, and arcely a trace on the third: in the dog, imination was somewhat slower. Speck ates that in Bright's disease the kidneys not eliminate iodine. Desprez gave otassium iodide subcutaneously, and succeeded in recovering two-thirds of it subquently from the urine, its earliest apearance in that secretion occurring enty minutes after the injection. He und that febrile conditions and disease the kidney delayed the appearance of e salt in the urine, prolonged the period uring which elimination occurred, and the case of Bright's disease, instead finding two-thirds of the drug in the ine, he found only a quarter, a sixth, d even an eighth. Bachrach, giving oderate doses of potassium iodate by e mouth to healthy subjects, and to ver patients, traced the drug in the ine of both within fifteen minutes, but injecting it under the skin, elimination the former occurred in five minutes, d in the latter forty minutes later.

The earliest and most marked evidence the constitutional action of the iodides furnished by irritation and catarrh of e mucous membranes. It is shown ostly in the throat and bronchi, the nose d eyes, parts that are exposed to conct with carbonic acid gas, which it is pposed decomposes the iodide as it is iminated, so that free iodine exerts its cal irritant effect. The irritation shows self by pain and sense of pressure over e frontal sinuses, edema, prickling, and eat about the nose and eyes, with sense stuffiness and discharge like that of ordinary coryza. The dose that will proce these symptoms varies a good deal ith different persons, some being acutely ffected by one or two grains of potasum iodide, others not by ten or even twenty grains, continued daily for a long time; in fact, raising the dose will often stop the symptoms. Ammonium iodide, it is stated, is more liable to cause iodism than the other salts, because it is more easily decomposed in the body.

The phenomena described, as well as the skin eruptions caused by iodides are included by Dr. D. Walsh in the term, "excretory irritation" (Baillieu & Co., 1897), *i. e.*, "disturbance set up by the eliminatory passage of the internal irritant through the essential cells of the excretory organs." He states that any drug or internal irritant that inflames the skin may be suspected of inflaming other excretory outlets, and such drug must be administered with great caution (pp. 48, 49).

Much disturbance of the nervous system sometimes follows the full action of the iodides. It is marked at first by excitement with restlessness, tremor, anxiety, and insomnia, but this state is liable to be succeeded by feebleness and depression; these symptoms are possibly due to increased thyroid secretion. Toxic doses have caused violent headache and sometimes convulsion. Rilliet described neuralgia, tinnitus, disturbed intellect, and convulsions, as prominent symptoms in some cases of iodism, but these are of exceptional occurrence. Trigeminal neuralgia has also been reported, but I have rarely met with such cases. Altered vision and paralysis were noted by Brodie. "Occasional hyperesthesia and temporary palsy of lower extremities" occurred in a man who was taking very large doses (ninety grains thrice daily) of potassium iodide. Such symptoms, however, must be considered rare, for H. Wood states that he has seen the nervous system affected only once, even "with enormous doses," and then the patient, who had been taking two hundred and seventy grains daily, became intensely sleepy and stupid, as if under the influence of bromide. Extreme depression is not an uncommon effect of even small doses in sensitive subjects, and sometimes compels the disuse of the drug.

Binz experimented with the sodium iodate and found that in large doses this salt caused narcosis in animals. It proved especially poisonous to the respiratory

and cardiac centers, and he suggests that both this salt and iodoform are decomposed, and liberate iodine in the brain and cord. Many years ago Reuger & Murrell, experimenting on the frog's heart, demonstrated by a series of tracings that potassium iodide exercised a much more depressing effect on the cardiac centers than either ammonium or sodium iodide.

[Written for the MEDICAL BRIEF.]

Medical Paris.

BY ALBERT SMITH, M. D.,
Paris, France.

In the MEDICAL BRIEF, of March, of the present year, there appears an article on post-graduate teaching in Paris, from the pen of Dr. Le Mare Bunch, whose familiarity with the subject of which he speaks is known to all. My only excuse for intervening in the discussion is that I too have passed many months in Paris studying at the various hospitals, and in special departments, and it seems to me possible that I may supplement the information already given by certain details which may be of use to intended American visitors.

In the first place, it is well to point out that Berlin and Vienna have no longer a monopoly of post-graduate instruction, and that their popularity in this particular connection is on the wane. They are, it is true, great medical centers, and in both there is ample wealth of material for clinical instruction, but they do not stand alone in this respect, and equally good cases, just as ably demonstrated, and with the same elaboration of detail, can be seen both in London and in Paris. It is probable that there are more good clinical teachers in France and England than in Germany and Austria, although this is a mere expression of opinion not susceptible of proof.

The great attraction of Berlin and Vienna to Americans in the past was that many short courses of instruction, especially during the months of August and September, were given in English. Medical men are not, as a rule, good linguists, and are too fully occupied with their purely professional work to become ad in French or German. The younger man teachers recognized the fact, laid themselves out to give instructio English, more or less intellige France, more conservative, relying on renown of the great Paris hospitals, the large number of students attracte the excellence of the teaching, was keen in catering for visitors and graduates from other countries. Du the last few years, however, there been a gradual alteration in this res and nearly all the coming men in P make a point of acquiring a conv tional knowledge of other languages, especially of English. It is a distinct vantage for visitors to have, at all ev an elementary knowledge of French, the fact of not being able to spea fluently or readily, can not be rega as a disqualification.

Much depends on the season of year in which the visit to Paris is The winter is often bitterly cold, an the houses are not warmed as they in America, the climate will be f somewhat trying. August and Sep ber are the hot months, but alth Paris is hot enough in August, it very different kind of heat to that perienced in, say Washington, at the s period of the year. May is the ideal t when not only Paris, but the surroun country, is at its best. The latter en September and the early part of Oct are delightful.

In the matter of hotel accommoda and cost of living there is endless ety. You may live luxuriously in the appointed hotels in the world, or, on other hand, you may be accommod comfortably, and for a very small penditure. The hospitals are not in center of fashionable Paris, but at little distance. The man of means find excellent hotels in the neighbor of the Rue de Rivoli, or the Rue Honoré, whilst the modest student meet with cheaper, although pos equally comfortable rooms in some o smaller hotels in the Quartier L Cabs are plentiful in Paris, and f couple of francs, less than half a d one can drive in an open carriage one end of the city to the other.

mnibuses and the electric tube will be ound a great convenience.

The stranger in Paris who wishes to ake any length of stay, and to visit the ospitals, should come armed with proper troductions and credentials. His first ep should be to present himself to Monieur G. Mesurer, Directeur de l'Admintration Genérale de l'Assistance Pubque, who will furnish him with an auorization. It may appear but a formaly, but it is one which should be obrved.

It is impossible to see the whole of the aris hospitals in a few days. They are idely scattered, and it is difficult to sit more than one in the day. In a eek, however, much may be seen, but ree weeks or three months may be ofitably employed. The visitor should ake up his mind at the outset what it is wishes to see, be it medicine, surgery, some special branch. Facilities in all partments are ample, but it is impossie to accomplish everything in a short ace of time.

There are one or two guides to the aris hospitals in English, but the most mplete work on the subject is Lavarne and Jayle's "L'Æsculape" (1905), a lky work of some eight hundred pages, ofusely illustrated. It contains a mass detailed information, and deals not ly with the hospitals, but the regulaons for obtaining degrees, and for the rious valuable prizes offered by the aculté de Médicine.

It is of interest to note that in Paris e number of beds available for the sick twenty-nine thousand, maintained at a arly expense of sixty-six million francs, roughly thirteen million dollars. On average, the daily cost per patient is ree and three-quarter francs, which mpares favorably with the expenditure most of the London hospitals. This onomy is, to a great extent, the result centralization, all hospitals being tered for at a Central Bureau. By this mbination of forces, provisions are obned at the lowest possible prices. ery day there runs into Paris a traind of oxen, sheep, and other animals, to slaughtered at the "Boucherie Centale." The less valuable portions are reied at a low rate to the poor, whilst the prime joints are distributed to the hospitals. The same system of buying wholesale, and in the cheapest market, applies to bread, butter, vegetables, eggs, wine, and even bedding, linen and clothing. Those interested in hospital administration will find much to admire in the attention given to detail in these matters. Another feature of French medical life is that no patient is ever refused admission to a hospital because the wards are full. The number of beds is elastic, and "extra beds" are put up as required. Sometimes in the winter months they are so close together that it is difficult to pass between them. The wards are, as a rule, large and lofty, and even at times of greatest pressure the air is not foul.

The duration of the medical course for students is five years, but many stay on two years longer as "externes," doing the ordinary work of dressers and clinical clerks. From these are chosen by competitive examination the "internes," or assistant to a "chef de service," that is, a physician or surgeon with wards. These internes live and board in the hospital, and are responsible for the care of the patients in the absence of the chief. They have considerable liberty of action, and are a privileged class. Many of them are men of forty years of age, and of more mature experience than the average house physician or house surgeon in London. It would be impossible to retain the services without pay or emolument of such men if they were subjected to vexatious restrictions. They can invite their friends as visitors to the common table, and are practically free to do as they like, provided that there is no interference with their duties.

Coming now to practical points, the first visit may well be made to the Hôpitre Saint Louis, an old and fine architectural building, which owes its origin to the plague. It was established in 1610, and contains one thousand two hundred and twenty-one beds. The visit should be made at half-past nine in the morning, and in case of difficulty it would be as well to ask for Dr. E. Gaucher, who has charge of the Salles Saint Louis and Henry IV, a clinique comprising forty-two male and forty female beds. In a couple of hours, under the guidance of

the professor, a better collection of rare and interesting cases will be seen than ordinarily falls to the lot of the average physician in a lifetime.

Here syphilis is represented in all forms and varieties, and scores of cases are exhibited, each of which is a veritable curiosity. Side by side with these will be found cases of rodent ulcer, melano-sarcoma, elephantiasis, ichthyosis, Paget's nipple, and many diseases, the names of which are hardly familiar to the average physician. The cases speak for themselves, but each is clearly demonstrated in a few pithy sentences, which leave a lasting impression on the memory.

The electrical installation at this hospital has been brought to the highest pitch of perfection, and cases are treated with X-rays, high-frequency current, and all the most recent additions in this special development of therapeutics. The Museum Baretta contains a marvelous collection of casts, the mere examination of which in itself is a liberal education.

Another morning may profitably be devoted to the Salpêtrière, the old buildings of which date from the seventeenth century. It contains 3,834 beds, and it was here that Charcot carried on his lifelong work.

Inquiry should be made for Dr. Raymond, who gives practical lectures on nervous diseases.

Dr. Déjarine's clinique should be attended, and in his wards will be found a number of cases treated almost exclusively by suggestion, and without hypnotism. This is one of the most interesting cliniques in Paris, and no one who has an opportunity of witnessing the excellent results obtained, can fail to be impressed by the strong personality of the professor.

Another morning should be devoted to the Hotel Dieu, a hospital which receives fifteen thousand patients annually. Dr. Dieulafoy lectures every Saturday morning at eleven o'clock, and his lecture is always largely attended both by men and women, students and doctors. He is a fluent speaker, and his action is dramatic. He has a marvelous power of imparting instruction; every fact is driven home, and even if one were ignorant of the language it would be impossible to fail to grasp the tenor of his remarks. On th surgical side is Dr. Lucas Championnièr who speaks English fluently if not accu ately.

It is impossible in the space of th short article to indicate all there is to b seen in Paris, but with this foundatio some progress will have been made, an Saint Antoine, Gochin, Lariboisière, an other hospitals will follow in due cours The most modern hospital in Paris is th Boucicaut, which is well worth visitin It is only necessary to mention L'Institu Pasteur and its annexes, for here will b found the most modern development o experimental research. The Dispensair Antituberculeux of MM. Jacques Siegfrie and Albert Robin, in connection with th hospital Beaujon, is well worth visitin and the stranger may esteem himself fo tunate if he can do so under the auspice of Dr. R. Blondel. Permission might po sibly be obtained to visit the physic therapeutic establishment of Dr. J Rivière, 25 Rue des Mathurins (Opéra).

Paris is a mine of medical wealth, an more can be seen there in a week than i any other city of Europe in a year. Th following are the chief general hospital in Paris, with the number of beds i each, exclusive of extra beds: Hote Dieu, 885; Pitié, 680; Charité, 654 Saint Antoine, 865; Necker, 478; Cochin 809; Beaujon, 608; Lariboisière, 990 Tenon, 947; Laennec, 618; Bichat, 196 Andral, 96; Broussais, 275; and th Boucicaut, 254. The hospitals for cutane ous and syphilitic diseases are Saint Loui and Broca. The lying-in hospitals are th Maternité and the Clinique Tarnier. Th children's hospitals are the Enfants Ma ades, Trousseau, Bretenneau, and Herold

[Written for the MEDICAL BRIEF.]

The Physician and the Philosopher

BY B. M. JACKSON, M. D., LL. B.,

Omaha, Neb.

'Tis not wit merely, but a temper whic must form the well-bred man. In the same man ner, 'tis not a head merely, but a Heart and Re olution, which complete the real Philosopher.- *Shaftesbury*

I have used a wrong title for this arti cle, because life is so strenuous, do no you know? It should have read, "A Heart

»Heart Talk With the Old Folks, Mid-
le-Aged Folks, Young Folks, and Babies
f the MEDICAL BRIEF's Family." I shall
ot now stop to explain the reason why.
othing would afford me as much pleas-
re as a weekly—even daily—talk to my
rothers and sisters of the medical pro-
ssion, and especially to those who con-
nt themselves within the family circle
the MEDICAL BRIEF. It is a great fam-
, indeed! And let me tell you, my
ethren and sisters, I know of no other
herein I can find as much consolation
d happiness as I do find within that
the MEDICAL BRIEF. I have tried my
rdest to content myself within other
edical circles, but for some reason or
other I did not succeed. I feel so much
ore at home here. So much so that I
n tempted to offer a "resolution"—some
you know how much I cherish to hear
is word—to the effect that we meet
ce a week hereafter, instead of once a
onth, as we do now. We could easily
complish this by requesting our beloved
ther, Dr. Lawrence—may he never die
to call us together oftener. Let him
arge us a V annually for the privilege,
is worth the price. Consolation and
ppiness are worth any price. There is
e obstacle, however, which induces me
postpone consideration of the resolu-
n, and it is this: some so-called re-
rmer may charge the fountain-head of
r family with making money. "Re-
rmers," you know, do not like to see
hers make money, for they are badly
need of "filthy lucre" themselves.
eaking of "reformers," reminds me of
he little father" of all the Russians.
e is just now trying (Ahem!) to "re-
rm" some evil conditions prevailing in
s bailiwick. Yes, these "reformers" are
eat people! They always work "for the
nefit of others." Witness Dowie, Elijah
, for instance, and the myriads of "re-
rmers" within our own profession. Every
eformer" is trying to make use of all
e words in Webster's dictionary to in-
ce us to follow "him," that he may
egulate" us. He works for "our" ben-
t, do not you know. He needs our
oney and liberty, and needs them badly.
npty your pockets and ask your respec-
e legislators to enact some more laws,
ys and girls. Speaking of laws—rather
the craving for them for the purpose of regulating the other fellow—yes, remember that some of us agree with the "reformer" that the other fellow must be regulated and "not us." Oh, no; not us (Ahem!), the other fellow, has led me to discover and name a new kind of mental disease, viz: Lawmania. Lawmania is an insane desire for laws to regulate the other fellow. It is due to a microbe known as sophistrycoccus. The disease is contagious and infectious. Remedial measures are known to a few, but it seems that the majority of physicians would rather die professionally than resort to specific treatment.

In the last few issues of the MEDICAL BRIEF, there appeared opinions concerning the treatment of lawmania, and at the risk of being mobbed, I shall ask: Are physicians acquainted with the pathology and morbid anatomy of that disease? In other words, are physicians masters of "the games of Law and Politics," hence able to offer remedial measures? If they are, their opinions may have some weight, and if they are not their opinions are practically valueless. Some physicians expressed opinions to the effect that we ought to have a Federal law "regulating" the practice of medicine; others doubted the wisdom of such a law, preferring State regulation, and still others prefer no regulation whatever. Now, if three doctors disagree, who shall decide? Obviously, one who knows more about the subject in dispute. Suppose that the subject in dispute is a disease with which physicians are more or less familiar, but they are unable to cope with it successfully, what is to be done? The only thing to do is to deal with it as best we know how, and trust to the inevitable. Suppose, on the other hand, that three, or more, physicians disagree about a subject foreign to their profession, what should they do? Obviously, ask for the opinion of one who knows something about the principles involved in the subject in dispute.

Now, suppose that a stranger overheard the dispute, and he is himself interested in the subject, may he not hazard an opinion voluntarily? I think he may. "Providing he is more competent than we are," you say. Granted. The writer

feels more or less competent to give an opinion, basing his competency upon the fact that he used to practice "the game" of law in State, as well as Federal courts, by virtue of licenses granted to him for that purpose. Before I do so, however, I must beg you to bear with me in order that we may ascertain the gist of the subject in dispute. Now, what is the subject in dispute? Law. What kind of law? Statute law. What is wanted with statute law? To regulate the practice of medicine. Are you sure that statute law is wanted for that purpose? Have not you now in every State, statute laws regulating the practice of medicine? "But we are dissatisfied with these laws, and we want a 'Federal law' instead," you say. Ahem! I see! You are dissatisfied with the statute laws of the several States, and you are anxious to replace them with one Federal law. Ahem! Let me tell you, boys and girls, this is the reason why I should have used the other title for this article. You all talk about wanting this, that, and the other law, in spite of the fact that none of you know the principles involved in that subject. The "game of law" is a most intricate one, and he who does not know its theoretical principles and practical side, should leave that game severely alone.

When you venture into a bucket-shop and offer your good coin as a margin on some real or imaginary stock, you have one chance in a hundred to win and make a profit; but when you venture into a legislative shop and offer your liberty and independence as a sacrifice, you lose them forever. I do not blame you for feeling dissatisfied with the laws of the several States, but your craving for a Federal law deserves the most rigorous censure. Yes, you deserve not only a scolding, but a sound threshing; for you are no different from a child which has been playing with burning matches, and because of a dissatisfaction with their slight combustion craves for the burning anthracite in the furnace. Do you want to jump from the frying-pan into the fire? It is queer! It is queer! Take my advice and leave "the game of law" severely alone, and study methods of escape from the frying-pan in which you are being roasted alive. I hope you will not charge me with impertinence for asking the f lowing question: How come you to placed in the frying-pan? Have you ask to be placed therein in order to expe ence the exhilarating effects of roastin In other words, have you asked for the actment of the statute laws with which y are now dissatisfied? A voice: "Yes, the purpose of regulating the practice medicine, but not to impose hardships us, nor to deprive us of liberty and in pendence." That is it. Well, let me t you a secret. Upon due and deliber consideration I have come to the conc sion that the laws never have regulat and do not now regulate, the practice medicine, and were never intended to so. The laws have been enacted for t purpose of using them as a club on y and they are so used. I have carefu studied the letter and spirit of every m ical registration law and, in my opini as now enacted, their main object is deny to physicians freedom and in pendence and to impose on them all kin of hardships. If the individuals wh you asked to represent you in legislat shops for the purpose of enacting la regulating the practice of medicine h done their duty, there would have be neither money in their pockets nor p tical power in their hands. What th were after was money (fees) and politi power, and in order to have both th enacted the present laws. If you are a ious for laws regulating the practice medicine only, you must ask for la which will do that. The present regist tion laws impose all kinds of hardsh on and deny freedom and independen to physicians, but they do not regul the practice of medicine at all. Now law which shall regulate the practice medicine only, should be passed in ea State, and provided (1) a board compos of three county school superintender or still better, a board of three profess of different colleges, none of which h a medical department, which board sh pass on the preliminary educational c dentials, lacking these to examine in c tain subjects would-be M. D.'s; (2) board of physicians, to be composed one allopath, one homeopath, and one lectic, who shall keep a record of the ti of entrance and graduation of a stude

owing that he has attended three or ır years, and (3) this board of physi- ans may, if they see fit, examine the nior students, previous to graduation. rsonally, I do not see the necessity for e third requirement. We must remem- r that human nature is afflicted with merous shortcomings, hence with re- rd to a newly-made M. D.'s qualifica- ns, it does not matter whether he is amined by his professors or some other ysicians; for, whether he really is qual- ed or not, time alone and results at the dside can tell. Do not delude your- ves with the belief that examinations close qualifications; they do cause rvous prostration, and that only. A deral law regulating the practice of edicine will necessarily create a bu- aucracy with all kinds of power over e medical profession, and against just ch boards the Russian people are in volt just now, and have been for cen- ries.

Power is power, and if you centralize in the hands of one set of men it is ed much more vigorously, and is much re oppressive than when the same wer is distributed among a number of s. The chief concern of physicians ould be how to take away the power m the hands of the numerous medico- itical sets extant—boards of medical aminers. No set of physicians are en- ed to power over their brethren, and e present medical registration laws ve created that set and endowed them h power. It will be just as difficult for n to take away the power from the ards of medical examiners of the sev- l States as it is for the Russian people take away the power from their oppres- s. People cast away their liberties as sily as one strikes a match, but ages st elapse and oceans of blood must be lled before they can be regained. Peo- care nothing about history, be it even ntemporaneous. No; they want mas- s to reform the other fellow. How pid! How stupid! "He who reforms nself has done more towards reforming e public than a crowd of noisy, impo- t patriots."—Lavater.

[Written for the MEDICAL BRIEF.]

Surgical Treatment of Certain Malformations of the Vagina.

BY CHARLES A. L. REED, A. M., M. D.,

Professor of Clinical Gynecology in the University of Cincinnati; Former President of the American Medical Association; Former President of the American Association of Obstetricians and Gynecologists; Author of "Text-book of Gynecology," etc. Cincinnati, Ohio.

It has fallen to my lot to have an unusually large percentage of cases of imperforate vagina. I have referred to my notes covering only the last eight years, and find that I have had twenty-two cases of atresia, including such cases as are ordinarily classified under the title of imperforate hymen. A number of these twenty-two cases should be designated as incomplete atresia, for the reason that the closure of the vaginal canal involved only a certain segment of the structure between the vulva and the uterus. In three cases I have had complete atresia, which is to say that the patients each presented a fibro-muscular cord extending from the vulva to the uterus, and lying along the septum, between the urethra and the rectum. In one case only have I had complete absence of the vagina, a case I shall allude to *in extenso*.

My motive in discussing these classified conditions is to call attention to certain features of technique which I have found useful in restoring the parts to the condition Nature designed; and it should be borne in mind that the amount of detail in these comparatively trivial operations is an exceedingly important question, and upon its solution depends the success or failure of the case. Thus, I recall in my very early experience, two cases of simple imperforate hymen resulting unsatisfactorily. This unsatisfactoriness did not consist in the fact that I was able to open the vaginal canal and drain away the accumulated menstrual fluid, but in the fact that having employed a simple puncture for this purpose I left *in situ* a cartilaginous band which, in two cases, produced such a degree of stenosis that secretions were retained, and in the other instance made it impossible for the patient to sustain the marital relation. Basing my practice upon this

experience, I have made it a rule to cut out a zone of tissue corresponding to the zone of atresia, and to bring the margins of the membrane together from above to below, and to secure them by interrupted suture. Even after having done this it sometimes becomes necessary to maintain dilatation by the frequent application of mechanical devices continued through a considerable period. This, to my mind, is an essential feature of the technique in operations for the restoration of the vaginal canal under these circumstances.

In complete atresia, viz., in those cases in which the rudimentary vagina exists as a fibro-muscular cord, with its interior duly sealed, I have found great difficulty in relieving the condition and resisting the tendency to a recurring stenosis. The operation of dilatation, after careful dissection along the line of the canal, and the subsequent maintenance of dilatation by the introduction of metallic or rubber plugs is not justifiable, as a rule, except in such cases as have presented the prodromata of menstruation, or in which there is obvious dilatation of the uterus, due to the accumulation within it of menstrual fluid. To settle the question of the condition of the uterus and adnexa in these cases, it is sometimes necessary to make an exploratory incision by the abdominal route. I mention the abdominal route because it offers much more accurate and intelligent observation than if the dissection were attempted by way of the perineum. If, upon such exploration, the uterus and adnexa are found to be sufficiently developed to justify further interference, the canal can be dilated and maintained in a condition of dilatation, as I have already indicated.

There are certain other cases in which it is necessary to consider the expediency of this operation, viz., in those cases in which the patient, in spite of our advice to the contrary, insists upon establishing or attempting to establish the marital relation. Under such circumstances it is important to prepare the vagina for coitional purposes. This is far from an easy task. In two cases of rudimentary vagina I have succeeded, under an operation such as I have already indicated, and have maintained dilatation by mechanical devices for a period varying from eight months in one case, to fourteen mont in another, establishing a patulous can of such caliber as to permit the marit relation. In this connection I have be singularly impressed with the fact th a vagina thus established develops fro the mere rudiments *in situ*, before t operation, a form of mucous membra that is not strikingly different from th which is found in the normal vagina. T canal, in each instance, possessed su cient secretory glands to maintain a n mal degree of moisture. In one instan in which the uterus was so rudimenta as to give no promise whatever of su sequent menstruation, let alone conc tion, developed under the stimulus of ition until shortly after two years a slig menstrual flow appeared at regular int vals. The flow was painful, so painf indeed, that it is a question whether t last estate of the patient was not wor than the first. The interesting physiolo cal experiment remains, however, th the developmental impulse is promot by functional activity, a general law, believe, but one which is nowhere b ter exemplified than in the case to whi I refer.

I now come to the most interesting ca in my experience, viz., one in which the was complete congenital absence of t vagina, but in which I succeeded by t technique which I shall describe, in c ating a vagina, which has since se served the purpose of coition. When say complete absence of vagina I spe advisedly, for in two very careful diss tions the rudiment of the vagina was n to be found. The details of the case a as follows:

A young woman, aged twenty-two, w referred to me, for absence of menstru tion. The patient was of excellent ph sique, muscular and had been in emplo ment for a number of years. Her breas were not large, but of the distinctly fe inine type. Growth of hair on pubes w scant, and the pudendal development w scarcely rudimentary. The labia mino and majora bore a relative developme of infancy. There was not the vestige a hymen. There was a small triangul perineal body, but a sound passed in the urethra could be so distinctly felt the index finger in the rectum that

eemed that there was but a slight interening septum. Careful bimanual examintion under anesthesia failed to reveal he presence of either uterus or ovaries. he had never experienced the menstrual r sexual impulse. I rendered my opinion nd advised non-interference. The paent urged, however, that I make surgical xploration, although she would not conent to an exploratory abdominal incision. he entered the hospital May 20, 1902. divided the septum to a depth of two nches, but not finding the remotest indiation of the existence of a uterus, or ven of the usual rudimentary vagina, I esisted. The incision, as might have been xpected, closed in spite of the patient's lort to keep it open, so that three onths after the operation, with the exeption of a slight external sulcus at the ottom of the genital fissure, she was recisely as she was before. In Novemer, 1904, she returned to ask some exlanation of the existence of the sexual mpulse to which, during the preceding ear she had been subject, much to her nnoyance. She had been seized with an rdent desire to be married, and was deirous of taking advantage of a presenting pportunity. I made another examination, hen I found that the changes in the obective condition had become almost as narked as in the subjective state. Her reasts were larger and the nipples were uch more distinctly developed than preiously. The pubes had become covered ith a heavy growth of hair. The labiæ ajora were as fully developed as is sual in a multiparous woman. The labiæ inora had become completely developed. he patient complained of periodical ains in the pelvis. This latter fact rompted me to make another explorason. She consented to a preliminary exloratory incision of the abdomen, and he operation was performed on the 6th of larch, 1905. The abdominal incision reealed the presence of two ovaries, rather bove the average size, but perfectly norial. The fallopian tubes were likewise ormal in development, and were entirely ealthy. The uterus, however, while norial in outline, was less than two and fiveenths c. m. in longitudinal diameter and bout two c. m. from one cornu to the ther. A sound passed into the bladder and pressed against the index finger in the cul de sac of Douglas, at a point just below the rudimentary cervix, failed to reveal the presence of even a rudimentary vagina. Two parallel incisions, two c. m. apart, were made from a point even with the meatus urinaris posteriorly to the perineum, a distance of about 4.5 c. m. Another diagonally across this quadrangle, thus making two long, narrow-pointed flaps, which were dissected up from the underlying structures. The vesico-rectal septum was now split up with a Kocher dissector until the point of the instrument could be felt by my finger on the inside of the pelvis. When the rudimentary cervix was reached it was made free by sweeping the point of the dissector around it. Sutures of silkworm gut were now passed through the vault of the newly-made vagina, one in front and the other back of the cervix, and were made to transfix the tips of the two cutaneous flaps at the vulval orifice of the canal. When these sutures were tied these flaps, one anteriorly and one posteriorly, were drawn into the canal, and there converted respectively into an anterior and a posterior wall of the vagina. The skin of each labia minora was now dissected loose, and by means of another suture was drawn into the vagina to the distance of two c. m., and fixed. This, of course, left the lateral walls of the upper part of the canal without epithelial protection, but it was thought that with the antero-posterior flaps secure *in situ* complete fusion of the proximal edges in the process of repair would be prevented. This point secure, it was felt that the subsequent development of the vagina might be left to Nature. The sutures were removed at the end of two weeks, when the implantation of the grafts was found to be perfect. On the nineteenth day after the operation the patient had a sanguineous flow, lasting three days, which looked much like menstruation. Careful examination at this time revealed the fact that it did not come from the cervix, but oozed from the upper third of the vaginal canal. Is it possible that it was a vicarious menstruation?

I have not presented the foregoing case merely as a contribution to teratological

literature, but from its extremely practical importance. These atresiæ may occur in the experience of any practitioner. They should be promptly detected, for if anything is to be done for the restoration of these cases it ought to be done during the developmental period of the individual's life. It is during this period that the forces of Nature are on the side of the surgeon. While it is true that in some of my cases development was stimulated by coition in persons who had attained mature years, the fact remains that in the majority of all instances recorded in the literature of the subject, the greater development occurs in the years preceding this period.

The Groton.

[Written for the MEDICAL BRIEF.]

Elementary Facts Regarding Pulmonary Tuberculosis.

BY HENRY L. SHIVELY, B. S., M. D.,

Professor of Internal Medicine in the New York School of Clinical Medicine; Visiting Physician to St. Joseph's Hospital; Physician to the Presbyterian Hospital Dispensary, Department of Heart and Lungs; Physician to the West Side German Dispensary. New York City.

It is estimated that one hundred and fifty thousand people die every year in this country from tuberculosis, and that three hundred thousand new cases are contracted annually. For the past ten years in New York State more than thirteen thousand deaths have every year been attributable to this cause. All other epidemic diseases combined, small-pox, scarlet fever, measles, diphtheria, cholera, yellow fever, and the Asiatic plague, do not cause half as many deaths as does tuberculosis alone.

One of the saddest features of this frightful mortality is that it destroys the individual at the most useful and productive period of his life, for it is between the ages of twenty and forty that consumption is most fatal. In childhood and old age, the disease often appears to run a more favorable course as regards danger to life.

The best scientific opinion teaches us that consumption is readily curable in its earlier stages, and that it is even more readily prevented. What, then, are these measures of prevention and of cure Tuberculosis is distinctly a disease c civilization, of housing, and of confin ment. The caged beast in the menageri domesticated animals, the prisoner in hi convict cell, the dweller in the unsanitar and overcrowded tenement, are especiall liable to become tuberculous. Among wil animals and savages living in a state c nature, the disease is unknown. Th American Indian, the African negro, an the native Australian, only fall victim to consumption after contact with civi ization, and after the decay of their prin itive habits.

These facts indicate a special cause fo the disease, and also the very great in portance of an abundant supply of air an light in methods of prevention and cur Experience has shown that in the jud cious use of these great natural agent combined with nutrition and baths, ou most successful treatment lies.

For hundreds of years there have bee in every generation among physician good observers and thoughtful student who believed that consumption was con municable from person to person, but remained for the genius of Robert Koc to demonstrate the living virus by hi brilliant discovery of the bacillus in 188 This minute rod-shaped germ, which ca only be seen with the aid of a powerfu microscope, he showed to be always pre ent in the lungs of persons suffering fro consumption. He succeeded in separa ing it, and grew it in a suitable soil, an produced the disease experimentally i animals by inoculation. There is n longer any doubt as to the necessary rol played by the Koch bacillus in causin consumption. His method of isolatin and detecting the germ is in daily use b physicians as a part of the routine exan ination of tuberculous patients. Lik most great discoveries, the principle is s simple as it is ingenious. The germ stained a deep red, with one of the anili dyes, which colors equally the tissues i which the microbe is imbedded, or th sputum in which it floats. At this stag it would be impossible to see the germ everything being of a uniform red colo The notable peculiarity of the bacillu however, is that it holds fast to the colo more tenaciously than anything about i

When the specimen is passed through dilute acids, everything is bleached, and loses color except the germ, which retains a brilliant red, and is thus easily distinguished under the powerful lenses of the microscope.

In the expectoration of a moderately advanced or advanced consumptive there are coughed up daily many hundred millions of these germs, each capable under favorable conditions of multiplying and producing anew the disease. It is thus at once apparent how important is the careful destruction and disinfection of the sputum, in order to prevent the spread of the infectious microbes. The patient should carefully collect his discharges in proper vessels, cloths, or paper napkins, which may be burned or disinfected. He should also avoid soiling his clothing or hands with particles of sputum. By so doing, he is not only protecting his family, and friends, and the public, but he also increases his own chances of recovery by avoiding the possibility of fresh infection. It is also desirable that the patient when coughing or sneezing should turn his head aside, and hold a handkerchief before his mouth and nostrils.

Fortunately the bacillus alone is not sufficient for the production of the disease. It must have a favorable soil, and is usually powerless to inflict harm upon the robust, well-nourished person, whose healthy tissues present insurmountable barriers to the invasion of disease germs. Were this not the case, civilized man would long since have been exterminated by tuberculosis and other infectious diseases to the germs of which we are constantly exposed.

Usually the disease itself is not hereditary, as is commonly supposed, except in the sense that a constitution of diminished vigor and resisting power may be inherited. The consumptive woman who marries will probably have one child; she may possibly have two, but she will not live to have a third. The danger of infection to the healthy partner in marrying a consumptive is much greater for women. In some seventy cases of healthy persons with no family history of tuberculosis who developed the disease after marrying a consumptive, there were six times as many women as men.

Dr. Brehmer, the father of the modern sanitarium treatment of tuberculosis, found that among his patients the later children are born with a smaller inheritance of resistance, and are most likely to become consumptives.

In childhood, tuberculous disease less frequently affects the lungs than in adults. The more usual manifestations in children are chronic sore eyes, running ears, lumps in the neck, abscesses, skin disease, and bone and joint disease, causing disabling and hopeless deformity. The hump back, the shortened and withered limb, the stiffened knee or hip, usually mean that the victim was a sufferer from tuberculosis in childhood.

Certain diseases of children, such as whooping cough, measles, scarlet fever, and broncho-pneumonia leave the child weak, and in a condition favorable to become a prey of the tubercle bacillus. After these diseases, or any long-continued exhausting illness, the child should be removed for a time to the country until he has regained health and strength.

The choice of an occupation has often an important influence in the prevention of tuberculosis. Indoor pursuits and occupations exposing the lungs to irritant dust and vapors, are to be avoided by young persons predisposed to consumption.

The abuse of alcohol is an undoubted factor in the causation of tuberculosis. In France, more than fifty per cent of all consumptives are confirmed drinkers. People who depend upon stimulants usually take insufficient food, and intemperance in drink leads to recklessness in living, over-exertion, fatigue, exposure and excesses which are sure to undermine the health, and render the individual less resistant to tubercular infection.

Excessive smoking of cigarettes in not a few cases has appeared to be a factor in the development of consumption. Habitual users of cigarettes make a practice of inhaling, and smoke more constantly than smokers of pipes or cigars.

When tuberculous disease actually exists, the first essential of successful treatment is its early recognition by both the patient and his physician. One of the greatest difficulties in combating con-

sumption is due to its slow, insidious course, which usually extends over many months, or even years. The patient at first is hardly aware that he is ill, and it is often difficult to persuade him or his family that he requires medical care. The one symptom which excites his alarm, and brings him to a physician, is the spitting of blood, and even this he may endeavor to explain away as having its origin in his throat or stomach. The patient during all this time has been ignorantly disseminating the germs about him in his home, and in the street.

A cough lasting more than six weeks, and associated with loss of weight, declining strength and failing appetite, is possibly the beginning of consumption, and should be made the occasion for a careful physical examination by a competent physician. If beginning tuberculosis is present, the patient should be told so frankly, for without such knowledge on his part he will not take the proper measures, nor continue them long enough to make possible his cure. His interest and co-operation must be secured, and this can be done by the tactful physician without alarming or depressing the most sensitive person, if he is made to realize the curability of his disease, and to how great an extent it is dependent upon his own conduct. If the patient can not go to a sanitarium, we must bring sanitarium methods, as far as possible, to his relief in his own home. Medicines while helpful, play a secondary part, and may often be almost dispensed with if a liberal supply of air and light are secured with a generous diet.

If the disease is progressive, and the patient has fever, no active exercise should be taken, but he should occupy, enveloped with warm wraps or blankets, for several hours a day, a steamer chair or cot in the open air, and protected from high winds and storms by an awning or some simple shelter contrivance which should not interfere with the free access of fresh air. Patients who are doing well and gaining in weight, and have no fever, may be allowed more liberty, and walks in the park, or rides in open cars, or short trips on the decks of excursion steamers in fine weather, are useful ways of taking the fresh air treatment.

In the diet of the tuberculous patie the main reliance is the administrat of milk, and I always feel that the ba is half won if the patient can continue take, month after month, as much as t or three quarts of milk daily. When i well borne, the addition of a little cre is desirable, and from four to six egg day are advised. In addition there sho be permitted as varied and ample a d of easily digested and nourishing foods the condition of the stomach will all such as broiled chops, steak, roast be chicken, fish, soups, butter, fruits a green vegetables. Sweets, pie, ca pickles, candy, and salt meats, or pork a veal, which have relatively little nutrit value, should be taken sparingly, if at and cereals, such as oat meal, fari hominy, etc., should have less of a pl in the dietary of the consumptive th in that of a healthy person.

The most successful physicians in treatment of consumption usually emp the simplest methods, and educate th patients in the intelligent use of the Mysterious cabinets, elaborate spray c trivances, complicated inhalers, hi priced nostrums, electrical applian and wonder-working machinery of kinds, are usually so much rubbish, a designed to impress the credulous pati rather than cure his disease.

In the measures necessary to succe fully combat tuberculosis, there will in dentally be secured many other valua reforms of scarcely less importance, in its broadest aspects the anti-tuber losis crusade is a warfare waged agai ignorance, uncleanness, intemperan poverty and social misery.

Enough has already been done in t city to effect a very considerable red tion in the mortality and prevalence tuberculosis, and it is not unreasona to look forward to a time when by effective application of the prevent means we now possess, this dread dise will be controlled as well as small-p which, in the eighteenth century, was most as great a scourge.

How to Live a Hundred Years.

BY GEO. HUMPHREY TICHENOR, JR., A. B. (TULANE), M. D. (TULANE),
mber Editorial Staff Dixieland Magazine, Organ of the United Confederate Veterans; Former Medical Inspector Louisiana State Board of Health, etc. New Orleans, La.

Claims of Quacks.—It has become a rious problem how physicians are to put emselves right with the public, and to them understand something of the vancement made in the art and science medicine, in order to give them a cor-t idea of those things which are con-cive to longevity.

Posing as advocates of physical culture, od fads, and magnifying the possibility "natural methods for curing disease," ere are magazines which are exerting influence on the minds of the ignorant d feeble, more to be dreaded than any d all the evils that may exist in our nks. Behind one of these magazines, iming a circulation of over one hun-ed thousand, is one of the most widely vertised and most dangerous rum rem-y institutions.

The Evils Existing Which Produce nerican Physical Degeneracy.—When consider that there are about $60,000,-0 of patent medicines (how many in-rious?) annually sold in the United ates; thirty-three per cent of the pa-nts of asylums in America are opium ters; not one-half the sale of mor-ine in our large cities can be traced to e legitimate demands of physicians and spitals; the money annually expended r liquors exceeds in amount the cost of the bread, meat, boots and shoes used the entire country during the same riod; more money is spent each and ery day for tobacco than is expended r bread; the percentage of adultera-on, sophistication, and misbranding of od largely exceeds five per cent of the hole—more correctly, perhaps, fifteen r cent; the amount of adulteration, bstitution, and impurity of drugs; ly two-thirds of the men and women of r country now ever marry, and this oportion is constantly being lowered; e total number of persons engaged in gainful occupations in 1900 was twenty-nine millions, seventy-three thousand, two hundred and thirty-three, which constituted one-half the population ten years of age and over, and nearly two-fifths of the entire population, of these four millions eight hundred and thirty-three thousand, six hundred and thirty were women, and one million seven hundred and fifty thousand, one hundred and seventy-eight were children, those of foreign birth aggregating five millions, eight hundred and fifty-one thousand, three hundred and ninety-nine, or two-fifths of the total number of gainful workers; during the last school year, one thousand one hundred and twenty-nine women were students of medicine, and five-sixths of these were in co-educational institutions; the people who died of consumption in the United States numbered one hundred and ten thousand and fifty-nine more than were carried off the same year by appendicitis, railway accidents, diphtheria, grip, cancer, and typhoid combined; the immigration inspectors have reported to Washington that almshouses, homes for orphans, and other charitable institutions in nearly every State of the Union have a large percentage of aliens, who are sent to the country because they receive better treatment than in similar places in Europe; the worship of the dollar, the neglect of religion, the constant over-exertion of physical endurance, mental gluttony, the lost art of total relaxation of mind and body; the high nervous tension of life, and immorality, social degradation of women, and disease of most villainous type, which is transmitted to the third and fourth generation, is alarmingly increasing—it is no wonder that thirty-five per cent of the children born never reach the age of five years, and Denmark is damnably rotten.

Remedy Existing Evils by Legislation.—Therefore, the first thing we should do in order to increase our longevity is to remedy these existing evils by legislation, and see that our environments are wholesome, as we can not help the constitution we are born with, but are responsible how we develop it.

The evils of heredity can be modified. While it is true that the sins of the fathers are visited on the children, but,

with the exception of actual disease (blood contamination and insanity), and intoxication, either from liquor or narcotics in the parents, infants are not affected before birth, but come into the world healthy. This has been proven in cases when both parents were consumptives, and the infant has been reared away from home, under sanitary conditions, the child developed into a healthy adult. It is after birth that the unfavorable influences (unsanitary homes, personal filth, evil associations, drink, narcotics, poor food, semi-starvation, lack of proper exercise, over-work, etc.), begin.

But even if the baby's parents were weak, and its surroundings unwholesome, there is a tendency on the part of the baby to revert to the racial type and standard of constitution, and if properly cared for may possibly rival in strength some far-away ancestor.

My own investigation among the mongrel races of Central and South America convinced me of this fact. For instance, the people who originally settled Costa Rica came from the Gallician portion of Spain, where the people are of Castilian and Moorish extraction, noted, I am pained to say, for their ugliness, owing to the fact that they have very prominent cheek bones and Moorish expression of face and stature. Notwithstanding the fact that, in many cases, where they have intermarried with the Indian, their children, in many instances, will be distinctly Gallician-Spanish in type, and the other brothers and sisters may be, to every appearance, pure Indian—other characteristics of ancestors also can be easily discerned.

It is a frequent expression of the public to attribute a great many of their afflictions to their ancestors, when, in a great many instances, it is the result of their own abuse of Nature. If this were not true, physicians would not live longer than other professional men, their average lease on life being over sixty. Only seven per cent die of tuberculosis (consumption), which shows that they guard carefully against infection. Over forty per cent are of nervous breakdown or heart trouble, almost unavoidable conditions, owing to the character of their profession. Again, investigations made by life insurance experts show that t statement is correct..

The New York Jew is, on the avera the most long-lived of the city inhal ants. The temperance of the Jews in things accounts for their longevity. for the Irish, Germans and Scandi vians in the United States, an investi tion by the combined American life surance companies, covering the polic of the last thirty years, and including between the ages of fifteen and seve years, shows the Swedes and Norwegia who are usually engaged in farming, be the most long-lived. This being case, what can we naturally expect, wh out of twenty-nine millions, nine hundr and fifty-six thousand, one hundred a fifteen men engaged in gainful occu tions, nine millions, four hundred a fifty-eight thousand, one hundred a ninety-four are in agricultural pursui

Rev. F. G. Gunsaulis points out the f that our brains and brawn come from country. "Out of one hundred of C cago's prosperous business men, I fou that eighty-four, beginning with Marsh Field, came from the country. Seven six out of one hundred of the best la yers came from the country, and seven one out of one hundred of the best phy cians came from the country." Th facts are strong evidences that the Am ican people are living at too high a pr sure, and our condition can be improv We need more temperance in all thin and should improve our inherita rather than impair an unhealthy inh ited constitution.

Statistics show "for each thousand population the number of persons fr forty to sixty years of age are: In G many, one hundred and seventy-nine; America, one hundred and seventy; o sixty, in Germany, seventy-eight; America, sixty-five."—Dr. Laquer.

"Although we are more temperate the use of alcohol than the Germans a working on an average of ten per c shorter hours, the American becomes hausted earlier in life," owing to t strenuous life. These proximate cau of failure of power in old age are n coming to be fairly well understo Every high school boy and girl kno that the different parts of the human

anism daily die and are renewed; that ıe scarf-skin loses the vitality necessary) protect the true and peels off, and that ven the cells of the bones are exchanged r new ones, until it may be said that ter maturity man retains no part of the dy he was born with.

This being the case, we naturally ask rselves the question, what are the most tent factors in assisting Nature in perrming this function, and what are those ings which are required of us in order keep our bodily machinery in good rking order, so that friction will be dinished and thus longevity increased?

In my opinion, the use of common salt d water and the proper care and exerse of the lungs are the most potent facrs in prolonging the life of healthy peoe.

Service of Drinking Water.—Yet there ver was a time when these factors were neglected as to-day. The present stress competition in all the walks of life puts e nervous system at a greater tension an ever before, while lack of exercise, or ventilation, and the impurities we nstantly inhale, especially in our large ies, cause the waste products in the dy to become greater, and if not elimined in sufficient quantities health is in short time impaired. Water is a harmss medicine, which will accomplish the mination of waste products, and the ygen it contains burns up the waste terial. It is strange that the abundce of water in the human system should t call the attention of the average nking person to the necessity of reenishing the system continually with it. composes, perhaps, four-fifths of our sh and blood, and each adult in active ercise needs about three pints per day.

Service of Salt.—Common salt in abundce, like water, is absolutely necessary the life of human beings. Therefore, ture supplies it in abundance. It does t enter into the composition of tissue e water, but it is essential to the propdigestion of food, and to the removal worn-out matter. It has been clearly oven that the disease-resisting power of od serum depends on the proportion of dium chloride it contains, and the same wer, if lost by abstraction of the mineral, can be restored by adding the same to the serum.

My clinical observations have also demonstrated this fact in the treatment of contagious and infectious diseases. Salt solutions, when used at the opportune time, will reduce the temperature of fever and restore the heart's beat to normal number of beats per minute. Experiments with the lowest forms of mammal life will show that injections of sodium and calcium solution into their veins after life is practically extinct, will restore for varying periods of time the heart beat in its normal rhythm and strength. Therefore, drink a glass of water in the morning when you get out of bed, and take a salt bath, then a sponge bath in cold water, and a brisk rub down, and enjoy the sensation of being clean on the outside and the often neglected inside.

Do you realize that sleep has absorbed the water in the blood, and a natural instinct would be to replenish and distend the blood vessels anew by drinking bountifully of cold water, and to stimulate the nerves to renewed activity for the day by a salt bath? The food which was eaten before retiring has disappeared, leaving a mucous substance in the alimentary canal, therefore you want to drink a glass of water in order to leave a stimulus behind for digestion and put a spur to the circulation by having plenty of salt in your food, as the circulation has grown sluggish during the night. The salt will help to remove the mucus which is being washed out of the alimentary canal by the water, and remove the waste products. Cultivate this habit. Use seven glasses of water a day and a salt bath on rising and retiring.

Proper Exercise and Care of the Lungs.—While you are cultivating this habit, take up another more important, also, deep breathing. In this day of physical culture and confinement in the house, the greater part of the day, it is well to know what part of the body is most important to exercise, and the proper care of same. If people would only practice the art of breathing, in many instances, there would be fewer cases of consumption and pulmonary troubles. On rising and retiring one should inflate the lungs to their full-

est capacity, allowing the air to escape as slowly as possible, repeating the exercise at least ten times in the morning and at night several. Also make it a habit to take deep breaths during the day. The lungs, like any other portion of the body which is not properly exercised, deteriorates. Again, deep breaths inflate the lungs to their fullest capacity, while "shallow breathing," which is the habit of most people, makes use of only a part of the lungs. Again, if we collect a quantity of expelled air and analyze it, we shall find its composition is not the same as that of the inspired air. When it entered the lungs it was rich in oxygen, a gas which burns up the waste material of the body; now it contains twenty-five per cent less of that gas. Its volume, however, remains the same, its loss being made up by a very different gas, carbonic dioxide, a poisonous gas which the lungs exhale.

Therefore, one can see at once the importance of a good apparatus. There is no doubt, in many cases, consumption is simply the result of "lung starvation." The Sanitary Commissioners for the European army barracks stated in their report: "A great amount of phthisis (consumption) has prevailed in the most varied stations of the army, and in the most beautiful climates, in Gibraltar, Malta, Ionia, Jamaica, Trinidad, Bermuda, etc., in all of which places the only common condition was bad air, which the barracks system everywhere produced." There has been, of late, a decline in consumption in these stations in proportion to the improvement of the condition of the air, which is certainly strong evidence in favor of the foregoing statement. Again, Bondin showed that while the deaths from consumption in the British army were, in the line, 8.9 in one thousand men; in the guards, 12.5 in one thousand, and in the navy, only 1.76 in one thousand, proving the effects of good air, salt water, and a temperate life in all things.

Conclusion.—Therefore, I believe by observing the rules I have laid down in connection with the following, which are a resume of the advices of the scientists of to-day, the longevity of our people could be increased to a hundred years: Nothing in excess.

Peritonsillar Abscess.

BY L. C. MCELWEE, M. D.,

Ex-President State Board of Health of Missou
Dean of the Homeopathic Medical Colle
of Missouri; Professor of Surgery in t
Homeopathic Medical College of Missou
St. Louis, Mo.

When a physician is called upon to tre an acute case of peritonsillar abscess, will feel a little more comfortable du ing its management if he feels assure that he has a certain means of offset all symptoms which may arise, and st more comfortable, if the "worst com to the worst," if he has a safe and su method of finally conquering it.

To him who has been defeated in fr quent well-directed and ordinarily suf cient efforts to evacuate the pus from deep abscess of the peri-, retro- or infr tonsillar areas, any scheme, which insur *invariable success* in evacuating the pu cavity, will be received with more or le gratification. Recently, a physician wh had failed in twelve unsuccessful a tempts to reach the pus in one of the abscesses, succeeded in the thirteenth e fort, by this method removing at once th pus, and with it the hoodoo supposed accompany the number thirteen.

I had a patient, only a few weeks ag who came to have his tonsil lanced. H told me he was subject to repeated a tacks of quinsy, and although he ha been in the British and American navi for more than a decade, during whi time he had suffered many attacks, he h not yet found a surgeon who had su ceeded in evacuating the pus, thou many had tried, being compelled to wa for its spontaneous discharge, which co pelled him to lay up for a fortnight more each attack. I assured him that had at last found his man! With a sick grin he mumbled that he hoped so, a lay down in my office chair to submit my ministration.

The method which I have devised w a natural and progressive evolution is, I see it, absolutely without danger, an therefore may be practiced by any ty Every practitioner has in his pocket-ca all the instruments necessary except t gag, which can be procured of any strument maker, or improvised by t

erator at will. The plan consists of the lowing steps:

. General anesthetic—administration

. Forcing mouth open with suitable g, and exposure of affected area.

. Superficial puncture of mucous mbrane *only* over highest point of elling.

. Deep puncture through interstitial sue into abscess cavity, with grooved ector, six or seven centimeters, if nec- ary, in the worst cases.

. Divulsion of the penetration canal.

The general anesthetic (chloroform pre- red). is *absolutely* necessary, because the insufferable pain caused by forcing n the mouth. In this and the puncture the deep structure lie the only danger the individual. The mouth is next ced open as wide as possible, and the g inserted between the molars on the ll side, when the patient is then turned the opposite side, so that the operator, o sits or stands at the head of the pa- ct, may have control of the gag with his t hand, and to promote the easy flow blood and pus out of the mouth, that it y not gravitate into the larynx or chea, and induce troublesome cough- .

An assistant depresses the tongue, ex- ing the swollen area, and, if possible, palpation, the softest spot on the ex- sed surface is located by the tactus ditus of the index finger of the opera- when puncture of the mucous mem- ane *only* above it is made with a sharp stoury, which is immediately laid aside. to this small opening is now inserted her a grooved director or probe-pointed stoury, which is pushed on through the tervening connective tissue into the ab- ess cavity, which is announced by a ces- tion of resistance, and usually by a flow pus at the side of the bistoury, or rough the groove of the director. The netrating instrument is then withdrawn d a hemostat (Kocher's preferred) is troduced closed, and when separated *in u* is withdrawn while open, thereby aking a wide canal for drainage, the eration then being completed, and the l bugbear of the internal carotid artery blown away.

Suburethral Abscess.

BY C. JEFF. MILLER, M. D.,
Professor of Operative Gynecology in the New Orleans Polyclinic.
New Orleans, La.

Suburethral abscess, or incomplete internal urethral fistula, may give rise to many annoying symptoms, and require long and tedious treatment. It may be located anywhere along the urethral floor, and presents a well-defined round or oblique swelling of the anterior vaginal wall, just under the urethra.

If it is situated in the lower third of the urethral vaginal septum, it usually bulges in the vaginal outlet, and can be seen without opening the labia. If it be located high up, it will be more difficult to recognize, and is frequently overlooked.

The cause of the affection is not very clear. These abscesses are seldom seen in the acute stage, and usually come to the gynecologist with a history of long standing symptoms. Chronic circumscribed urethritis, or glandular urethritis of gonorrheal origin, is probably the most frequent existing cause. Diverticula of the urethral wall, injuries following confinement and retention cysts cause a type easily differentiated from abscesses following periurethral suppuration, and if the sac is draining there is a history of constant discharge of pus from the urethra. Frequent urination and tenesmus are noted, and are much more exaggerated when the abscess occurs near the neck of the bladder.

Palpation will detect the thickened edges of the wall of the urethra if the trouble has followed periurethral inflammation. The urethral speculum is of the greatest diagnostic value. It is introduced deep into the urethra, and as it is withdrawn a congested mucosa is revealed, and as the end passes the abscess orifice in the urethra, pus is seen to exude. The bent probe can then be introduced, and the sac explored.

Experience has shown that surgical treatment should be prompt, although one is prone to adopt general cleansing measures. Daily emptying of the sac and cleanliness may cure some cases, but such treatment at best is tedious, and requires time.

A complete fistula is not more annoying to the patient, and much easier to relieve, if the proper treatment is observed. If the urethra can be thoroughly dilated, and the pus opening enlarged so that drainage is thorough, spontaneous cure may follow, but when the condition is due to periurethral inflammation, this is not always possible. The sac is incised over the vaginal site, and a retention catheter introduced, or the bladder should be emptied at regular intervals with a soft rubber catheter. An elliptical portion of the sac may be incised, the entire sac dissected out, and the wound closed with sutures as in an ordinary case of fistula.

Simple incision is all that is usually necessary, thorough incision and cleanliness, and the employment of the catheter. Most cases will close in from eight to ten days.

A Question of Diagnosis.

BY W. R. JACKSON, M. D.,
Professor of Principles and Practice of Surgery and Genito-Urinary Diseases, in the Medical Department of the University of Alabama. Mobile, Ala.

I was very much impressed by this particular case as being one of unusual occurrence, and out of the regular order of things. It indicates a mistake in diagnosis which any surgeon is liable to make, and this procedure may be a lesson to someone meeting the same conditions in a patient.

Female, aged twenty-seven, gave a menstrual history as normal from the time of puberty up to the present time. Married seven months ago. Menstruation ceased three months ago, attended with all signs of pregnancy. Upon examination a large fluctuating tumor could be palpated through the vagina extending above the brim of the pelvis, of the size of a fetal head. No cervix uteri could be felt on digital examination, a large cavern marking, on the left side, the existence of what was supposed to be the vagina. So extensive and so cavernous, that ordinary digital examination failed to detect anything else on the left side; in the region of the appendix was a mass about the size of two fists, with a fluctuation, giving sensation of a pregn uterus.

The diagnosis was "pregnancy with ovarian cyst."

The patient was advised to accept op ation, with a view to removing ovarian cyst, and pregnancy to be lowed to go on to full term.

On making an exploratory incision very large tumor was found on the l side, extending above the brim of the p vis, of the color of a pregnant uterus, a another smaller one, connected with first, extending to the right, and filli the right iliac fossa, also presenting appearance of a pregnant uterus. B fluctuated on palpation, giving the sen tion as if containing a semi-solid flu or a sensation of pregnancy. Upon l ing the two bodies up, and an incisi made, we found a bi-cornuated uter one horn of which was very large, wh we considered to be a pregnancy, furth developed possibly than the other si but on exploratory incision of the larg mass, it proved to be menstrual blood colloid nature, and an accumulation ten or twelve years.

The diagnosis was then very plain that we had a bi-cornuated uterus to d with, one cornua of which was complete atresied, resulting in an accumulation menstrual blood for years. The oth cornua, giving the same sensation, changed our diagnosis, believing possib that was also an accumulation, but exploratory incision showed pregnan An atresiaed cornua on one side, and pregnant uterus on the other. We remov both portions of the uterus, severing t tubes at their attachments, and leavi the ovaries in, opening up the atresi portion of the uterus below, and letti out all the clotted blood, leaving t stumps of the uterus. In other wor performed thorough emasculation of t patient, leaving the ovaries.

The important question is, whether th woman will menstruate again, having b the stump of the uterus and the tub severed from it, the ovaries still maining. The case will be watched wi great interest. The patient made an u interrupted recovery. Since the oper tion she complains of no pain, for the fi time in twelve or fifteen years.

162 St. Michael Street.

[Written for the MEDICAL BRIEF.]

Tabes Dorsalis.

BY G. P. EDWARDS, M. D.,

Professor of Neurology, Dermatology and Electro-Therapy in the Medical Department of Vanderbilt University.
N shville, Tenn.

Tabes dorsalis is a parasyphilitic disease characterized by a degenerative process of the sensory elements of the nervous system, and manifesting symptoms varying with the locality and extent of involvement.

While it is possible that other conditions may produce similar changes in structure and function, the most universal and prolific cause of the disease is unquestionably syphilis. The tabetic symptoms may appear in one to thirty-five years after the primary infection; the most frequent period is ten to twelve years.

The milder cases predominate in tabetic sequelæ, probably because the treatment is more often neglected in this type of the disease.

The disease may appear in childhood from hereditary syphilis, but in the acquired form it occurs between twenty-five and fifty years of age, the greater proportion occurring about the age of forty.

The disease predominates in males ten to one.

A neuropathic heredity is an important predisposing factor. Occupation only in so far as it relates to opportunities for acquiring syphilis, may be considered as a predisposing cause; soldiers, actors, artists, and professional men are much more often found among its victims than country laborers, clergymen, etc.

The disease is essentially degenerative, and in the direction of the physiological impulse—afferent.

These changes are of the Wallerian type, beginning in the peripheral sensory nerve, and progressively extending to the spinal nerve roots and ganglia, tracts of Lissauer, columns of Burdach, Goll and Clark, direct cerebellar tracts, Gower's columns, and the visceral sympathetic fibers, in the relation named.

The cord lesions are usually symmetrical, but occasionally are not so. There may be circumscribed areas of meningeal inflammation overlying the sclerotic patches. All the cranial nerves are liable to degeneration, but the optic and auditory nerves are most frequently involved. The lesions found in the cerebrum are those of paretic dementia, a condition arising from the same specific cause.

The symptomatology of tabes embraces almost every function in the body, the clinical features of which could not be enumerated within the scope of this article, and I shall attempt to enumerate only some of the chief symptoms, and the more important clinical features. Among the first to attract the patient's attention are the motor symptoms; they are ataxia, involuntary movements, and palsies.

Loss of muscular sense, associated with peripheral dysæsthesias, produces the peculiar inability to recognize attitude or posture without the aid of the eye. It is also responsible for the inability to distinguish the difference in weight of bodies held in the hand. The loss of this posture sense renders the patient unable to retain his equilibrium when standing with the eyes closed. The symptom known as the Rhomberg sign is more readily detected in attempts to walk backwards with the eyes closed, or by reducing the base of support as in the attempt to stand upon one foot. The ataxic gait which characterizes the disease is due to this co-ordinate deficiency. The gait is characterized by lack of precision in all the movements, varying in degree with the stage of advancement of the disease. In marked cases, the patient rises from the sitting posture with a sudden jerky upstart, hesitates a moment to acquire his equilibrium, suddenly steps out, plunges forward, the legs being thrown out in an irregular, rigid, jerky manner, the foot lifted high and brought down with considerable force, on the heel or flat foot. The muscles of the body are under constant, irregular, jerky action in efforts to maintain the posture. The patient evinces a marked distrust of every movement, and is wholly dependent upon his sense of sight in their execution.

The upper extremities, and, indeed, any part of the muscular system may manifest inco-ordination of movement, but it is usually more pronounced in the lower extremities. Involuntary movements of

a choreic type are common at all stages of the disease.

The paralytic features of the disease are due to the involvement of the anterior gray horns, and a consequent muscular atrophy, or they may be due to changes in the cord or brain of an organic or vascular nature. They embrace facial, lingual and laryngeal palsies, hemiplegia, monoplegia, and paraplegia.

These palsies are more or less temporary, but may be permanent. The sensory disturbances vary greatly, and cover a wide range. They may be early, late, or both, and persist with more or less irregularity throughout the course of the disease.

Lightning pains are among the earliest manifestations, and are intermittent, fleeting, lancinating, boring, or twisting sensations occurring in any part of the body. When occurring in the visceral or other special organs they are known as crises. They are frequently atrocious in character, and may require the most energetic measures for their relief. Other sensory disturbances, such as the girdle sensation —a sense of constriction about the body— paraesthesias, and various disturbances of tactile pain and temperature sense are quite common and familiar to all. Disturbances of reflexes are early symptoms. The patellar reflex is diminished or lost in nearly all cases. The iris reflex to light is frequently abolished early.

There is a general loss of tonicity in the muscles. Temporary or permanent ptosis or squint, unilateral or bilateral, are common at any stage of the disease. The pupils are affected in the majority of cases, inequality, irregularity, mydriosis, myosis, sluggishness, loss of light reflex, loss of reflex to pain and absolute iridoplegia. Paretic dementia is the only disease which manifests such wide range of symptoms as tabes, and the disease is now believed to be a phase of tabes. The optic nerve degenerates in about ten per cent of tabetics. Early optic atrophy is generally followed by arrest and improvement of the ataxic symptoms.

The auditory nerve is subject to the same changes as the optic, and such changes are associated with impairment of hearing. There may be tinnitus and aural vertigo. More rarely the sense of taste and of smell are impaired or lost Paroxysmal attacks of pain and functional disturbance may involve any visceral organ, and are among the most frequently misinterpreted symptoms These visceral attacks are called "crises," and though of great variety are usually limited and uniform in a given case. Gastric crises consist of violent pain in the stomach, vomiting, and vertigo of variable duration and intensity. Intestinal crises consist of very painful colic attended with diarrhea.

Laryngeal crises are severe attacks of dyspnea, due to a spasm of the glottis and associated with paroxysmal cough Cardiac crises are attacks of angina pectoris. Renal crises resemble attacks of renal colic. Cystic, rectal, urethral, and testicular crises are characterized by acute pain in these organs, and, indeed no organ or member is exempt from these lancinating pains. Urinary disturbances as difficulty in starting the urine, incompleteness of the act, dribbling and incontinence, are early and persistent symptoms. There may be cystitis or glycosuria.

There may be early exaggeration of the sexual appetite leading to over-indulgence and followed by partial or complete loss of function. More or less anesthesia and analgesia of the external genitalia is usually present. Hyperesthesia or anesthesia of the soft palate, and increase or diminution of laryngeal and pharyngeal sensibility may be found separately or variously combined. Arterial sclerosis, cardiac abnormalities and vascular diseases are frequent.

The temperature is usually normal, but may be altered by intercurrent disorders.

All of the structures of the body are liable to disturbances of nutrition, and some are involved more or less in every case. A depraved condition of general nutrition is not infrequent, giving the victim a cachectic appearance. There may be spontaneous fracture and dystrophic arthropathies, which are generally marked by absence of pain. Trophic changes occur in the skin, such as herpes zoster, hypertrophies, loss of nails and teeth, hyperidrosis or anidrosis.

Perforating ulcer, a painless ulcer on e sole or palm, may occur, usually late. Muscular atrophies may complicate the ease, and are due to the involvement of trophic cells in the anterior horns. ere may be dementia and delusional in- ity.

The diagnosis of tabes during the xic stage is comparatively easy. Fre- ently other diseases are mistaken for es, and the early symptoms of tabes frequently overlooked or mistaken for er diseases. Crises are mistaken for ceral disorders, especially when occur- g during the preataxic stage.

Symptoms of this class should arouse examiner's suspicion, especially if a tory of syphilis can be obtained, or if tellar or pupillary reflexes are impaired lost. A condition frequently mistaken tabes is polyneuritis. In this disease have a rather close resemblance, but re are some distinctive features which ke the diagnosis comparatively easy to areful observer.

A patient of mine who was suffering m an attack of alcoholic neuritis was is mistaken for tabes by two prominent ysicians of this city. The patient died ut six weeks later from bulbar paraly- a frequent termination of this dis- e, especially when the cause is not hdrawn.

shall enumerate some of the differen- symptoms of these two diseases. dle symptom, loss of muscular sense, o-ordination, perforating ulcers, joint ons, osteopathies, Argyll-Robertson il, optic atrophy, visceral troubles, es, fecal incontinence, and paretic de- ntia, are symptoms of ataxia which are found in neuritis.

ensitive nerve trunks, amyotrophy, ma, lividity, epithelial changes foot- p, toxic amaurosis and rapid develop- nt of the disease are symptoms found polyneuritis, but absent in tabes. es is comparatively rare in females, ritis much more frequent in females n males. The gait in tabes is due to s of muscular sense, and it is with h knee action; in polyneuritis it is e to paresis, and the foot is not lifted dragged. The tabetic does not walk a straight line, the neuritic does. The ritic tends to rapid recovery when the cause is removed, the tabetic does not. No other disease presents a resemblance of sufficient importance to justify differentiation in this article. The prognosis of tabes depends upon the stage of development of the disease. Cells and tracts which have become sclerosed are, so far as is now known, beyond the range of restorative agencies. In the so-called benign cases the degenerative processes may be spontaneously arrested. Treatment instituted during the early stages does in many cases apparently retard and arrest the progress of the disease. Early optic atrophy may be considered a favorable indication of the arrest of degenerative changes. Symptoms of paretic dementia or bulbar extension are of unfavorable import.

In the treatment of tabes dorsalis there is some difference of opinion. To retard the development of the disease is, in a manner, a success. To arrest the disease and maintain the *statu quo* is viewed by many as eminently satisfactory. To completely arrest its degenerative invasion, to restore the partially impaired cells and their function, and maintain a symptomatic cure, may, indeed, be accepted as a medical victory.

Granting in occasional cases that there is a tendency to temporary arrest and improvement, and that this fact does and should disparage the verdict in favor of any method of treatment, yet it does not warrant the attitude of hopelessness taken by many who doom the victims of this disease without even a feeble effort to stay its ravages.

Dr. Church says, and there are many who concur in the belief, "In spite of the immense importance of syphilis in the causation of tabes dorsalis, it must be kept in mind that the nerve lesion is not comparable to the tertiary or secondary lesions, and is not amenable to antiluetic treatment." And this injunction is "kept in mind" by many who tell their patients that nothing can be done, to make themselves as comfortable as possible, observe the rules of temperate living, and await the inevitable.

A similar advice was given to a patient not long since, who was rapidly tending toward helplessness, and whose condition has improved fifty per cent during a few

months' treatment. In behalf of these unfortunates, I make a plea that we lay aside this stereotyped verdict, and make an earnest, intelligent effort in every case to rescue them, in part, at least, from the consequences which threaten them.

The treatment should be directed to the removal of any syphilitic processes present or suspected, to the improvement of the general health, to stimulate the functions of the cells impaired but not lost, to encourage restoration of co-ordination in the muscular system, and correct any incidental disorders which may retard or complicate the desired result.

Notwithstanding the views of many to the contrary, I believe that any stage or condition of tabes may be improved or benefited by properly directed treatment. I believe that the development of the degenerative changes can be arrested completely in nearly every pre-ataxic case, and that much of the lost function can be restored. I believe that these results may also be obtained in a large majority of the ataxic cases, and that this majority is reduced somewhat in proportion to the duration and intensity of the ataxia, and the abuse of the specific remedies employed.

My clinical observation aggregating fourteen cases in my private work has been so uniformly satisfactory as to warrant the deductions enumerated above.

In these fourteen cases, embracing a variety of conditions and degrees of advancement, all have responded to treatment in a most satisfactory manner. In every case the disease has been arrested and continued so to the present time. In nine cases, marked improvement in co-ordination, gait and general health, has persisted. In five cases the knee jerk has been restored to normal, all painful sensory symptoms have disappeared, dribbling of urine has ceased, and little evidence of the disease remains. In two cases the pupillary reflexes to light have returned to normal. In six cases the Rhomberg sign is barely noticeable with both feet close together and the eyes closed. In two cases the patients can stand upon one foot with the eyes closed.

I have demonstrated to my own satisfaction, at least, that the X-ray, when of sufficient penetration to obliterate t shadow of bony structures, will stimul cell activity in the diseased cord, fac tate the restoration of the lost functi in cells not completely destroyed, and lieve the crises and other lightning pai I am certain that the effluve of the h current, or by direct supersaturation pronounced in its effect on the metabo processes, and in facilitating the elimi tion of effete products of the disea That fourteen consecutive cases could perchance, be of the class which tends spontaneous arrest, is highly improbal and that any spontaneous arrest would followed by restoration of reflexes bladder tone is not probable.

May we not hope for advancement in therapy of this disease as well as tuber losis, cancer, and many other conditio as witnessed in the advanced therap tics of our day?

[Written for the MEDICAL BRIEF.]

The Passing of General Anesthe in Rectal Surgery.

BY A. B. COOKE, A. M., M. D.,

Professor of Rectal and Genito-Urinary Disea Medical Department University of Nash ville; Fellow and Secretary American Proctologic Society, etc.
Nashville, Tenn.

From the patient's standpoint, chlo form and ether are the bugbears of s gery. Refinements in methods of adm istration and modification of the age employed have done much to lessen t danger and discomforts of general an thesia, but little to diminish the popu dread with which it is universally garded.

Adequate means of local anesthesia to-day the most conspicuous need of s gery, a need recognized and admitted the entire profession. The announceme of every new method and measure is ceived with open enthusiasm. Cocai eucaine, and the numerous later che icals of that type, ethyl chloride, spi analgesia, and even hypnotic suggesti each met with eager welcome, only to followed by disappointment as its limi tions became apparent.

While surgery in general has felt and ill feels this need, rectal surgery has ffered especially, and from the writer's oint of view, peculiarly, by reason of it. his statement is justified by several conderations. In the first place, diseases of e rectum and anus are, perhaps, more idely prevalent than those of any other rgan, and certainly a larger proportion them are of a surgical nature. Again, hen we stop to consider the character of e ordinary operations performed upon is part, the conclusion is unavoidable at they properly belong to the domain minor surgery. Yet the road to relief hich the surgeon is accustomed to point t to these sufferers usually begins with eneral anesthesia, and ends some weeks ter on emerging from the hospital, a utine which only the exigencies of major rgery should justify. It is not strange at the quack should have flourished and ttened in a field which the regular prossion has cultivated so poorly.

The writer would not be understood as plying by the title of this article that ctal surgery and general anesthesia ve been entirely divorced, nor that such end is ever likely to be attained. On e contrary, certain operations, as colosmy, resection, excision, etc., ranking they do among the severest known surgery, will probably always require r their successful performance those nditions which only the profoundest stemic narcosis can furnish. Happily ch operations are comparatively rarely manded.

What is claimed, however, is that the eat majority of the surgical ailments of ese parts are amenable, under local angesia alone, to radical treatment in hich nothing of thoroughness is sacrited, and many positive advantages ined. Credit for the method which renrs this possible is due to Dr. Gant, of ew York, not, strictly speaking, for disvering new principles, but rather for cognizing the value of old ones, and by instaking work perfecting the technic r applying them in rectal surgery.

Briefly, the principle of the method is ressure analgesia and its mode of applition, distension of the area to be oprated with sterile water. When the ethod was first announced, and its technic described, the writer was one of the many who doubted its feasibility. It sounded too simple, and seemed too good to be true. But a few days' observation of the method in the hands of its originator quickly brought conviction, and the satisfaction of a long-felt want realized. Within the past eight months I have employed the method twenty-seven times in a series of cases including fistula, prolapsus ani, fissure, and external and internal hemorrhoids. After ten years' experience in rectal surgery with the old methods, the results have invariably provoked astonishment.

In internal hemorrhoids, perhaps, the method has seemed most wonderful. I esteem it one of the rarest privileges of my professional experience to have been able to perform the radical operation for this condition in sixteen cases with the patients lying perfectly passive, or laughing and chatting with bystanders as the work progressed.

The purpose of this brief article, however, is not to voice the enthusiasm awakened by the success of a rather limited experience, but simply to again direct attention to the method, and to bespeak for it the cordial reception it merits. Following are a few of the advantages which the writer from his personal experience feels warranted in claiming for the method:

1. It is simple, safe and effective.

2. It eliminates the dangers and discomforts of general anesthesia.

3. Pain at the time of operation is usually absent, and always so slight as to be easily borne.

4. Post-operative pain is less by far than after the old methods.

5. Confinement to bed is a matter of expedience rather than necessity.

6. Detention from business is reduced more than half.

7. Under this method the hospital becomes a convenience and luxury rather than a dreaded essential.

8. It appears a thoroughly reliable means of relief in many cases which would otherwise be unsuitable for operation.

9. It robs these operations of their terrors, and makes it possible to reclaim this

work from the hands of the "no-knife" advertisers.

Faith in a surgical method is best evidenced by the use one makes of it. The writer makes use of the method herein referred to with increasing frequency, and, in the light of past experience, confidently believes that his need for general anesthesia in rectal surgery will continue to diminish.

Chemical Synthesis as Applied to New Remedies.

BY CHARLES E. CASPARI, A. B., PH. D.,
Professor of Chemistry and Physics in the St. Louis College of Pharmacy.
St. Louis, Mo.

The science of chemistry has for a long time been intimately associated with medicine, though, perhaps, at no time more closely than at the present day.

Every year sees vast numbers of new synthetic remedies brought on the market, which are purely the product of the chemist, intended for use by the physician. Many of these have proven themselves valuable, and are daily used by physicians all over the world. Thousands of products have been prepared, but on account of disagreeable secondary effects on the human system, have not met with favor.

Instances might be cited of synthetic remedies which are manufactured at the present day in large quantities, the preparation of which has cost much time and labor, but, perhaps, the most astonishing conquest in the field of chemical synthesis has been the production of artificial indigo. The example of indigo serves to illustrate not only the amount of time, labor and money necessary to accomplish a definite synthesis, but also illustrates the plodding perseverance of modern chemists.

Indigo is taken as an example, because of its manufacture in such enormous quantities, because millions of dollars are invested in the enterprise, and because the results on mankind of the substitution of artificial indigo for the natural are most far-reaching. About thi years ago the first attempts were ma to prepare indigo synthetically, hithe the natural product alone having be used, but it has only been within the l five years that the chemists' efforts ha been crowned with success. The synt sis of indigo has cost the labor of fi trained chemists working at only one ject for thirty years. The results ha been such that to-day the artificial pr uct has practically driven the natural d from the market..

The annual production at present of digo is about fifty-five hundred tons, w a value of fifteen million dollars. T acreage of land large enough to cultiva sufficient indigo plant for the producti of fifty-five hundred tons of indigo wou be about two hundred and fifty thousa acres. When indigo was first synthesiz a cry was raised that the land which h formerly been used for the cultivation the indigo plant would have to lie id that the people who earned their livi by cultivating the plant would be depriv of the means of livelihood, and that dire catastrophe would be wreaked up the country where indigo was grow The contrary, however, has been found be true, as the indigo plant was m largely cultivated in India, which, as well known, is subject to frequent perio of famine. Now, the two hundred a fifty thousand acres of land which we suddenly rendered available can be us for the cultivation of foodstuffs, a thus go far towards alleviating the s ferings incident to the famines of Indi

It is evident that three distinct adva tages accrue from the synthesis of indi viz., the people of India have been plac in a position to better withstand the e gencies of that country. The cost of digo has been reduced, and the quality the dye has been improved.

What has been said of indigo is true a less extent of probably all synthe remedies, that all have a specific acti on the human organism, and hence c be used, bearing in mind that specific tion.

Not only are new synthetic remed being put on the market, but many remedies which were formerly obtain from vegetable life alone are now p

pared synthetically, and of these the most important class is the vegetable bases, among which are many of our leading narcotics and stimulants. The increased manufacture of these products has reduced their cost, and has made it easier for the habitues of narcotics to obtain their favorite one. Increased precaution is, therefore, necessary on the part of the physician and pharmacist to see that these compounds are dispensed legitimately.

Post-Nasal Adenoid Vegetations in the Negro.

BY GORDON KING, M. D.,

Professor of Diseases of the Ear, Nose and Throat, in the New Orleans Polyclinic; Surgeon in Charge of the Ear, Nose and Throat Department in the Eye, Ear, Nose and Throat Hospital of New Orleans; Lecturer and Clinical Instructor in Diseases of the Ear, Nose and Throat in the Medical Department of the Tulane University; Member of the American Laryngological Association, American Otological Association, etc. New Orleans, La.

It is a fact generally conceded that no race has been found to be exempt from post-nasal adenoid vegetation, an affection so common to childhood in every country and in every climate, and one that is responsible directly or indirectly for many pathological phenomena of early life.

In reviewing the writings of different authors on the subject, however, one is impressed with the fact that very little investigation has been made in regard to the influence of race upon the etiology of the affection or any difference in the pathology or symptomatology of the growth as observed in children of different races.

Practitioners in the Southern States and especially those who devote part of their time to the children's clinics, have ample opportunity to observe that the negro exhibits many peculiarities, such as the great prevalence of tuberculosis, syphilis, small-pox, pneumonia, etc., which are accepted facts, and which can be traced to disregard and ignorance of the laws of hygiene and sanitation, morality, and their irregular habits and occupations.

Other eccentricities pathologic of the negro race are to be explained only by certain physiological and anatomical characteristics familiar to the student of anthropology and anthropometry. Evidences of these different influences can be found in every branch of pathology, and especially in diseases of the organs of special sense, do we find a fruitful field for observation and investigation along these lines. In the limited scope of this article, I can not go into the subject in detail, but merely desire to record briefly a few facts deduced from a large number of cases of adenoid hypertrophy in both the white and negro races.

As to the frequence of adenoid growths in the negro, it is a general impression that the condition is less frequent than in the white races, and while statistics might tend to prove this to be true, there are several reasons why the correctness of this impression may be questioned. In the etiology of the affection it is universally conceded that the so-called lymphoid diathesis is usually the underlying cause of the enlargement of the gland, and in a vague sort of way this lymphoid tendency is allied to what we call a strumous or tuberculous diathesis.

Some authors go so far as to maintain that the adenoid hypertrophy is always a feature of the tuberculous diathesis, a contention which, though not generally admitted, is strongly supported by the fact that the affection is very frequent in children of undoubted tuberculous predisposition, and that the tubercle bacilli have often been found in the enlarged gland. If this is true, then the negro who is predisposed to tuberculosis should be a common victim.

Other predisposing causes, such as bad sanitary and hygienic environments, malnutrition and exposure, account for the prevalence of adenoids among the poorer classes. The negro belongs essentially to this class, and, in addition, their habitual carelessness in regard to proper nourishment and clothing of their children is well known.

In view of these accepted facts, one is justified in the belief that adenoids are more frequent in the negro than in the

white child, whether such statistics as are available tend to this view or not. In my opinion, the true reason for this is not that adenoids are less frequent in the negro than in the white child, but that the laity is becoming more familiar with the objective symptoms of adenoids in their children, and then only the more intelligent classes who recognize in the dull expression, the open mouth, and noisy respiration, restless sleep, and other unnatural phenomena, some pathological condition requiring relief at the hands of a surgeon.

The negro, in his ignorance and indifference, pays little attention to these evidences of disease, and it may be only discovered when the child comes under the physician's care for some other illness, or an independent affection of the ears or respiratory organs.

Still another fact that throws some light on the subject is that owing to the racial characteristics of wide, roomy nasal cavities, broad pharynx, and large post-nasal spaces, peculiar to the negro, the presence of hypertrophic adenoid tissue in the nasal pharynx gives rise to less obstruction than in the white child, and hence, mouth-breathing and the train of symptoms depending on that condition are not so markedly in evidence. This is a matter of daily observation in the clinics of the Eye, Ear, Nose and Throat Hospital of New Orleans, where, in the past twelve years, the records show that more than five thousand cases of adenoid vegetations have been treated, of which about nine hundred were in negroes. Thus, the phenomena so commonly observed in white children afflicted with adenoids, such as the characteristic adenoid facies, irregularity and crowding of the teeth, the peculiar arching of the palate, the prognathous jaws, are rarely seen in full-blood negro children. This, in my opinion, is due to the fact, stated above, that even though the adenoid growth is large in the negro child, it does not cause the same degree of interference with nasal respiration. Nasal obstruction from any cause is less frequent and less noticeable in the negro on account of the natural conformation of the nose and nasal cavities.

These facts are, I believe, sufficient offset the apparent absence of adenoids the negro, as shown by the statist which I have obtained in a brief sur of the hospital records, and which sh that of the total number of negroes of ages admitted for diseases of the eye, e nose and throat, 3.7 have adenoids, a of the white, 6.7 per cent.

Laboratory Diagnosis of Typhoi Fever.

BY CHARLES E. SIMON, B. A., M. D.,

Professor of Clinical Diagnosis in the Maryl Medical College; Author of "Clinical D nosis"; Member of Medical and Chirurg Faculty of Maryland, etc. Baltimore,

In the diagnosis of typhoid fever l oratory methods have now become pr tically a *sine qua non*. Especially int esting and important are the chang both morphologically and biological which can be made out in the blood. Qu characteristic is the comparatively l leucocyte count, which can generally recognized after the first few days of disease. This low leucocyte count may regarded as one of the most import points in the differential diagnosis of disease. Equally characteristic, perha are the deviations in the various perce ages of the leucocytes. While during first days an increase of the blood poly clear, neutrophilic elements undoubte occurs, a distinct drop subsequently ta place, which is offset by a correspond increase in the number of the small mo nuclear leucocytes. This increase comes steadily more marked, and c tinues well into convalescence. The eos ophilic leucocytes at first disappear, a remain absent until the beginning of c ervescence, when they reappear, a again reach normal numbers with the ginning of convalescence. This alte distribution of the various forms of l cocytes is undoubtedly one of the m characteristic features of the disease, a unfortunately only too little recogni by the general practitioner. The exa inations which are necessary to de mine the points in question are compa

ively simple, and require no elaborate apparatus.

Quite well recognized at the present ime is the value of the Widal reaction in yphoid fever, but unfortunately this ethod of diagnosis has not been avail-ble for the general practitioner, except n our largest cities where municipal bac-eriological laboratories exist. As is well nown, the Widal test depends upon the act that as a result of the typhoid infec-ion, bodies develop in the blood of the yphoid patient, which are capable of ausing an agglutination and arrest of otility of typhoid bacilli, even in com-aratively high grades of dilution.

The necessary outfit for the purpose of aking this test has heretofore consisted n a virulent typhoid culture, not more han twenty-four hours old, a microscope, nd an incubator. Such an outfit, of ourse, is not to be found in the office of very physician, and even where a micro-cope would be available, a virulent cul-ure of the typhoid organism would prob-bly rarely be at hand.

Recognizing the fact that the reaction n question is in a sense specific of the isease, it has been rather unfortunate hat physicians, in country districts es-ecially, have not been able to avail them-elves of this one aid in the diagnosis of he disease, which possibly exceeds in alue all the others.

In view of this fact, the recent discov-ry that the agglutination test can also e carried out with dead cultures of the yphoid organism is especially important. his fact has been utilized by Ficker, and t the present time there is on the mar-et a comparatively simple and inexpen-ive outfit, which will enable the general ractitioner both in the country and in he city to carry out this test in his own ffice, or even at the bedside.

A small amount of blood is procured y puncture of the finger, received in a terile cup, and the blood serum then iluted with normal salt solution in the roportion of one to ten. From this dilu-ion little tubes are prepared in which urther dilutions are made with a suspen-ion of dead typhoid bacilli in the propor-ion of one to fifty, or one to one-hundred, tc.

The liquid in these tubes, owing to the presence of the suspended bacilli, appears cloudy at first, but, on standing, the organisms are agglutinated; if the blood under examination has come from a typhoid patient, the little columns which are formed sink to the bottom, and the supernatant fluid becomes clear.

It will be observed that the reaction in this case is a macroscopical reaction, that no microscope is necessary, and no costly bacteriological apparatus, no virulent culture to injure the physician or his household.

With the introduction of this method into general practice, and especially into the country, it may be anticipated that the diagnosis of typhoid fever will be rendered less difficult in the early stages of the disease, and that from a prophylactic standpoint especially, much good will as a consequence result.

[Written for the MEDICAL BRIEF.]

The Importance of the Family Physician in Retro-Displacements of the Uterus.

BY W. P. MCADORY, A. B., M. D.,
Professor of Physiology in the Birmingham Medical College.
Birmingham, Ala.

The most important treatment for the retro-displacement of the uterus, like the treatment of any other condition, is preventive. The family physician should be careful in instructing the mothers as to proper methods of living on the part of their growing girls, in order that the genital organs may develop properly. They should especially insist upon the habit of relieving the bladder and bowels promptly and regularly every day. They should be thoroughly impressed with this necessity, since a full bladder pressing upward upon the fundus of the uterus, and a full rectum having a tendency to elevate the cervix at the time of the development of the uterus often causing a beginning retro-displacement, and possibly some so-called congenital displacements and malformations.

The family physician, who is, as a rule, the sanitary officer for the school, homes,

etc., should see that the water closets are inviting and conveniently arranged at both places, so that there will be no hesitancy on the part of young girls to make use of them. If every physician will stop and think a moment, he will see the great responsibility that rests upon him in this respect, and how crudely he carried it out in the past.

It is recognized that accidents and mismanagement during childbirth, and immediately afterward, causes the vast majority of cases of retro-displacement in women who have borne children. As it is the general practitioner who has the care of women at this important time, he should carefully inform himself as to the best means of preventing these accidents, and treating them at the proper time when they occur, in order to prevent retro-displacement of the uterus. The most frequent accident incident to childbirth, and one that gives rise to most suffering, is an infection. There has been a great deal written, and more said, upon the necessity for surgical cleanliness in this operation, but I consider it the duty of everyone who writes upon this subject to insist upon surgical cleanliness, not only of the doctor, but of the woman as well, and all examinations during childbirth. Next to being surgically clean is the immediate repair of lacerated perinei and cervix. All of these three complications retard involution, consequently, if the woman is allowed to be up before the uterus is decreased in size and weight sufficient for the normal supports to hold it firmly, it falls backward.

The old custom of delivering a woman under a sheet, which is rapidly going out, and of depending upon digital examination to determine the presence of lacerations, has been, in my opinion, responsible for allowing tears to go unrecognized, consequently unrepaired. It is the duty of the physician who delivers a woman to make a careful examination after the placenta has been delivered, not only with his fingers, but with his eyes, and if there have been such tears, to repair them at once. The popular idea, for which the practitioner is largely responsible, that when a woman is torn in childbirth it is the doctor's fault, which we all recognize as erroneous, is also responsible many times for the attending physician re ing to admit that there has been a t because if he does, and insists upon immediate repair, the family will sider that he is to blame. Here the mo stamina of the physician will come i play until the people are educated as the true cause of these conditions.

A great deal has been written lately to the proper care of the woman dur the puerperium, and of making a th ough examination before allowing her get up. This is so important that much can not be said until it becor the general practice of every practitio of medicine who delivers a woman, carry out these teachings in their pr tice. Before a woman is allowed to up, she should be carefully examined to the condition of the perineum and vix, and the uterus should be exami to see whether it has undergone invo tion properly, and she should not be lowed to get up until this has been acc plished.

This condition is best brought about having the woman lie on her side in Sims position as much as possible, and her back as little as possible, and assu the knee chest position three or four tir a day, staying in that position ten or teen minutes. Hot douches twice a d properly given, that is water as hot as can be borne, allowing it to run slo through the vagina, so that at least o half an hour is consumed in using th quarts of water, the patient lying on back, with the hips raised. I frequen tampon the vagina of the woman in k chest position, using cotton tamp moistened with glycerine, or whate medication I think is necessary. And the woman has suffered from retro-d placements prior to this time, I frequen keep the tampons in until after she is lowed up, for at least a month after livery, supporting the uterus, and all ing the normal supports to unde proper involution. This will relieve cure quite a considerable number of th cases which have had retro-displaceme to begin with.

The acute retro-displacements in wom who have not borne children usually cur as a result of some accident or str producing severe symptoms such as p

n the back, lower part of the abdomen, nd in the limbs, which is usually so se- ere that it confines the woman to bed for veral days.

Gall Stones.

BY C. M. NICHOLSON, M. D.,
St. Louis, Mo.

The gall bladder is, normally, pear- haped, measuring three to four inches in ength, and one to one and one-half nches in width, having average capacity f twelve drachms. Its fundus is directed ownward and forward to the right, and ouches the anterior abdominal wall at point where the costal arch meets the uter border of the rectus abdominis. The xtent of peritoneal investment varies nuch in different individuals. In five per ent a distinct mesentery exists, so that he gall bladder may be moved freely in he abdomen. The walls of the gall blad- er narrow into the cystic duct, and a ear-shaped curve is formed, just beyond he first turn of which a stone may be mpacted.

There are a series of valvular projec- ions known as valves of Huster, ar- anged along the entire length of the ystic duct. They are crescentic shaped n foldings of the mucous membrane, laced alternately upon one or upon the ther side of the duct; the upper three or our are well marked. The cystic duct is ne and one-half inches in length, and oins the hepatic duct to form the com- mon bile duct, about three inches in ength, terminating in common with the uct of Wirsung.

From the days of Galen up to a com- aratively recent date, the belief was uni- ersal that gall stones were the result of gglutination of bile, induced by increase f heat in the liver. It is now known hat the chief constituents of gall stones, holestrin and bilirubin calcium, are roduced by special inflammatory changes n the mucous membrane of the gall blad- er, which results in desquamation of pithelium, and increased production of mucus. The bacillus coli and bacillus hosus are specific organisms con- cerned in the formation of cholestrin cal- culi. Stones may be either pure chole- strin, laminating cholestrin, ordinary gall bladder stone (in which no crystalline structure is visible), the mucous bilirubin, or pure bilirubin. They may be single, or their number may reach two thousand.

The characteristics of the enlargement of the gall bladder are, first, tracing the margin of the liver to a gradually dimi- nishing edge attached to the upper sur- face of a gall bladder mass; second, al- ways continuous with surface of liver; third, sharp projections over this margin. A stone may be present for an indefinite period without producing any symptoms. *Post-mortem* records show that in from six to twelve per cent of cases stones are found in the gall bladder; probably in a very small per cent have any symptoms been recognized.

A stone passing through the duct pro- duces the classic symptom colic; the pain in right hypochondrium referred to epi- gastrium, and there may be nausea, vom- iting, jaundice and epigastric tenderness with or without fever, and as long as the stone continues to advance in the duct, colic continues; when it becomes station- ary, there is marked cessation of pain.

The diagnosis of cholelithiasis mani- fested by the classic and well-recognized symptoms, colic, nausea, vomiting, local sensitiveness, and icterus, all of which appear in the order mentioned, has for the past hundred years been made without difficulty. The pain is never due to distention or inflammation of the gall bladder, though Kehr and Erich support the theory that the last named condition is responsible. This occurs when a for- eign body is being transmitted through the gall duct, the lumen of which is smaller than the diameter of the foreign body, and results from contraction of the muscular wall. When the stone enters the duct, either it passes into the duode- num, returns to the gall bladder, or be- comes lodged.

It is in those cases where the diameter of the stone is greater than that of the duct that the symptom colic exists. Ob- structive flexions of the duct never give rise to the colic. The symptom is, there- fore, absent in every type of biliary ob-

struction except those of foreign bodies, calculi, echinococcus, ascarides, clumps of mucus or polypi. Nausea and vomiting are reflex symptoms, and occur just as nausea and vomiting in obstructed appendix or ureter. Local sensitiveness is elicited by deep palpation below the ninth costal cartilage on the right side. Jaundice is present in about twenty per cent of cases, in the large majority of which enlargement of the gall bladder exists. In eighty per cent of cases of obstruction of the common duct, due to stones, there is contraction of the gall bladder, while in ninety per cent of cases of enlargements of the gall bladder the obstruction is due to other causes than stones.

[Written for the MEDICAL BRIEF.]

The Continuous Bath.

BY FRIEDRICH GROSSE, M. D.,

New York City.

The term "continuous full bath" is applied to that class of bathing where the patient remains immersed in water up to his neck for many hours, sometimes days and weeks, in extreme cases even years, being taken out merely to attend to his physical necessities. Usually the bather is laid on rubber cushions or on a sheet suspended around the brim of the tub, and hence the term, "hammock bath," which corresponds to the German "Wasserbett." It is superfluous to use the word "warm" in this connection, because of necessity the bath must be so to permit a warm-blooded being to remain in it for such prolonged periods and we shall, therefore, briefly call it the "continuous bath."

According to its temperature it belongs to the neutral or indifferent baths, *i. e.* those that do not materially change the temperature of the body during the customary bathing period of from fifteen to thirty minutes. The temperature of the neutral bath, according to Wick, lies between 34.8° and 38.4° C. (94.6° and 101° F.), while others, like Kisch, (1) call it in round numbers 35-37° C. (95-98.6° F.). When the duration of the bath exceeds half an hour, it is called a prolonged, or a protracted bath. To draw a sharp distinction between th and the "continuous bath" is hardly po sible, and would serve no object, since is obvious that the physiological effec must necessarily be different at long duration.

So far as we have reliable sources information, Hebra seems to have be the first who had the courage to entru a human being for so long to the w element. Riess (15) during the 70's ma extended experiments with this, and sin then it has been applied in many place and for manifold diseases. Though t results have been mostly good and oft brilliant, and, indeed, often bordered the miraculous—for the treatment w resorted to only in such cases, perha where other methods were nearly, if n quite, hopeless—yet, on the whole, markably little is known of the "contin ous bath."

The technique of the procedure is si ple and sufficiently manifest from t above statements and the following e cidations. Moreover, this is unexceptio ably covered in the literature on hyd therapy, and we must refer to this in gard to the numerous details.

With the *physiology* of the continuo baths, it is, however, quite different. Ev the most thorough text-books on hyd therapy uniformly confine themselves a repetition of the earliest views, and f quently do not at all mention the cont uous bath as distinguished from the p longed bath. The fruits of the last twen years' research are almost wholly nored. For instance, according to Baru (2), and Kellogg (2), who at least scribe this form of bath under a separ chapter, its effects are exclusively "n ative," acting merely as a sedative up the nervous system, by means of the clusion of external irritants. Further, a result of Heymann's and Krebs' wor during the 70's, it is often assumed th the nervous irritation is reduced by i bibition of the end-organs in the sk Kellogg conjectures "that other bod functions" may be "affected, if not p foundly, at least to a noticeable and portant extent," but what he suggests partly obscure and partly no longer te ble at this time. Much more circumst tial and based on later results are t

elucidations of Kisch, but even these are neither unexceptionable, nor complete.

This confusion, however, with regard to the continuous bath is excusable. Views concerning the indifferent bath, in the usual sense of the word, have simply been applied to the continuous bath, since in most works it is not apparent where the former ends and the latter begins. The references in medical literature, nevertheless, that clearly deal with baths of at least six to eight hours' duration, have up to date become numerous enough that the attempt may be worth while to gather together whatever may belong in a common category. A very superficial examination of the exceedingly interesting histories of diseases so treated, soon shows that the old physiology must be entirely inadequate. It may be well, therefore, to first group the reported cases according to uniform points of view. A comparison of these with experimental work will then perhaps throw some light into the "how" of the physiological process.

The *first* group embraces diseases of the skin. It was these that Hebra, since about 1862, first treated with the continuous bath. Actuated by the favorable effects of warm and indifferent partial baths, he prescribed full baths in cases where it was not only a question of diseased extremities, but of a large portion of the body's surface. He left his patients in the water longer and longer until they soon remained immersed twenty-four hours. Only hesitatingly, but encouraged by good results, he prolonged the baths from two to six days, then still further, one to nine months, and, finally, kept them in the hammock bath just as long as the case appeared to require it. No injurious results were ever observed, except that after four to five days the thick epidermis of the soles of the feet would swell up uncomfortably, and these swellings would soon detach themselves with some pain, though this was alleviated by simply pressing the soles against a rubber cushion. An itching, papulous eczema also often appeared after eight to fourteen days, which soon vanished on inunction with ol. rusci.

In 1877, Hebra, Jr., (12) made an exhaustive report on two hundred and three histories gleaned out of five hundred cases, authentic data as to the balance being lacking. Among these were one hundred and twenty-seven burns of the most serious kind, of which seventy-one cases died and fifty-six recovered.

The decomposition of the blood, caused by the burn, with its consequences, was, of course, in no way influenced by the bath, but all other symptoms were, and in a most surprisingly favorable manner. Pain disappeared so quickly that one man, for instance, refused to believe that his back was as badly burned as the front of his body, which was visible to him. Infections of the wound, such as lymphangitis, erysipelas, and pyemia, were avoided, cauterization but rarely required, suppuration was sparse, new skin was readily formed, and the scars were better than under other treatment. Among fifteen cases of pemphigus, vulgaris was represented nine times, and foliaceous pemphigus six times. The former were cured, the latter died, of course, but life was prolonged, and suffering materially alleviated. In a case of confluent small-pox, complicated by pneumonia, the five to seventeen-day bath was applied; there was moderate fever, the fever of suppuration was barely noticeable, and the scars good beyond expectation. Gangrenous bubos were represented twenty-eight times, of which twenty-five were healed. Of these he says: "Where the necrosis of the web is no larger than the palm of the hand, an increase in strength is observable, even after forty-eight hours, the fever disappears, sleep and appetite set in, and with them the conditions of possible cure." Three phagedenic chancres arrived at a cure. Further, there are mentioned, large, obstinate syphilitic ulcers, phlegmon, gangrene of the skin. All these cases that were put into the water hammock were serious ones, and had defied other treatment. Similarly favorable results are constantly reiterated, and besides these, there are mentioned sores caused by contusions, inveterate psoriasis and eczema. Riess also treated bed sores in cases of diseases of the spinal cord with the continuous bath, and made the unexpected discovery that the original disease underwent remarkable improvement.

We now come to the *second* group, including diseases of the entire nervous system; in the first place chronic affections of the parenchyma, as well as the various forms of meningitis, where cerebral and spinal diseases are concerned. In all these affections local, as well as excentric pain, was alleviated, spasms and contractions relieved, and various forms of paralysis and ataxis were improved. Although I do not find any instances of tabetic crises mentioned, I believe, considering all things, that these would lose their horrors in the continuous bath. Moreover, there come under this head the various states of delirium and nervous agitation. The water hammock is, perhaps, the ideal hypnotic. Extravasations in cases of apoplexy, of various forms of meningitis, as well as cerebral tumors, have been treated by the bath with results that could hardly be attained by other means. In such cases it is the absorption of the infiltrations, and most certainly the absorption of the fluid exudations that turn the course more favorably, although the removal of cutaneous irritation, and the consequent ideal quiescence of the central organ may have some influence. It should be mentioned in this group that, according to Rose, better results are also obtained in cases of epidemic meningitis than have thus far been known under other forms of treatment. Furthermore, there are to be considered as adapted for the continuous bath anatomical injuries to the nerves, *e. g.*, seritus, obstinate sciatica and, finally, functional neuroses. Among the last named hysteria and hyperesthesia have been thus treated. Brochu (3) reports a case of acute chorea, "one of those serious cases that usually terminate fatally." As especially interesting I would conclude with Legendre, who recommended prolonged baths in cases of hyperchlorhydria.

The *third* group is composed of mental diseases. Bleuer (4) recommends the bath for acute psychoses, including melancholia; and along the same lines it is praised by Kræpelin, Alzheimer and Sander. We have circumstantial reports made by Alter (17), Wuerth (16), and from the clinic at Heidelberg by Beyer (5). According to the latter, cases complicated by bed sores, phlegmon and injuries, as well as patients who are uncleanly a maniacal, who tear off their clothing, et and, finally, epileptics and alcoholics a treated with the bath. Maniacal exci ment responds to it with almost absolu certainty. It is especially indicated d ing menstruation. It is of general int est in these reports that a permanent crease in the number of attendants w never necessary, that, on the contra this form of treatment made nursi easier for them. Despite the great nu ber of maniacal patients treated the di culties of handling them were no great and the patients submitted to the ba much more readily than was expect Besides, expenses for destroyed and soil linen, gloves, etc., were considerably le and all these reports establish the c tinuous bath as one of the best psych tric sedatives. "It dispenses with t greater portion of cells and isolati rooms;" they "regard it as a material richment of psychiatry." Lately syste atic attempts have also been made in t Manhattan State Insane Hospital, and t results fully confirm the above.

In the *fourth* group of diseases, which the bath is indicated, I place inc ient inflammations and exudations of kinds. Absorption of these in the ba has already been touched on in a numb of previously mentioned diseases. Un this head are to be classed the wonder results obtained in cases of rheuma and gouty deposits, concerning which must point, in addition to the fine s cesses of Hueter and Rose, to the expe ences of several decades at Bath Le Switzerland. Our literature further te of cases of pericarditis, pelvic exudatio sprains, contusions and fractures. Es cially remarkable is the unanimous pra where absorption of dropsies, due to rious causes, is concerned; dropsical domens, for instance, registered a dimi tion of six c. m. after one bath, and in c tain cases the loss in weight was up 1,500 grammes after an eight hours' ba

Finally, we add, as the *fifth* gro acute infectious diseases. But we m here anticipate that this group does in every respect fit into the baths un discussion, which should be strictly in ferent, while the baths under this h head are usually given considera

cooler: that is, even down to 31° C (88° F.), so that they should rather be classed with the baths that withdraw heat. Here again we owe the best observations to Riess, who has at his disposal the material from over one thousand cases of typhus. With respect of details we may refer to the works of this investigator, as well as to the lucid treatment of the question in Baruch's text-book. Nevertheless, room must be given to the conclusions arrived at in these works. According to these the continuous bath is—

1. More comfortable for the patient.
2. Applicable also in such cases that are not adapted for the Brand bath.
3. It influences fever, nervous phenomena, diuresis, etc., quickly and effectively.
4. It shortens the duration of the disease to a marked extent; and,
5. Causes little difficulty with regard to nursing.

Aside from typhus, the continuous bath has been tried and praised in connection with serious attacks of measles, scarlet fever and erysipelas (A. Rose). The observations of this author in cases of epidemic cerebro-spinal meningitis have already been mentioned in the second group. Finally, Perdijo has lately reported exceedingly favorable results with tetanus (6).

According to these citations the application of the hammock bath is, therefore, exceedingly manifold. It assumes a still more important aspect when we remember that, aside from the systematic experiments of Riess, and the reports from the insane asylums, only the most difficult cases of their kind, for which other methods were out of the question, and which until then had been persistent, were treated in this manner.

As already stated, a mere superficial study shows that the physiology of the continuous bath thus far laid down can not be complete. What effect could the avoidance of surface irritation produce in cases of dropsy, infections and the cure of wounds? Undoubtedly, therefore, much more potent influences must be present. Indeed, Kussowsky (7) has already called attention to the fact that even the indifferent bath of 34-35° C., and fifteen to twenty minutes' duration, appreciably reduces the surface, as well as the internal temperature of the human body, though not very considerably; and Stifler (10) established the proof that during indifferent sweet-water baths typical changes took place in the pressure of the blood and the amplitude and frequency of the circulation and respiration.

According to Landois (Physiology) the temperature of the human skin is 31-34° (35°) C. (88-93° (95°) F.); according to Oehler, 33.5-35° C. (92.3-95° F.). Riess puts the thermal point of neutrality of the bath—that is, the point at which there is neither withdrawal nor introduction of heat—between 34° and 35° C. (93-95° F.), while Wick allows a greater latitude, 34.8-36.4° C. (94.6-97.5° F.), and Liebermeister even calls baths 35-37° C. (95-98.6° F.) neutral. Generally the feeling of the patient is consulted, but as a rule 35° C. (95° F.) might be assumed as the medium temperature. According to the last-named investigator, the loss of heat during a fifteen to twenty-five-minute bath at 34-35° C. (93-95° F.) is the same as that in the air when dressed.

This temperature, therefore, may not, or may not materially, influence the temperature of the body during the duration of the usual indifferent bath, but we may nevertheless be permitted to assume, despite the lack of direct experiments, that at longer duration there occurs an increase in the loss. Kisch rightly points to Schueller's experiments with rabbits, where by immersion into an indifferent bath there occurred at the first moment a dilatation of the vessels of the pia mater, which, however, was quickly followed by a contraction, and a simultaneous sinking in of the brain. Judging by this experiment, therefore, the surface had become richer in blood, which is plausible enough when we simply consider that the bath in any event is still 2° C. warmer than the skin, and that the blood must, therefore, flow toward the latter. Now, since the blood is certainly warmer than the bath, it follows that with an increased quantity of blood at the surface must come an increased loss in temperature of the body. However little or negligible this may be in the neutral bath, during the continuous bath the sum total of the loss of bodily heat must be great. And

this fits in with the observation of all that fevers are reduced, even when the bath is not of the low temperatures mentioned by Riess. With the baths of this author the reduction in temperature has, of course, never been questioned, and the bath of Riess must be understood as a special form of heat-withdrawing water application, which can hardly any longer be called indifferent. Inasmuch as the withdrawal goes forward very slowly and with avoidance of any irritation to the skin, so that no reactive warming can take place, we must assume that the loss of heat is much greater than with other heat-withdrawing methods. It might be recommended, therefore, to distinguish this 31° C. (88° F.) bath, lasting up to twelve hours, from the continuous bath, and perhaps to call it, to correspond with the Ziemmssen bath and Brand bath, the Riess bath, or the protracted lukewarm bath, and to discuss it separately, along with other heat-withdrawing applications.

Increased loss of heat, it must be borne in mind, is equivalent to increased metabolism, and this is true not only of the non-nitrogenous substances, but, by effective lowering of the body's temperature, also of the albuminates. This, according to Lépine, Flavard and Formanek, is true not only of the albumen in the food, but of that of the body itself. In harmony with this Riess has found the excretions of nitrogen increased.

It was formerly believed that the activity of the skin ceased while bathing, and even that the skin absorbed water in the bath; views that can not be supported today. The warmer and the richer in blood the skin is, the more active it is. Ordinarily, the body's loss of moisture attains its maximum at 32° C., being about fifteen hundred grammes in twenty-four hours; beyond that perspiration sets in. That this is true of the bath also, Riess has certainly shown beyond question. For he observed, in the first place, considerable loss in weight and unquestionable decrease of existing hydropsy, even when the amount of urine diminished; and, in the second place, Riess and Willemin established the fact that there was an increase of chlorides in the water of the bath exceeding the proportional per cent of perspiration. In consonance with th are also Keller's results in regard to di inution of chlorine and phosphorus co binations in the urine. "The more rap removal of the fluid in the perspirato glands by means of the maceration a softening of the uppermost skin laye and the rejection of the older layers the epidermis, lead, according to the la of diffusion, to an augmented transud tion from the inner parts towards t surface."—Kisch. Finally, the loss CO_2 from the skin must be greater, cause the skin is warmer in the bath a deprived of its impeding horny coveri

The chemical composition of the blo must also undergo a transformation the continuous bath. The works of Poe Senator, Kuthie and Strasser (8) ma it highly probable that augmented exc tion of CO_2 renders the blood more all line through the change of neutral a acid phosphates into bases. Since blo alkalinity runs parallel with microbici properties, we may conjecture an inf ence upon infections also in this rega

According to these citations, moreov it seems that the earlier assumptions Heymann and Krebs that the irritabil of the nerves is reduced by saturation water of the nerve termini in the sk must fall to the ground, because not or does no absorption of water by the sk take place, nor any retention of it, but investigations, as we have seen, point an augmented excretion. Neverthele even without this imbibition, the qui cence of the nervous central organism maintained on account of the absence cutaneous irritants.

It is only on the basis of these cons erations that observations made at t bedside, which one and all point to mighty augmentation in metabolism, c be explained; only thus are we able comprehend the removal of deposits gout, chronic rheumatism, apoplexies, s ous exudations, meningitis, etc.

The above-mentioned experiment Schueller furnishes also an explanati of the favorable influence of the contin ous bath upon fever symptoms, if adopt the view that not the temperatu alone and the change in breathing a blood pressure are the causes of the tr ble, but the variation in the circulati

nd blood distribution, in harmony with hich Breitenstein demonstrated an ac-umulation of red corpuscles in the liver fter over-heating.

Equally undeniable is the regulating in-luence of the bath upon the circulation, n the sense of a flow toward the skin. Thus, in the first place, possible internal ongestions and inflammations, where not oo far advanced, are more quickly sup-lied with blood and thus improved; and, n the second place, an augmented trans-dation takes place in skin diseases which urnishes fresh material for the building f new tissue. An increased activity oward rebuilding is also favored by the oist heat of the bath, especially as in-urious products of wounds are immedi-tely and thoroughly washed off. Two xperimental works further confirm that he conditions for the cure of skin dis-ases are, as a matter of fact, the best. 'enzo (11) found in Bizzozero's labora-ory, as an indication of accelerated rowth in moist heat, an accumulation of itroses enormous as compared with *that* ar of the rabbit that had not been thus reated. Schaeffer (13) arrived at simi-ar conclusions by other experiments. He rew threads soaked in carbolic acid, sub-imate of mercury, or bacteria cultures, hrough the skin and found that upon pplication of moist heat no accumulation f white blood corpuscles resulted, and nly a considerable dilatation of the blood nd lymph vessels took place, accompa-ied by augmented saturation of the tis-ue, while by the application of cold (ice ags) these phenomena were not pro-uced. Both investigations find clinical onfirmation in the publications of Lang-nbeck, 1855 (14), Stromeyer, Esmarch, chede, Rose, Reclus, Hamilton, Fraser, lodges, etc., concerning the accelerated ure of affections of the extremities by neans of warm, prolonged local baths, hich, in their turn, explain the successes f the full bath.

In conclusion, we might thus sum up he effects of the continuous bath: That :—

1. Acts quiescent upon the central ervous system.
2. Changes the circulation, in the ense of disencumbering the inner organs nd diverting the blood toward the skin.
3. Favors the nutrition of and the heal-ing processes in the skin.
4. Augments heat withdrawal greatly.
5. Accelerates metabolism.

Vast clinical experience and experi-mental investigations justify the asser-tion that the continuous bath constitutes an exceedingly effective remedy, which, though apparently troublesome to admin-ister in some respects, justifies expecta-tion of good success, where other, less la-borious methods, fail. The inevitable in-ference from all this is that it would be desirable were the continuous bath to find wider consideration.

Is Prostatectomy the Cause of the Enuresis that Sometimes Follows This Operation?

BY M. R. BARKER, M. S., M. D.,
Chicago, Ill.

In discussing this subject, we should, perhaps, review briefly the anatomy of the urinary bladder, especially its musculature and nerve supply, and the prostate body, in their normal conditions, and in their relations to each other.

The prostate gland is located at the neck of the bladder. Its base is in contact with the bladder wall. Its apex is directed from the bladder, forward to the posterior layer of the triangular ligament. The prostatic urethra passes through the gland, somewhat nearer the upper than the lower surface. The bladder wall consists, partially, of one muscular coat, which is divided into three layers. The fibers of the external layer originate from the posterior surface of the os pubis, and from the capsul of the prostate in front of the gland. From this narrow origin they diverge, passing longitudinally over the anterior surface of the bladder to the fundus, over the fundus, and back over the posterior surface of the bladder converging as they return, to be inserted into the capsul of the prostate posteriorly.

This layer of the muscular coat is known as the detrusor urinæ muscle. The middle layer of this muscular coat consists, mainly, of an aggregation of muscu-

lar fibers surrounding the neck of the bladder, and is known as the sphincter vesicæ. It is in contact with the base of the prostate. It is somewhat misleading to use the term neck in connection with the bladder. The bladder really has no neck, or projection from it, such as we usually term a neck. The urethral outlet, and the structures about it, are called the neck of the bladder, but there is no projection from the bladder wall.

To illustrate: If we were to make a small opening in the side of a football, and into this opening place a rubber tube, and then make a coil three or four inches in diameter, in each turn of which the strand is a little smaller than the preceding one, from the center out, leaving a hole in the center of the coil; and, if we should slip this coil over the rubber tube and back against the side of the football, and fasten it there; then if we shou'd mold a piece of putty into the shape and size of the prostate, and make a hole through it and slip this over the rubber tube, and back against the coil, we would illustrate, in a homely way, the urethra, sphincter vesicæ and prostate body, their relations to each other, and the neck of the bladder.

We must remember that the base of the prostate is in contact with the sphincter vesicæ, and that it measures, normally, a little more than an inch transversely. The internal layer of this muscular coat is of little importance. Its fibers are arranged like those of the external layer.

The musculature of the bladder is controlled by nerve fibers, from the vesicle plexus of the sympathetic system, and by branches from the third and fourth sacral nerves. The branches of the sympathetic system which supply the sphincter vesicæ, and the detrusor urinæ at the neck of the bladder, pass with the middle and inferior vesicle arteries, along on each side of the vesicle trigone, and close to the posterior border of the normal prostate, to the muscles they supply. The function of the urinary bladder is to receive and eject the urine. It performs this function normally, as follows:

The urine flows into the bladder (the bladder being in a perfectly passive state), until such a quantity has entered as to cause a stimulus to the nerve ters. This quantity varies with diffe individuals. The detrusor urinæ mu then contracts, forcing the urine in bladder directly to the urethral ou The sphincter vesicæ then contracts u the urine, and, both muscles workin unison, forces the stream of urine the urethra, and against the exte sphincter which surrounds the memb ous urethra, and which is known as compressor urethræ muscle. This mu is controlled by cerebro spinal nerves, is subjected to the will of the individ The pressure of the urine against muscle causes the desire to urinate, the escape of the urine is controlled the will of the individual, exerted thro the nerves controlling this muscle, aided in no small degree by the ac of the cerebro spinal nerves distrib to the walls of the bladder. By this rangement the individual controls flow of his urine for a long perio time.

The above being the normal relatio the structures to each other, and the mal operation of the bladder under t conditions, what deviation from should we expect from an enlarged p tate? First, let us note the changes take place in the musculature at the n of the bladder. As the prostate enla the origin and insertion of the detr urinæ muscle broadens, or its fibers come separated more and more as process continues. It is well known the gland enlarges, sometimes to fou five times its normal size. In such c the origin and insertion of this musc extended four or five times more tha normal. It is obvious that when muscle now contracts, it does not di the urinary current directly to the thral outlet, as it normally did, but space four or five times as large, an there is no depression at the neck of bladder, or trumpet-shaped mouth to urethra into which the urine flows, forced against the side of the bla wall. It is plain that a force applie this manner, to the volume of urin the bladder, would be much less effic in emptying the bladder than if it normally applied.

We also know, by careful dissection, hat there is a close connection between he fibres of the detrusor urinæ muscle nd the fibers of the sphincter vesicæ. It s not hard to understand, then, that hen the fibers of the detrusor urinæ uscle are spread out to five times their ormal distance, the fibers of the sphinc-er vesicæ, to which the detrusor fibers re attached, must be rendered inefficient. ts contractile powers being overcome, t can not fulfill its function normally. Hence, if there were no other disturbance han that to the musculature, produced in his manner by the enlarged prostate, ysuria would result. But when we con-ider the well-known facts, that the hy-ertrophied prostate is very susceptible to he influences of cold and wet, and that s a result inflammatory processes are set p in it many times, and lying as it does n close contact with the sphincter vesicæ, nd the detrusor urinæ having its origin nd insertion in it, how unavoidably this nflammatory process must involve these uscles, and adhesions take place, bind-ng them all together, and destroying very semblance of their normal action, nd when we further consider that the nlarged prostate has impinged upon the erves and their ganglia which supply hese muscles, and has thus greatly in-erfered with their action, if not com-letely destroyed it; when we further nsider that the enlarging of the pros-ate is a slowly progressing condition, re-uiring years, and that these muscles and erves are encroached upon slowly, the rst involved being under the ban many ears before the last are involved, hence robably always dead, before a prostatec-omy is thought of. When we consider ll of these things that do happen, and re inevitable consequences of a hyper-rophied prostate, then we know that dys-ria, enuresis, and complete stoppage of he urinary flow, are inevitable conse-uences of this trouble.

For what do these patients seek relief? urely not from an enlarged prostate. hey desire relief from their urinary roubles. Why do we advise and do the peration of prostatectomy? Not simply or the removal of the prostate, for that s a benign thing, and in and of itself oes no harm. We remove it because it has destroyed the normal function of certain organs by disarranging them, and by causing such conditions in them as to make them useless, and urinary troubles are the result. We take away this enlarged body so that the organs it has crushed and distorted may assume, again, as nearly as possible, their normal condition and function.

Is it strange that some of these urinary troubles, in a few cases, persist for a time after the operation? Is it not more of a wonder that the operation cures such a large per cent, and so promptly?

Much has been said, and written, about how to perform the operation, so as to avoid the catastrophe of enuresis and other urinary troubles. Much has been written attempting to explain how the nerve supply to the various organs controlling micturition in health, are injured by certain methods of operating, and not effected by other methods; hence, enuresis or not, according to the method of the operator. The facts in the case being, all the time, that all the urinary troubles they are trying to charge to the operation were present before the operation was thought of, and had been, in many cases, for years, and were the only conditions which suggested the operation.

Have you forgotten, my dear doctor, that when some of these old patients came to see you they were wearing a napkin, folded and held in place in such a way as to absorb the dribbling urine, and the good wife who accompanied them carried a little hand satchel containing other napkins to take the place of the saturated ones? If you have forgotten these, you could not have forgotten the stained under-clothing, and the smell of urine about them. This was all before the operation, was it not? Then why charge these disagreeable things to the operation, and seek a method of operating that will not produce them? We all know, if we think at all, that prostatectomy may not cure the trouble for which it is done at once. It is not like an appendectomy which removes the offending organ in a few moments, and with it the whole trouble. When we remove the prostate, we only put the organs, which are damaged, in a way to recover, and then trust them to the good offices of

time and nature. How many thousands of operations have been performed upon the male urethra for stricture, many times portions of the urethra being completely obliterated by disease, and the most diligent search failing to find it, by reason of which an artificial urethra has been substituted for the lost portion, the walls of which are cicatricial tissue, and have to be sounded, more or less frequently during life, to keep them from closing.

Surgery is replete with operations wherein large vesicle calculæ have been dragged the whole length of the urethra, causing more traumatism than could be inflicted by a prostatectomy, and yet enuresis is not a sequela of these operations. This is sufficient proof that enuresis following prostatectomy is not due to the handling of the urethra during the operation. The bladder has been operated upon for all kinds of troubles, and subjected to traumatism of the severest nature, hundreds of times, without producing enuresis. In view of these facts, is it just to charge the enuresis that occasionally follows prostatectomy to the operation?

Doctors do not, as a rule, belong to the miracle-performing fraternity. If a thing is dead, it must remain so. The surgeon can not revive it. If a hypertrophied prostate has so impinged upon the muscles and nerves of the bladder as to place them beyond the powers of nature to restore, they will remain in that condition after the prostate is removed, and the patient will be deprived of their services the rest of his life, and must endure it. If the structures are only half dead, when the prostate is removed, the patient must bide his time until Nature can revivify them.

We do not wish in this paper to convey the idea that the obstruction to the urinary flow is never purely mechanical, due to the enlarged prostate, or some portion of it. We know this is often true. We do not admit, however, that enuresis follows prostatectomy in these cases. On the contrary, we are more and more convinced that it does not.

As to the surgeons who have reported hundreds of cases of prostatectomy, with no urinary troubles persisting after the operation, I should feel much better satisfied with a consultation with their patients than with their writings.

[Written for the MEDICAL BRIEF.]

Nursing.

BY EVELEEN HARRISON,
Graduate Nurse, Author of "Home Nursing" and "Emergency Roll."
New York City.

MODERN METHODS OF NURSING.

We are advancing with rapid strides in this wonderful twentieth century, and as we swing along through the years, reaping to the full the harvest of successful enterprises, planted by our forefathers we are inclined to look back a trifle skeptically at what we used to call "the good old days," encircled assuredly by a halo of romance, but when viewed through the lens of modern civilization, and analyzed under the high light of modern discoveries, present a woeful lack of what we now regard as the very necessities of everyday life.

A patient recovering from a surgical operation, related thus her interesting experience:

"I dreamed, while under the influence of the anesthetic, that I was lying in a large room, every inch of which was filled with eyes—the eyes of all the women who had ever lived throughout the ages—and these eyes were fixed upon me with intense earnestness, watching to see whether I fully realized the blessings of modern surgery, and modern methods of alleviating pain. These eyes were filled with the suffering the women had lived in their lives, and seemed to be jealously on guard, to make sure that I understood and was properly thankful for the great discoveries of the age in which it was my privilege to be alive."

This little illustration touches the heart of our subject, for in no other branch of science has such marvelous development come to light, as in the science of medicine, and in no department of medicin have there been greater improvement than along the line of nursing.

"Sairy Gamp," placed side by side with an up-to-date trained nurse, makes but a sorry spectacle, and although she was a

exception even in "the good old days," still the fact that she was tolerated, and the tales we have been told of the truly remarkable way sick people were cared for, makes us glad to be alive in the twentieth century, as long as it is ordained that mankind has to undergo the "ministry of suffering" in the shape of bodily ailments.

There are few modern towns, great or small, without a well appointed hospital, and staff of trained nurses; at the same time, there are thousands of homes scattered over the country, as well as in towns and cities, where, for obvious reasons a trained nurse is not available, and home talent takes her place.

The thoughts and suggestions gathered from the long experience of the writer, are gladly passed on to these home nurses, to be of service to them when "comforters are needed much, of Christ-like touch."

AN UP-TO-DATE ROOM FOR THE SICK.

Let us commence at the foundation, and build up for our use an up-to-date room for the sick.

Just picture to yourself, fair reader, the kind of room you would select should you be called upon to lay down for a time the life of active service, and take up the hard duty of serving by patient endurance.

A large room? Surely, because more airy, more restful, far less trying to tired nerves. With the many duties of the nurse, requiring much passing backwards and forwards, a good sized room is a help to both nurse and patient; again, a large room implies two windows, an untold advantage when we touch the question of ventilation and light. When a choice of room is possible, especially if preparing to battle through a long, tedious illness, always choose a room with a fireplace. A cheery open fire forms a bright spot, even on the gloomy days, and unconsciously has a strong influence in toning up the mental and physical health of the patient. It is difficult to remain depressed with such a bright comrade as an open fire, filled with beauty sparks, and we may add another advantage, its aid in securing good ventilation.

An important point to be remembered in our selection of a room is quietness. Take your patient as far as possible from the family living room, and the noise of the kitchen. An upstairs room is best, even at the top of the house, and do not hesitate to take the sunny side.

"A glare of sunshine pouring in on the sufferer!" you exclaim. Far better, indeed, than a room without a ray from our life-giving friend; besides, dark blinds, window shades and screens will "temper" the glare to any desired tone, and for a few moments every day a warm bath of the glorious light will do more for your patient than oceans of medicine, and put color into his thoughts as well as his body.

Ventilation—few people, even in these modern days, understand the absolute need of good ventilation in health, and fewer still recognize its importance in sickness. We all acknowledge that oxygen is in reality the very breath of life, and know that in many severe illnesses a large supply of oxygen has frequently turned the balance when life has been shaking hands with death, and yet in many homes fresh air is resolutely shut out, day after day, and the used-up atmosphere breathed in and out of the lungs by all the family, until the doctor has to be called in to prescribe for many troubles that might have been avoided by the use of plain common sense.

When one comes to a sick man, battling for his very life, pure, fresh air is almost the best help one may give him, so through the open windows let in plenty of "God's out of doors," and the fight will be half won.

In the patient's room the windows should be left open at the top a few inches, night and day; hot air rises, and cold air descends, so the fresh air will circulate slowly around and down through the room without blowing directly on the bed, or causing a draft.

Should there be only one window in the room, open it a few inches above and below, slip a piece of firm cardboard, or thin slat of wood, over the lower opening, so that the air may enter in an upward direction, and a fresh supply of oxygen will always remain in the room, in "heaven's sweetest air."

One of the many foibles which have found their grave, in this age, is the one

claiming that the night air is bad for people, and should be shut out of the house. As a matter of fact, it has been proven that the night air is pure and healthy, and even more desirable than the air during the daytime, so let us gratefully inhale all we may.

If the patient still clings to the worn-out theory of not changing the air of the sick room, do not try to argue—argument with a sick man is unwise, and utterly unconvincing—but open the window in an adjoining room, leave the door open between, and he will gain some benefit in spite of his perverseness.

HOSPITAL TRAINING APPLIED IN HOME LIFE.

And now in regard to the furnishing of the room for the invalid: Infectious fevers, or major surgical cases, require a room specially prepared, about which we will talk in a succeeding chapter; at present we shall consider the preparations in an ordinary case of sickness.

First, the bed, a single iron bedstead, is, without doubt, the best, and in a severe illness is necessary, but under ordinary circumstances the patient remains in his own bed; one point of importance, however, is a hair mattress.

There may be a warm corner of the heart reserved by a few old-fashioned people for the feather bed of yore, but it may well be numbered amongst the relics of the past, and certainly has no place in a room where coolness, cleanliness, and facilities for nursing reign supreme.

The bed should stand out from the wall on all sides, to allow a free circulation of air, and sufficient room on three sides for the nurse to reach the patient easily.

On no account allow the bed to face the windows. If no other way is possible, put the patient's head at the foot, so that his back should be turned to the light. Have you ever remarked that in the majority of bedrooms one enters, the beds face the windows? and for two or three hours before rising, the occupant has a glare of light pressing in on the eyeballs, which eventually must cause trouble of some kind, for the eyes, obliged to face the light, and used every moment of the day, require eight or nine hours rest from light, if we would preserve their usefulness and clearness to the highest point.

Might not the early morning headache which clouds the temper of some people be due to the disregard of this fact?

To return to our sick room, in many diseases the eyes are weak, and must be guarded from too vivid a light, so let us think of this when arranging the bed, and, in addition, place a screen at hand that may be used when required between the window and the bed, or to screen the light from lamp, gas, or candle.

A screen is indispensable in the sick room, for many purposes, and if one is not obtainable, we must invent a substitute. The clothes horse from the laundry, covered with a soft shade of art muslin, makes an admirable screen, or one might fasten a strong cord, across the room, between the window and the bed, and hang a curtain on it to be moved backward and forward at will.

A small table close to the bed is most useful, also a couch, and one or two easy chairs without rockers—as the constant movement is trying to sick people; add to the list a bureau and side table, and the necessary furnishings of the room are complete. It is good policy to have the room as free from other furniture as possible; the air will circulate better, and the room is far easier to keep clean and in good order. Many people, when sick, are very nervous, and it confuses them to see a variety of things around, in the shape of bric-a-brac, drapery, or heavy ornaments. Apart from this is the all-important question of the hygiene of the sick room, and one may readily see how much time it would take to dust and cleanse an elaborately furnished room, to say nothing of the lodging house for germs caused by an accumulation of trifles.

Heavy curtains should be removed, and simple white muslin ones substituted. A few interesting books, pictures and magazines lend a home-like air to the room, while flowers—"God Almighty first planted a garden"—fill the very air with healing, so powerful they are to uplift our inner selves, and give us strength to overcome the bonds of sickness.

All the necessary appliances for use during the illness, viz., medicine bottles, glasses, feeding cups, surgical dressing, etc., are relegated to a closet, behind a

screen, or to an adjoining room well out of sight of the sufferer, for a model sick room must be so arranged as to contain nothing which may continually impress the patient with thoughts of sickness.

A long row of sticky bottles, or surgical dressings, ranged on a table in full view of the patient will never for a moment allow him to forget that some horrid tasting medicine has to be swallowed at regular intervals, or that a painful dressing has to be undergone.

Cheerfulness should be the dominant atmosphere, the keynote of the room, and no gloomy thoughts, or gloomy faces allowed to cross the threshold. When the "home mother" occupies the chamber of suffering, all knowledge of household cares and household disturbances should be rigorously excluded, and each member of the family do his share in promoting peace of mind to the invalid, by upholding this rule, and bringing only bright, cheery news, and pleasant out-door tales, to fill the mind of the invalid with happy thoughts, and thus hasten her recovery.

In regard to the temperature of the room, about 70° F. should be maintained, except in cases where the patient has a very high fever, when the thermometer should not average much over 65° F.

Early in the morning—between two and five o'clock—the atmosphere is cooler than at any other hour, and as the vitality of the body reaches its lowest point at the same period of time, extra blankets must be ready to throw over the patient; during a serious illness, especially in the care of an old person—hot drinks are required, in these hours, hot water bottles to the feet, and a close watch kept on the pulse, lest it flicker and die away in the "wee sma' hours anent the dawn."

[Written for the MEDICAL BRIEF.]

Cerebro-Spinal Meningitis.

BY R. M. GRISWOLD, M. D.,

Kensington, Conn.

In the June number of the BRIEF I note two articles upon the above subject, one by Dr. Annie K. Bailey, of Danbury, Conn., the other by Prof. Henry N. Read, of the Long Island Medical College, Brooklyn, N. Y.

In view of the gravity of this disease, and the great apprehension occasioned by its appearance in a community in epidemic form, not only among the laity, but among the profession as well, and in view of the further fact that little is really known either of its etiology or pathology, it becomes one writing upon the subject for publication to be at least reasonably sure of their facts before making positive and unguarded statements such as are made by both these writers. Such a course is especially to be deprecated when emanating from such a supposed source of authority as a professional teacher in a medical college, whose published statements are supposed to be founded on facts already demonstrated, or capable of demonstration.

Meningitis, both spinal and cerebral, has been specifically recognized and carefully studied for more than one hundred years. For the past two years, no disease, with the possible exceptions of cancer and tuberculosis, has been more thoroughly and scientifically investigated than cerebro-spinal meningitis, and yet there is no disease of whose cause and successful treatment we know so little.

Under the circumstances it is more commendable to admit one's ignorance than to pretend to a definite knowledge, which those of us who have had a long experience with this disease know is not possessed, at the present time, by either layman or profession.

With an assurance which should be displayed only in the presence of absolute knowledge, Dr. Bailey says, "Cerebro-spinal meningitis, or spotted fever, is caused by a change in the blood constitution," or "a deterioration of the blood caused by a gradual accumulation of nitrogenous waste products therein," and then goes on to describe the poisonous effects of these waste products upon the nervous system, "causing the characteristic hemorrhagic spots."

This explanation might do very well, if it did not apply with equal force to rheumatism, gout, and other forms of auto-infection, but when we remember that the very large majority of cases of meningitis, especially cerebral, occur in children, often in infants, in whom the "gradual accumulation of nitrogenous

waste products" is very much less than in adults, I think the Doctor will pardon me for suggesting that this interesting, but delusive theory, could not have been evolved as the result of a large experience in the observation and treatment of this most elusive and deceptive disease.

The Doctor further goes on to state that "The deterioration of the blood, which is an essential factor in spotted fever, is also caused by a solution of the red corpuscles of the blood, which manifests itself in the hemorrhagic spots, and is due in a proportion of cases to the pernicious effects of coal-tar products," etc.

In reply to this statement, I wish to say, first, hemorrhagic purpura is by no means characteristic of cerebro-spinal meningitis. It is as well characteristic of certain forms of scurvy in children, especially Westhoff's disease, is often seen in the rheumatism of children, also in splenomegalia, marked by gastric and cerebral disturbances, pain, diarrhea, and vomiting, a case of which I have seen diagnosed as cerebro-spinal meningitis by one of the best diagnosticians in New England (and no discredit to him). It was characteristic of the old-fashioned typhus fever, which usually had associated with it a more or less severe form of meningitis, from which came the name "spotted fever," now quite wrongly applied to all cases of cerebro-spinal meningitis, except traumatic. These hemorrhagic spots are much more characteristic of low forms of chronic malarial poisoning than of meningitis, and yet the Doctor assures us, with great positiveness, that they are due to coal-tar products, "in a proportion of cases." This is another case where we are constrained to ask, "How do you know?" and, do you not know that cerebro-spinal meningitis, typhus, malaria, scurvy, and all other conditions associated with purpuria, were common long before coal-tar products were known?

Prof. Read now announces with equal positiveness that "the cerebro-spinal variety of meningitis is due to the diplococcus intracellularis."

At this point possibly an apology may be due for the presumption of an obscure country doctor, who for thirty years has been obliged to draw his deductions from his observations of, and experiences in, combating actual disease, rather than from laboratory work, to one holding an honorable position in a high-class institution of learning, and whose spoken and written word should carry with it the weight of fact, unobscured by theoretical vagaries.

Perhaps I may also be pardoned for asking a pointed, but, it seems to us, pertinent question, which may seem to imply a doubt as to the positive certainty of the Professor's statements. Nevertheless we presume to put the question, viz., "How do you know that the diplococcus intracellularis alone produces cerebro-spinal meningitis?"

The fact that it produces fatal meningitis in guinea pigs is not proof that it produces it in the human.

The fact that it is found in cases of spinal meningitis is not proof that it is the producing cause, any more than the fact that the Klebs-Loffler bacillus, found in diphtheria, is proof that the bacillus is the producing cause.

As the Klebs-Loffler is found in many people who have not diphtheria, so the diplococcus intracellularis is found in many who have not cerebro-spinal meningitis.

The presence of either germ is presumptive proof that it is productive of the disease attributed to it, but presumptive proof ought not to warrant positive assertion, and this same diplococcus is found in purulent empyema, and in certain forms of septicemia.

Dr. Read states, further, "Diagnosis of the cerebral variety of meningitis is readily made."

I should wish to modify this positive statement by saying that in an experience of thirty years, during which time I have seen a larger number of cases of cerebro-spinal meningitis than falls to the lot of the average practitioner, either urban or rural, I have learned that the disease is frequently hidden in obscurity, and often not to be accurately and positively determined by the most acute diagnostician.

The late Prof. Alfred L. Loomis once said to me, while seeing a case in consultation, "It looks like a case of cerebro-spinal meningitis, but the symptoms are quite obscure, and only a *post-mortem* will determine it."

Theoretically, the diagnosis of the disease is simple, but brought into frequent contact with it, we are often forced to admit there are many things we do not "know," and the more one sees of meningitis the less he will be inclined to express any very positive opinion upon either its causation or treatment.

One further criticism of Dr. Read's article: He says, "The fever, as a rule, is not very high." His modifying words, "as a rule," I believe to be correct, but one of the most frequent and characteristic signs of meningitis, especially cerebral, is the erratic temperature. Frequently decidedly sub-normal, it may, in a short time range from 103° to 106° F., and extremely high temperatures are not uncommon. Neither is the extremely high temperature of necessity an indication of fatality. I have a little patient now, whose temperature on one occasion, three weeks ago, reached 109° F., and he stands a good fighting chance of recovery.

A few words as to the results of my personal observations upon this disease:

First, I think it will be found that the history of cerebro-spinal meningitis epidemics for the past one hundred years will confirm the statement that the disease almost invariably follows a prolonged and cold winter.

Second, That a careful investigation of each case will show that most of them have been preceded by a recent and generally severe case of grip.

Third, That when two or more cases have occurred in the same family or house, both cases were due to the same primary cause, but there is a possibility, by no means yet proven, that there exists a certain amount of contagion capable of conveying the disease from the infected to the well.

Fourth, That no specific plan of treatment has yet been demonstrated as successful. The plan of Thomas Watson, and other observers of seventy-five and one hundred years ago, is not improved upon by later-day methods. Absolute quiet, plenty of fresh air, a nourishing liquid diet, the judicious use of opiates, circumscribe our range of remedial agents.

In my own hands, I have had more than the usual per cent of recoveries following the use of hyoscyamine, codeia or morphine, and aconite, supplemented by the cold pack, and cold rectal injections, but I should not wish to recommend my method as specific, or commend it as superior to any other treatment which is dictated by ordinary common sense, and the only thing I object to in others is the putting forth of unfounded theories as facts.

The simple truth is, we do not know what causes cerebro-spinal meningitis, neither do we know what will cure. We know as much as our grandfathers did about it, but no more. We look to the future with hope and the belief that some investigator will shed the light of certainty upon a path which is now entirely dark, but we have to admit, if we are absolutely honest with ourselves, that at present our knowledge of the cause of meningitis is equaled only by the profundity of our ignorance as to its proper treatment, and that any theory as to its cause can be readily disproved by a fairly accurate observer of plain facts.

[Written for the MEDICAL BRIEF.]

Malaria.

BY ALEX. B. MCCASKELL, M. D.,
Albany, Ga.

Thirty-six years ago, when fresh from college, where I had been lectured to give quinine in small doses, at frequent intervals, in order to subdue malarial influenza, I made plantation contracts to care for the sick in that notoriously malarial lime belt in Houston County, Georgia, and my patients as well as nurses were negroes exclusively and chills and fever the prevailing malady. I would give the purgative and leave the quinine to be given by the nurses in small doses and at frequent intervals (as I had been lectured to do). I found that some of my patients got well at once and others lingered, which fact puzzled me no little, and upon a close and vigorous investigation I discovered the cause, *i. e.*, the nurses of those who rallied first, rather than be troubled to give the quinine as prescribed, would give it all in one or two portions: hence the results stated (experience vs. teaching).

[Written for the MEDICAL BRIEF.]

Some Practical Items.

BY E. R. ELLIS, M. D.,
Detroit, Mich.

One of these is on the subject of *post-partum* hemorrhage, or that which swiftly follows the conclusion of labor. The mouth of the womb becomes occluded with clots, and that organ is then filled with blood without the doctor becoming aware of it, unless he is very watchful. Such a case occurred to me a few days after my graduation in 1857, and such cases occur all too frequently in every vicinity, even to this day. The patient will die right under the eye of the doctor, even before he becomes aware of the true situation. He then has to expain that it was "heart failure" or a "mysterious Providence," in order to let himself out from a blunder.

The case alluded to above was that of a young woman in her first confinement. The labor was concluded in a very natural manner, and I requested the nurse to watch her and report if there was much flow. She reported none and that all was well. Suddenly the patient exclaimed that "aH was dark, that she could not see." This meant great loss of blood, and sure enough the womb was full of blood and the abdomen distended almost as much as before labor began. I lost no time in clearing the womb of clots and inducing contraction of that organ. The nurse present was a mature woman and had quite a large practice as a midwife. She tried to interrupt my efforts and insisted that "the clotters should never be removed." Probably a gallon of clots and blood were speedily removed and with hot drinks and stimulants she was restored, but she had become unconscious and had for a time paralysis of the left side and limbs. That experience caused me to lose confidence in midwives. Two women in that vicinity had previously died in that way and I have no doubt that this patient would have been added to the list in five minutes or less had there been that much time neglected.

Probably the most effectual means to prevent such a mishap as this is to secure a firm and permanent contraction of the uterus immediately after labor. For th purpose I always secure this by disten ing the thumb and fingers and placi them over the womb, hold it for five fifteen minutes before placing the ba dage in position. When thus contracte there can be no hemorrhage of cons quence.

It is important to mention that woman who has had repeated confin ments, at short intervals, is more like to have undue hemorrhage, or other mi hap, than others. If the uterus is th overworked, it (in a measure) loses i contractile power, becomes more placi and fails to undergo proper involutio hence the obstetrician should never cea to be watchful.

Again, he should be alert to keep o convulsions. A premonition of this, the last stages of the labor, is the patie has her eye attracted to an imagina point in the ceiling, with her fing pointed upwards, and a whistling sou escapes her. Keep your eye on her fa and the first sign of this command he in vigorous tones, "to stop that," and gi all her attention and strength to the wo before her. In several instances I b lieve this has prevented the onset puerperal convulsions.

Next, as to the bandage, which shou never be omitted, as it gives most nece sary support to all the internal orga and favors a correct involution of t womb. Occasionally a doctor comes o with denunciation of the bandage, b that is most emphatically wrong. T bandage serves a useful purpose in relaxed conditions of the abdomen. was said that during the late civil w soldiers with chronic diarrhea could ba dage the abdomen firmly and march day. As proof of this I will relate a ca which came under my notice about t months after I began the study of me cine. Cholera prevailed in this city a one night my preceptor asked if I wou like to see a case. I assented, and took along with him another doctor f counsel. The patient was a man of abo twenty-five years. He lay on the be rolling from side to side, groaning wi pain, and made the never-forgotten mark, "Oh! if I only had something me." The doctors had gone into an a

joining room for their counsel, and I sat beside the bed. I put my hand on his abdomen, which was so "caved in" that the vertebra could be felt. All that he took came up or went through him. It occurred to me that he could be "filled up" from the outside, and as an extra hard pillow lay upon the bed I placed this across him and pressed it down firmly. In a minute he was easier, turned over with the pillow under him and presently he was asleep. Fourteen years afterwards I moved to Detroit to practice medicine. About my first call was this man, who asked if I "remembered curing him of the cholera." The support which that outside pressure gave him was what contributed to his cure and, perhaps, saved his life, and this is what the bandage will do in many cases.

There is another matter which all should oppose strenuously. It is that of curetting the uterus in abortion, or when abortion is threatened. All violent means in such cases are unnecessary and dangerous. If but a slight hemorrhage takes place that is sufficient to destroy the life of the fetus, and then if left entirely alone Nature will throw it off in her own time with perfect safety. It will often take a few days for this, but Nature is a good doctor and he will do best who goes least counter to her ways.

Another important item, in this connection, is the manner in which babies are treated in their bathing. Scores of times, in receiving their first wash, have I seen the nurse expose the entire surface of the baby to the air. Many times have I remonstrated vigorously and explained that when a wet surface is exposed to the air, evaporation is greatly increased, and this lowers the temperature; even ice is formed artificially by rapid evaporation, as most persons know. Repeatedly have I known babies to sneeze and snuffle on their first washing from this cause. (Will some microphobist kindly inform us whence comes this "specific germ," and how he is enabled to get to work so speedily?) Only one limb at a time and a small portion of the body, when wet, should be exposed, and then well covered with flannel while other portions are undergoing the same process.

[Written for the MEDICAL BRIEF.]

"Dietetics."

BY MARY H. WILLARD, M. D.,

New York City.

"Good diet with wisdom best comforteth man."

The Century dictionary informs us that "dietetics is that department of medicine which relates to the regulation of diet." Following this definition, with an extract from Herbert Spencer to the effect that "it must not be supposed the whole of dietetics lies in determining whether or not bread is more nutritive than potatoes," leads us to the conclusion that dietetics cover a far larger field in the world of science than the first definition implies.

The apostle of the "Simple Life" might have taken a step further in his explorations and entered this field of knowledge with vast profits to the people; admitting that the health and morals of the individual depend largely on the quality of the food he eats, and the kind of home he inhabits; does not the prosperity or adversity of the nation take its vice from the health and morals of the individual?

Our lives are short at the best, three score years and ten (shall we quote a well-known authority for only two score years of really capable life?). The world is teeming with glorious possibilities ready to be taken up by the man or woman possessing good mental and physical caliber, and we cannot afford to miss even one day out of our short lives by eating food which may render us unfit for the world's work; herein lies the great importance of a knowledge of dietetics in health, as well as disease.

Our ancestors—in the good old days—had to work hard, physically, for their daily food: from the turning up of the soil, to the well-spread table, all preparations were accomplished by hard labor, chiefly in the open air; hence, their appetites were healthy, therefore easily satisfied; their food simple, therefore easily digested; their digestion good, therefore many of the modern diseases were unknown and there was no need for practical dietetics, especial diet lists, etc.

To-day our living is far more artificial. Much of our food is manufactured and brought to our doors ready for the table.

Mental effort has largely taken the place of physical labor; indoor, the place of out-door life, and overwrought nerves are a force to be reckoned with in every part of our being. Diets have been formulated for all diseases; especially prepared foods are advertised everywhere, and, as in the case of all the best modern improvements are, by some, carried to the extreme, giving rise to the "diet habit."

I visited a home once where every member of the family was taking a different course of diet, and the dinner table daily took on the appearance of a restaurant, each plate surrounded by an array of especial dishes.

So much for the extreme side of the question; on the other hand, we recognize fully the inestimable value of the study of dietetics. There are few things, even in this wonderful twentieth century, so necessary to our mental and physical well being.

The fuel value of food has become an important subject, and the many experiments along these lines have demonstrated the value of the proper kind of food to suit various organisms. The terms, "vomb calorimeter," "respiration calorimeter," "oxidation of foods," "measurement of respiration," "heat of body," "application of results to prove true value of food," "effects of preservatives on health and digestion," etc., etc., *ad infinitum*, conveyed no more meaning to our forefathers than the technicalities of modern electric apparatus are familiar to the student of dietetics and domestic economy.

In a modern cook book we find six recipes for "Hygienic Griddle Cakes;" whereas the word, "hygienic," was rarely to be found in the vocabulary of our great-grandmothers.

Twenty years ago a well-known writer said that the time was ripe for a system of dietetics and domestic economy which might be applied to the family life; today, we have a well-established method of teaching this branch of science in the public schools and institutions, so that the rising generation may have no excuse for ignorance on the value of food in relation to the health and morals of the community.

Our ideas, in regard to diet in disease, have undergone even more marvelous changes in the last few years. We no longer "feed a cold and starve a fever," irrespective of the condition of the patient, but are learning the importance of sterilization of food, predigested albumin, medicated food, vegetable diet, relative values of mutton, chicken and beef, and a host of other important topics. The knowledge of dietetics is, as yet, in its infancy, and few of our home-mothers know whether a basin of broth, a glass of milk, or a mould of wine jelly contain the most nourishment for the individual case under her care.

Sir Henry Thompson, the well-known English authority on dietetics, declares that "more than half the disease, which embitters the middle and latter half of life, is due to avoidable errors in diet." One has only to visit a children's ward in any of our large hospitals to feel assured that this applies to the care of our little ones. The regular tenement-house breakfast, for the whole family—not excepting the two-year-old baby—consists of strong coffee and hot rolls.

It is impossible, in a short sketch, to do more than skim over the surface of such an extensive subject as dietetics. When it is realized that the peoples of the world are groaning under a burden of suffering, which, in the large majority of cases, may be traced to indiscretions in the form of diet; over-feeding the system with highly-seasoned viands; starving it with unnutritious food; planting in it germs of disease, which bear fruit a hundredfold; or, through ignorance, neglecting the kind of diet to create a wholesome body: we see clearly demonstrated the true importance of the science of dietetics.

[Written for the MEDICAL BRIEF.]

Static Electricity in Appendicitis.

BY O. HOUTS, M. D.,
Hiawatha, Kans.

In the past two years I have treated fourteen cases of appendicitis with the static machine; but little medicine was given. Some of the cases had run six weeks, some one-half day. Some were

hauled in from the country on cots. The mode of procedure was as follows:

First, the patient, either sitting on a chair or reclining on a cot, placed on the static platform, was given ten minutes brisk static insulation (positive), then the long-handled sponge electrode was met in warm water connected up with the negative side of machine, with a cord. The machine is started with the prime conductors closed after the machine is going at good speed; draw out the prime conductors until the limit of tolerance of the patient is reached. The positive side of machine is grounded. Continue treatment ten or fifteen minutes longer; repeat in twenty-four hours, if needed. Follow up with a saline laxative every two hours, and with injections of one part glycerine, seven of water, high up in the bowels. No relapses have followed. One case that had run seven weeks, with right leg drawn up to body; almost impossible to get him to the office. The induration as large as his head.

Treatment.—The negative electrode from galvanic battery, No. 3, was placed over appendix. Positive over lumbar region, size 6 to 8 current, gradually increased for fifteen minutes, up to thirty-five milliamperes. He was then placed on static platform and given the regular treatment with sponge electrode. He took seven treatments, when he could stand on both feet. Gave treatments every third day.

I will continue to treat all my appendicitis cases as above.

[Written for the MEDICAL BRIEF.]

A Case of True Abscess of the Ovary.

BY S. C. MISH, M. D.,
San Francisco, Cal.

Mrs. H. W. S., age twenty-four, menstruated at fifteen, and married at seventeen. Her first child was born in 1901. Breech presentation. On the twelfth day, feeling well, she went downstairs.

In March, 1903, her second child was born. On the fourth day after labor, hearing a noise in the house, she jumped out of bed and went about the halls for some time.

She returned to bed and in fifteen minutes had a very severe chill, which was soon followed by fever. A physician was sent for, and after an examination said she had taken cold, and that inflammation had set in about the womb and ovaries.

He ordered poultices on the abdomen and gave medicines internally, for the chill, fever, and pain.

This attack kept her in bed two months. In May a swelling was first noticed to the left side of the abdomen.

Since the above attack she has had chills and fever continually, there being also more or less nausea. The urine contained no casts or albumen. She was put upon a good, nutritious diet, tonics, etc.

My diagnosis was a suppurating tumor, either in the left fallopian tube, ovary, or broad ligament.

A month later I opened the abdomen and found a tumor the size of three billiard balls, extending up to the umbilicus. Following it down into the pelvis, I found that it was the left ovary, with firm adhesions to the uterus, broad ligament, small intestine and surrounding parts. The fallopian tube was drawn up over the tumor.

While gently manipulating in separating the adhesions the sac wall, being so thin in the pelvic cavity, gave way, and its contents of offensive pus poured out. The tumor was separated, a pedicle formed, a ligature applied, and the tumor removed.

The abdomen was thoroughly washed out with an abundant supply of warm water. The excess water was sponged out, leaving a moderate amount still in the cavity. Monsell's solution of iron was applied to the oozing from the separated adhesions.

A glass drainage tube was inserted, and the wound closed with Chinese-silk sutures. The right ovary, being diseased, was removed. The patient reacted well from the operation. Chloroform was the anesthetic given.

The morning of the fourth day, her temperature being 99½° F., pulse one hundred and six, respiration twenty, and no fluid being drawn from the tube, it was withdrawn. The patient made an excellent recovery.

The case is of interest in several respects.

The pathological reports show the tumor to be a true abscess of the ovary.

We are aware of there being a distinct difference between this condition and abscess of the fallopian tube and the pelvic cellular tissues in and around the broad ligaments.

The extensive use of Monsell's solution of iron to arrest the copious oozing from the separated adhesions and its success is a point of interest.

Some surgeons are opposed to washing out, and are in favor of sponging out the abdominal cavity. In abdominal operations where there is much oozing of blood, which forms into clots among the convolutions of the bowels, or along the spinal column, or under the diaphragm, or liver. or behind the stomach or spleen, or deep down in the pelvis, it is almost impossible to cleanse these cavities thoroughly by sponging. Moreover, lengthy sponging delays the operation and produces a great amount of unnecessary irritation of the abdominal and pelvic viscera, thus enhancing the danger of shock.

Some surgeons also dispute the efficacy of the drainage tube in abdominal operations. Drainage through the abdominal incision, when properly done, is not against gravity, as usually implied. I refer to those cases only where drainage is necessary, for the tube, if used, is the opening through which we can draw off the fluid as it gravitates there.

Education.

BY JOHN A. WELSCH, M. D.,

Farber, Mo.

This is the war cry of the medical politician. And when you come to analyze one of them there are few men in or out of the profession who actually possess less of it than the stickler for higher requirements (?). Plain tincture of aconite has been just as effective in my practice as tinctura aconitum. And so with all remedies which I have used during my fifteen years' experience as a student and practitioner of medicine, which includes attendance and graduation at two regular medical colleges. Take, for instance, the one who manifests an aggravated form of hysteria at the mention of medical advertising, and who insists that one must possess numerous literary degrees before being permitted to enter a medical college, and he will tell you that typhoid fever, pneumonia, and almost every known disease, is self-limited, and should be treated on the expectant (?) plan. This means, write a few Latin prescriptions in which you have no confidence, and wait. While you are waiting organize a county society on the reorganized plan, and try to get a bill through the Legislature which will permit you to bleed the real physician who believes in medicine, and the English language, and which will enable you to live in luxurious idleness with your skepticism. This is modern education, according to the medico-political dictator, who at present controls and exploits the regular profession, and is trying to include the manufacturers of proprietaries in the bleeding process. It would seem he has struck more than he can handle at this game, as the proprietary interests embrace an immense capital, as well as brains, and a desire to run their own business.

Now then, brethren, if this close corporation of medico-political dictators should meet with the rebuke and defeat they deserve by this unjust attempt to appropriate private property, do not permit them to lay the whole thing on the rank and file of the profession, as they are almost sure to do, for remember they have already appropriated everything we have; our liberty, which includes our standing with the State and the public-at-large, is subject entirely to their individual whims, without recourse under the law. A dean of a certain medical college has been lamenting the fact that the increased requirements (?) may cause a deficiency in the production of physicians to the extent of making the supply not equal to the demand. He bases his opinion on the decreased number of matriculates in the medical colleges at present. But the organ of the medical trust hastens to assure him that there is no decrease in first-year students at the really high-class (?) medical colleges.

I wonder if this dean sees the point? you do not subscribe to the trust you e not high-class—in their estimation. ıt you are true to the principles on ıich this Government was founded. You e an American without notions bor- wed from effete monarchies which have kinds of tyrannical laws and more acks (?) than we have. Education is necessary element of success, and the ysician who would succeed is not going handicap himself by neglecting his n. And in America all our institutions learning should be open to everybody thout any previous political red tape extortion. If you would purify and vate the profession eliminate the medi- political dictator and give them liberty.

[Written for the MEDICAL BRIEF.]

How Medical Law is Used in Washington.

BY J. W. LOCKHART, M. D.,
St. John, Washington.

We have here in Washington the most spotic medical law that was ever con- ved within the brain of bigots or ty- ts. This law makes each separate act practice a crime, punishable with a e of not less than fifty dollars, or im- sonment of not less than three months, both fine and imprisonment. So it is y to see that the penalty for illegally cticing medicine in this State might, some cases, amount to life imprison- nt and total confiscation of property. e law has, however, one good quality. penalties are so severe, so entirely de- d of honor and justice, that there can found but few Torquemadas in the pro- sion who care to have it enforced. This , like all medical laws, is more honored the breech than by its enforcement. at these laws exist for no other pur- e than to limit competition in the prac- e of medicine, is now an undisputed t. I have never known the aid of one these laws to be invoked in any way the protection of the general public. e fact is, that the more successful is the licensed practitioner the sooner will law be enforced against him; and that, by the public, but by some disgruntled ensed doctor who is losing his practice.

Nearly three years ago I found that it would be necessary for me to give up the larger part of my practice. I had suffered severely from nervous prostration, the result of trying for more than two years to do two men's work. One day a young man of good personal appearance came to my office and explained that he was looking for a location in which to practice medicine. Said he had graduated from a medical college in San Francisco, had passed the California State board examination and practiced two years. He had not passed the examination in this State, but thought he could easily do so at the next meeting of the board. I said, "Doctor, if you will treat me and my friends on the square and prove to be the man that every physician should be, you need look no further for a location that will give you more than a good living. I will give you a hundred dollars or more of practice every month and you are welcome to all you can get beside. The offer was accepted. The doctor proved to be honorable and successful in practice. I gradually gave up most of my practice to him. He tried hard three successive times to pass the State board examination, but for some unaccountable reason, failed. Then came an evil day. He was called, over the phone, to see a patient for whom another physician had prescribed a few days before. The doctor was not informed that another physician had been called, and was, therefore, perfectly innocent of any intention of trespassing on professional preserves. However, some ugly stories got afloat about the case, and the offended doctor peremptorily notified my friend that he must immediately give up his practice or be prosecuted to the full extent of the law. I advised my friend that unless he was able to carry the case to the Supreme Court of the United States, discretion would be the better part of valor, and that he had best give up his practice until duly licensed. The doctor left here with the sympathy and best wishes of the entire community.

This case speaks for itself and needs no comment. This case shows plainly the practical working of medical laws. The general public here denounce the law and express indignation at its enforcement.

The question is, how long will the medical profession belittle itself by standing sponsor for such destruction of human right? Have individuals no right to choose their own medical advisers? I know of licensed doctors in this State who could not practice medicine if they had a car load of licenses, for the obvious reason that people will resort to patent medicine, self-prescribing, etc., or die without a doctor before they would employ some of these licensed incompetents. The Supreme Court of the United States has recently decided that the eight and ten hour labor laws of the several States is unconstitutional, because they infringe the right of individuals to contract for any number of hours they may deem proper. The right of contract is held to be a sacred, inalienable right of individuals; that State legislatures may not infringe or abridge. If the same principle of law applies to professional labor, it would seem that an individual might contract with whom he pleased to give him medical advice or assistance. I understand the court to mean that "the right to contract for anything that is right and honorable is, now and forever, beyond the scope of State police regulation." If that is correct, Liberty has won the greatest victory of the century. If not, the battle must yet be fought.

The Supreme Court has more than once decided that any law "enacted for the promotion of the public health or morals must bear a real and substantial relation thereto," or it is unconstitutional.

How to Keep Bright, Clean Instruments.

BY C. D. R. KIRK, M. D.,
Shuqualak, Miss.

I perform a good many minor surgical operations and extract a great many teeth, and after having tried various methods for keeping instruments bright and clean, I have found that a good article of kerosene oil and a woolen cloth is the quickest, best way to clean instruments and keep them bright and ready. Kerosene oil will dissolve blood in a ond and remove it with only a little bing. It is superior to any chemica cleaning wood or metal. It show stain on the sponge or cloth used, t fore the chemical constituents are solved and changed. It also pre rust or tarnish, and I think it is a excellent disinfectant. Try it.

Irritable Bladder in the Fema

BY W. B. WOOD, M. D.,
Los Angeles, Cal.

There are few diseases so common at the same time so stubborn and dif to treat as an irritable bladder in female. There are many causes for trouble. Some of which are malig growths, tumors, stone in the bla pregnancy, uterine displacements an flex irritation from some rectal dis If, upon close examination, none o above causes are found, its origin mu of a neurotic character. Some of symptoms are pain, a feeling of w and uneasiness in the region of the der, constant desire to urinate, vo only a few drops at a time, accompa by most excruciating burning pain straining.

Treatment.—First correct the torp of the liver by giving broken doses o omel and soda, followed in a few h by citrate of magnesia. To allay the vousness, fever, and to a certain ex the pain, give elixir acetanilid*, teas ful every two hours; also,

R.	Specific Tr. Elaterium	2 dra
	Sulph. Atropia	½ grai
	Mucil. Acacia	1 oun
	Aquæ Dest q. s.	4 oun

M. Sig.: Teaspoonful every three hours.

This dose can be increased until pupil becomes dilated and mouth then give smaller doses. Locally, us hops, or cloths wrung out of hot w and turpentine. Recumbent position perfect rest.

This is my favorite.

---

* Elix. acetanilid is made by dissolving tw one-half grains of powdered acetanilid t drachm of simple elixir, with just enou alcohol to hold it in solution.

Sabbatia Angularis.

BY J. A. BURNETT, M. D.,
Cecil, Ark.

All physicians who practice in malarial districts should give sabbatia angularis a trial, as it is a very useful remedy in most all forms of malaria. According to my experience here, within two miles of the Arkansas River in a malarial district, sabbatia angularis is a more reliable anti-periodic than quinine, and the most useful remedy we have in the treatment of malaria—that is, it will meet more conditions, and come nearer curing all forms of malaria without the aid of another remedy than any drug in the *materia medica*. It will prevent a chill when given in doses of ten or fifteen drops of the fluid extract every hour, for six doses, beginning so that the last dose will come one or two hours before the chill is due. At other times it should be given in half drachm doses every three hours. The anti-periodic action of sabbatia angularis is increased when combined with sweet flag—calamus—or when combined with capsicum.

When the pulse is weak, or much stimulation is needed, it should always be combined with capsicum. Sabbatia angularis will clean a coated tongue, and stimulate the liver. If the liver is very torpid, and the tongue heavily coated, it should be combined with chionanthus, which will greatly increase its usefulness in this condition.

Sabbatia angularis is not only a useful remedy in malaria, but in various other conditions. It is a valuable nervine, and will sustain the nervous system. In general debility and summer complaint of children it is often a valuable remedy to sustain the vital force, stimulate the liver, and to regulate the digestive system.

Often nux vomica will be a useful remedy to use in combination with sabbatia angularis in such conditions. Sabbatia angularis is well received by the stomach if the stomach is in condition to receive any remedy. It is a stomachic, and useful in chronic dyspepsia, when there is lack of tone in the stomach. A warm infusion will promote the menstrual flow when delayed from weakness. It is valuable in female weakness, prolapsus, etc., when combined with caulophyllum.

Sabbatia angularis deserves close study, as it has an extensive, wide range of usefulness in various diseased conditions.

Peculiar Ureters.

BY BYRON ROBINSON, B. S., M. D.,
Chicago, Ill.

I. THE SWAN-SHAPED DILATATION OF THE URETER.

For years in autopsies I had noted ureters dilated in certain shapes from different causes. However, one form of ureteral dilatation arose with a certain frequency. I have termed it the swan-shaped dilatation of the ureter. It consists in the ureteral pelvis assuming a dilatation in the form of a swan, as may be observed in the accompanying figure, No. 1. The explanation of the dilatation is that in certain kidneys the neck of the ureter lies in a groove in the distal renal pole, firmly bound by connective tissue. The renal groove and firm encasing of connective tissue enables the ureteral neck to withstand more dilating force than the ureteral pelvis, which gradually becomes more and more expanded. So far I am not aware of the present explanation being elsewhere presented, and it is original with me.

In the accompanying figure of a swan's neck dilatation of the ureter, it appears that the etiology was ureteral valves (V). Perhaps the prostatic hypertrophy (L), and especially the hypertrophy of the middle lobe of the prostate (T) enhanced the ureteral dilatation. The bladder presented extensive hypertrophy and vesical calculus at V.

SWAN'S SHAPE DILATATION OF URETER.

Fig 1.—This illustration was drawn with extreme care from a specimen which I secured at an autopsy through the courtesy of Prof. W. A. Evans. 1. Calyces; 2, dilated (swan shaped) pelvis; 3, ure-

teral isthmus (proximal); 4, lumbar spindle; 5, middle isthmus; 6, dilatation of the pelvic ureter, showing three valves on each side (V); 7, distal ureteral isthmus. The specimen is accompanied by the sympathetic nervous system. S and P, abdominal brain. right side has two renal arteries and spermatic vessels. The left side has spermatic arteries, but one sperm vein. The dilated ureters are surrou by a network of nerves.

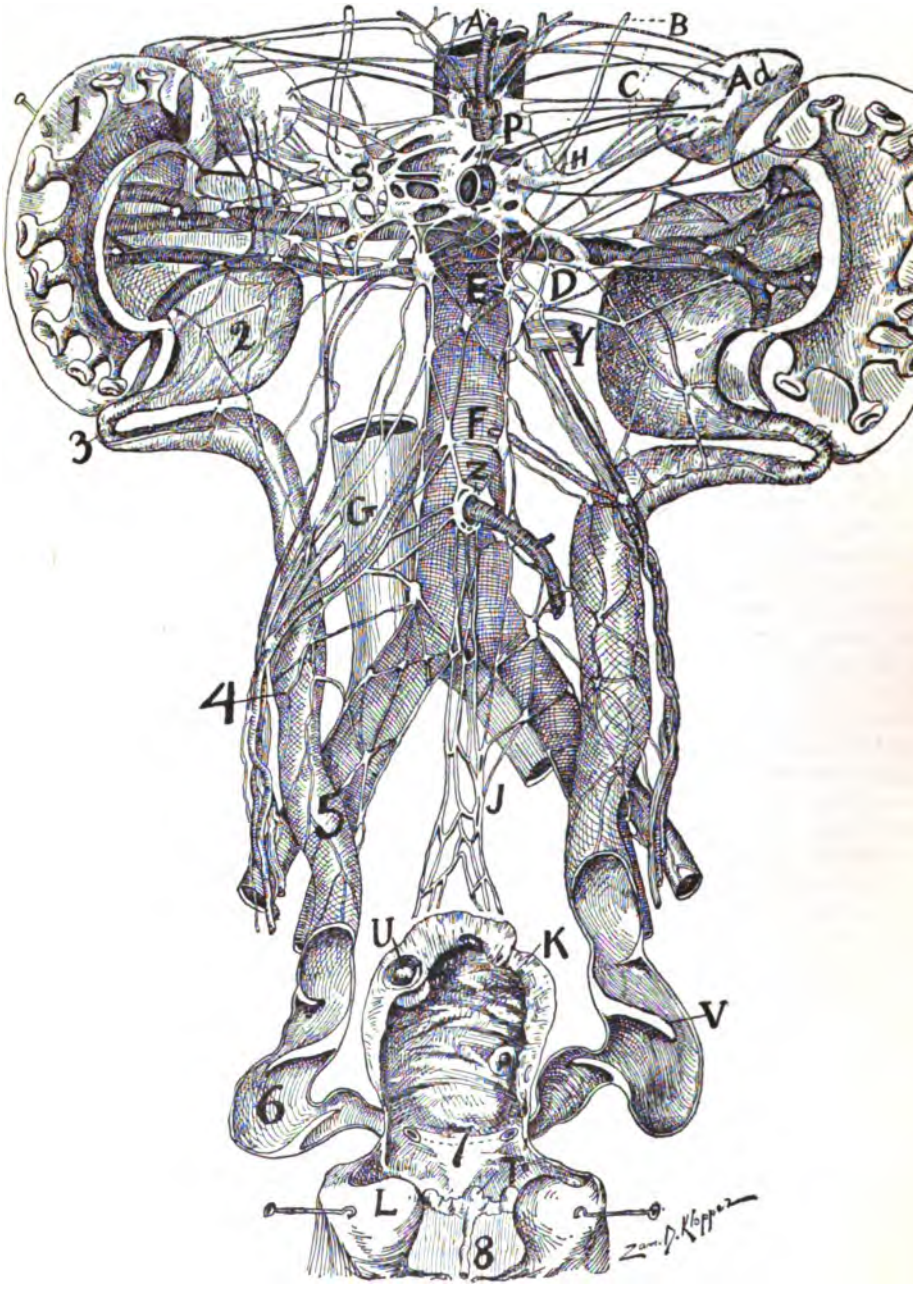

FIGURE 1.

II. CONGENITAL DISLOCATION OF RIGHT KIDNEY.

The accompanying illustration (Fig. 2) is an instructive phenomenon to the practitioner, as relates to diagnosis and surgical intervention.

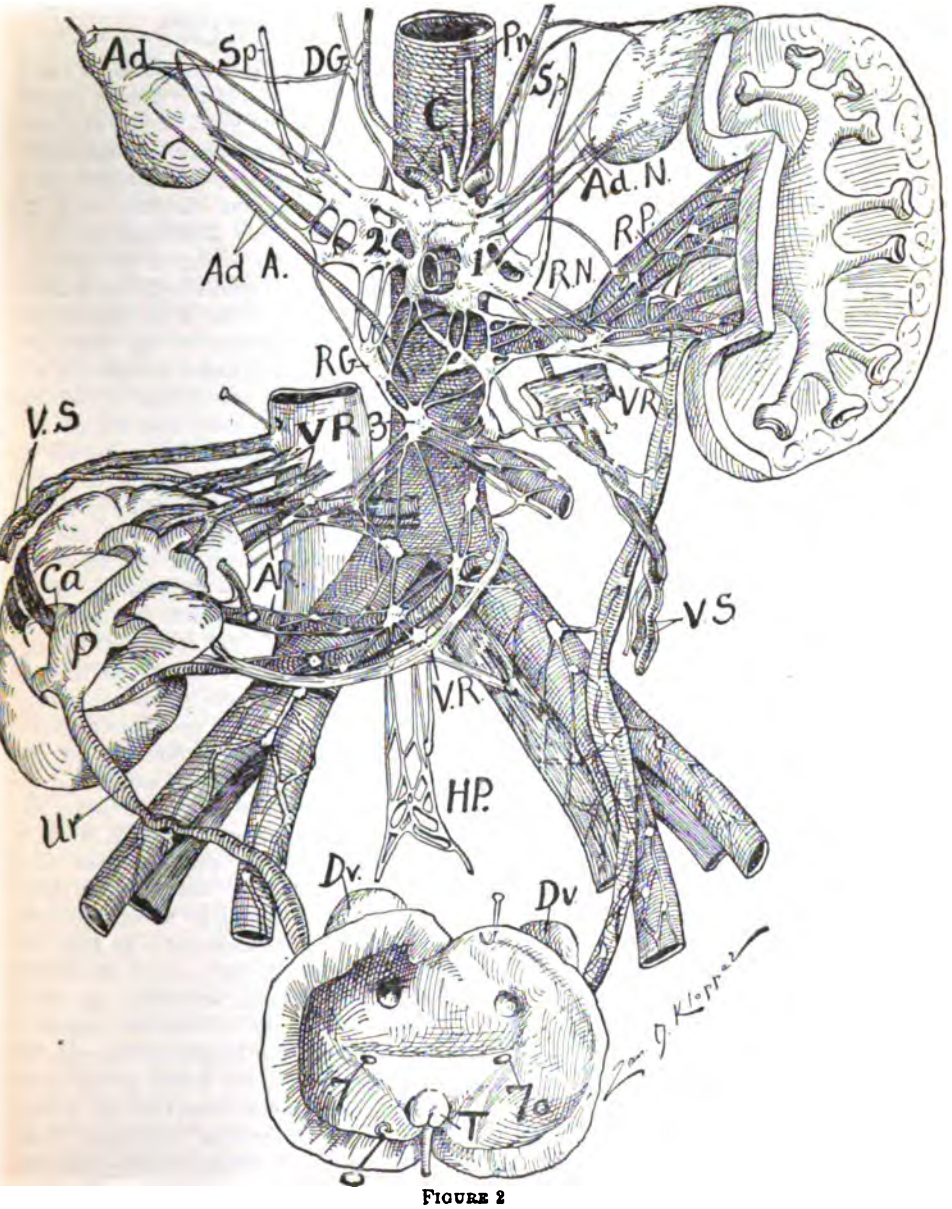

FIGURE 2

The adrenal is in its original location, and appears to have appropriated the renal artery for nourishment. However, the kidney possesses a spermatic artery and vein (V. S). This illustration makes prominent the general proposition that anomalies do not occur singly. The right kidney is nourished by one large artery from the abdominal artery (accompanied by two veins in V R), and by one large artery from the left common iliac (accompanied by a vein), the origin of which is the left side of the vena cava, and one vein originating in the left common iliac

vein (V R). The ureteral pelvis (P) is practically external to the kidney, *i. e.*, it is not in the renal sinus. The kidney (right) has no renal hilum. The left ureter is 11.5 inches in length; the right is five inches in length. This dislocated right kidney could be well palpated during life. The bladder possesses numerous diverticuli (DV) and (DV), which were one and one-half inches in depth, and would retain a tablespoonful of fluid. The bladder wall was hypertrophied, as well as the middle (only) prostatic lobe. The kidneys are drawn from exact measurements. The right was three and one-half, and left was five and one-half inches in length. The right had about one-half the amount of renal parenchyma of the left. The location and distribution of the sympathetic nerve was also abnormal, as noted in the second illustration. The rotation of the right kidney is due to the larger blood vessels supplying the dorsal lip of the renal hilum, which forced the dorsal renal lip ventralward, and finally lateralward.

CONGENITAL DISLOCATION OF THE KIDNEY.

Fig. 2 is an illustration of dislocation of the right kidney on the right common iliac artery. It had a double renal artery as well as duplicate renal veins. The adrenal is normal in location. The left kidney is normal except it is hypertrophied (compensatory). The right kidney is rotated one-quarter of a circle, presenting the calyces and pelvis ventrally. The rotation consists in the dorsal lip of the hilum passing ventralward and lateralward. This is due to the larger blood vessels supplying the dorsal renal lip. The sympathetic nervous system, especially the ganglia, are abnormal in location, dimension and number. 1 and 2, abdominal brain; AD, adrenal; DG, diaphragmatic ganglion; S P, splanchnic nerve. This rare specimen I secured at an autopsy through the courtesy of Prof. W. A. Evans.

100 State Street.

I wish the MEDICAL BRIEF all success. There are too many good things in it to be lost for the omission in sending one dollar a year.—J. C. LOVEJOY, M. D., Bachellerville, N. Y.

[Written for the MEDICAL BRIEF.]

Potential Energy, Irritability and Stimulation, the Indefatigable Factors of Life, Health, Disease and Death.

BY WM. PROTZMAN, M. D.,
Lincoln, Neb.

I do not intend this article to be a mo umental revelation of the hidden myste ies of nature, neither do I make any gre pretensions to psychology or metaphysic nor that I am possessed of a sagacious brilliant imagination, clothed with th charms of seducing language, but in unique and synthetic way I do claim th right through the columns of the BRIEF awaken the empirical drift, morpholog and miragic slumbers of our noble pr fession upon the dynamic forces and ph siological laws of nature that govern an control the human body, and if I shall successful in arousing the potential e ergy of a solitary molecule in the bra of a single reader of the BRIEF, I sha feel myself amply paid. I will ask a answer my own questions, and allow yo to be the judge. First. What is life? answer, life is an attribute of three co mon factors, viz., (1) potential energ the power of matter; (2) irritability, th distributing and motor power of energ and (3) stimulation or excitomotor pow of irritability; these factors are not co fined to the human body alone, but a found in all kinds of matter, whether an mal, vegetable, or mineral, in a latent inactive state (*nil*) and harmless whe undisturbed, but the Creator of all thing devised certain means by which these fa tors could be utilized, such as food, a water, chemicals, light, heat, electricit mental and physical exercise, and man other excitomotor stimulants, some which are constantly stimulating the fa tor of irritability, the motor power of li that liberates, converts and in disea perverts the factor and liberation of e ergy. Now then, when we take into co sideration that every action and though every movement of muscular and nerv fiber, the vibration of every atom an molecule which depends upon the liber tion of one or more of these factors, do it not make life a very interesting stud

for the erudite student of medicine? The exhaustion of potential energy in the human body is certainly very great, as every action and thought, every movement of muscular and nerve fiber depends upon the liberation of this factor; it is the mother of all other energies in the human body, its nutritive resources are derived, according to physiological chemistry, from the proteid or albuminoid food. Now then, cut off the appropriation or liberation of this factor and the human body can not survive a moment. It stands in the same relative position to other energies and functions of the human body as fuel coal stands to a steam engine; whereas, without fuel the engine is dead, unable to turn a wheel and will decay and rot, but if we use a small quantity of fuel the wheels begin to turn, when we add more fuel the wheels increase their revolutions in accordance with the amount of fuel used. So, in like manner, in the absence of liberated energy the body is not unlike the engine without fuel (dead); when there is a normal amount of energy liberated we have health, but where there is an excessive or deficient amount of energy liberated, we have excessive or diminished oxidation of tissue, and a pathogenic condition for disease.

Yet, with all this wonderful locomotive power, potential energy has no control over its own functions, is dead, cold, and lifeless; but old Dame Nature provided a means by which its functions could be utilized, and gave us the factor of irritability, clothed with the phenomenal power to liberate, control, convert and pervert potential energy into kinetic, chemical, physical, heat, and other energies of the body. We also find that the factor of irritability is not unlike the factor of potential energy, has no control over its own functions, will decay and rot, side by side with potential energy when unmolested. But Nature, again, in her wise provision, created a third, or stimulant factor, to liberate the functions of irritability. Now then, this indefatigable law of the different factors we see exemplified in the meteoric stone that is floating in space, cold and lifeless, yet full of energy and irritability in a latent state, but when the stone is attracted by the earth it falls; when it strikes the earth the concussion arouses the stimulant factor that awakens the factor of irritability that liberates a surplusage of potential energy, causing every atom and molecule to vibrate persistently, which produces kinetic energy, and the stone becomes red hot. Or a keg of powder, full of energy and irritability, will also decay and rot when undisturbed, but when we apply an electric spark we have instant explosion of protoplasm. We also see the effects of the physiological laws of nature exemplified in many different ways. We see them exemplified in procreation, or beginning of life, when the sperm of the male and the germ of the female come in contact; both full of energy and irritability, have no control over their own functions and are cast off as effete matter, unless a third or stimulant factor that is contained in the maternal circulation awakens the factor of irritability that liberates the potential factor, and that moment both life and soul of man are created. I do not believe that the soul of man is hovering in space awaiting an opportunity to vitalize a fecundated ovum. We also see these laws exemplified in the administration of remedies; the intelligent physician never prescribes stimulant remedies in fever with a temperature of 102.3° or 102.4° F., and why? I answer, the stimulant factor from some intrinsic or extrinsic cause is already unduly excited, from which there is a surplusage of energy liberated that causes excessive oxidation of tissue, on which the heat of the body depends, but when the physician finds a sub-normal temperature, with vital powers ebbing, he (the physician) at once prescribes some powerful stimulant to arouse the factor of irritability and liberation of energy to vivify the circulation by increasing the vessels of the heart, and oxidation of tissue to restore the normal heat of the body. The law of conversion and perversion of energy applies with equal force to mental emotion over organic functions of the human body; as an illustration, take a strong, muscular man with equal strong will power; yet we find in disease surrounding environments a potent factor in his death or recovery. We also read in physiology where scientists experimented

upon the minds of condemned criminals to test the power of mind and its influence on the human body, when the criminals died at the appointed time set by the scientists without any organic disease of bodily tissues. The physician sees daily examples of will power and mental emotions over the bodily functions when he visits the sick room, the patient at once reads the doctor's countenance, as well as every action and movement of his body, etc. Therefore, the physiological sunbeams of a physician's countenance and actions are veritable factors in the presence of a sick patient. They will illuminate fresh hope in a patient's mind, restore tone to his nerve centers, calm hyper-excitability, restore brightness of intellectual vigor and establish co-ordination of the circulation and functions of his body, all of which can only take place through the normal functions of stimulation, irritability and potential energy. But how often do we see these warnings violated, especially among the noted and rich men of our own country. In proof of this arraignment, when a noted or very rich man is taken sick with a temperature of 103° or 104° F., his friends become alarmed, and at once notify three or four noted physicians to hasten to the bedside of the patient, where they hold consultation after consultation, both day and night, and appoint one or two of their number as watchers to observe every symptom and change that may take place during the night, etc., regardless of the effect upon the patient's mind. Pathogenic microbes, blood, urine and organic tissue changes attract their special attention for the newspapers, and to satisfy the clamor of an excited public. During the excitement in and about the sick room, usually the patient is perfectly conscious of surrounding conditions and this, together with the presence of three or four eminent physicians, causes the patient to believe that some grave disease has attacked him, from which he can not recover, etc. When his mental emotions over-stimulate, the liberation of energy raises his temperature two or three degrees, until the factors of energy, irritability and stimulation exhaust themselves and the patient dies from physical and mental anemia; whereas, if one or two competent physicians would give apply the same remedies with words good cheer and encouragement to sti late his confidential hope, sagacity physiological laws of nature of his bo the patient would have much be chance for recovery.

Health.—In addition to what has ready been said in regard to the functi of energy, irritability and stimulat we find their attributes or accessory gans, called leucocytes and phagocy that are constantly standing guard to tect the human body in every resp against poisons, contagious and infecti germs, especially exemplified in imm persons.

Disease.—I do not wish to be un stood by the readers of the Br that disease, whether mental or p sical, is entirely due to the perver of the afore-named physiological fac of the human body, as I am well aw that a want, or perversion, of the elen tary principles of tissue, viz., iron, po sium, magnesium, phosphorus, lime sodium, are not only contributing, primary causes of disease. Sometir also, pathogenic microbes, chemical other poisons will produce disease. H I answer, by causing molecular char that stimulate the irritable and poten factors that increase the circulation oxidation of tissue, with increased l and general heat of the body. Now t while the physiological factors of the man body are not directly responsible every disease, yet without their operation disease could not exist.

Death.—Death, we are told by physi gists, is the last effort of muscle plas and the formation of sarcolactic acid. addition, I will add, a cessation of at ico-molecular changes and prolifera of cell growth and development, cau from want or appropriation of the mentary constituents of tissue that controlled by the three principal fac of the human body, viz., stimulation, tability, and potential energy.

And now, in concluding these uni synthetic and, perhaps, miragic or l brative thoughts, etc., allow me to that, while I have no implacable des or malevolent feelings against any the or school of scientific medicine, I ask

eaders of the BRIEF, with its forty-odd housand subscribers of educated men, re we not daily prescribing remedies mpirically, instead of physiologically? o we not prescribe remedies because our xperience and our books have taught s to prescribe them without a moment's hought or reflection how those remedies ntagonize pathological tissue changes, r how they affect the physiological laws f the human body?

[Written for the MEDICAL BRIEF.]

A Queer Case.

BY JOHN C. WEAVER, M. D.,
Apopka, Florida.

On April 23, 1905, I was hastily summoned to Mrs. H., aged twenty-eight, white, multipara; approaching her bedside, found that she was having convulsions, and had had, up to the time of my visit, five very hard ones, coming on at short intervals. Being alarmed at the situation, I resorted to venesection, taking about a half-pint of blood from the left arm. I also used chloroform inhalations during paroxysm, and afterwards veratrum viride hypodermically. This treatment seemed to control the spasm, as there was no return.

I found this woman seven and one-half months advanced in pregnancy, with general anasarca, and most of the secretory organs inactive. I got the bowels and kidneys acting freely, and the swelling was soon reduced. For two or three days following the convulsions she was, to a great extent, unconscious, not knowing even her husband or children. When consciousness was restored, she complained of being blind, and could not believe that she had been sick. Everything appeared to her as a dream.

During all this time she suffered no abdominal pain, and no uterine contraction took place.

Up to the time of the convulsions she felt the motion of the child, but since then there had not been the least movement. Within a week from the date of the convulsions, she was up and about her usual vocation, seeming well and hearty, with a good appetite, and not the least swelling about the body.

On June 10th, six weeks later, I was again summoned, as she had now reached the full term. I found her in labor with a breech presentation. The delivery was quick, but, of course, the child was dead. In previous pregnancies the placenta had always been retained, and she suffered from great loss of blood.

On this occasion she and her husband were both delighted that the placenta had come away entire, and not the least loss of blood. I will state also that she had no afterpains, and her breasts gave her not the least trouble.

Query.—1. Were those convulsions uremic?

2. Could the child have remained in the uterus six weeks dead without having undergone decomposition, or having set up uterine contraction?

3. Is it not possible that the child could have received through the placental or umbilical cord enough sustenance to keep it viable, and yet not enough to give it strength for movement?

4. Was I justifiable in my course of action as regards this particular case, or should I have brought on premature labor, as many would have done?

5. Would not the forcing of labor have been more detrimental to my patient than the leaving of it to Nature?

I trust the BRIEF readers will throw some light on these questions, as they are really interesting and important.

[Written for the MEDICAL BRIEF.]

A Few Jottings from Arkansas.

BY W. S. ROBINSON, M. D.,
Nashville, Ark.

First, in all cases of sickness the physician must be master of the situation, and should be well-grounded in physical diagnosis. From day to day he should have in his mind's eye a clinical picture of diseased conditions, and remember that the supreme element in all diseases is rest. Especially in typhoid fever, complete rest in bed is imperative from the first day that the disease is suspected. The bowels should always receive prompt and careful attention from first to last, keeping them aseptic, if possible. A few

small doses of calomel given early and sometimes later in the course of the disease, I believe are helpful. Active elimination through the kidneys is always necessary. A generous supply of pure water usually attends to that point. As to the different plans suggested in the treatment of typhoid fever, they are as many as there are "boodlers" in hades, and every fellow reports success. I am in favor of a great deal of common sense and very little medicine in this disease. In the matter of nourishment, a moderate amount of liquid diet is allowed, buttermilk being my favorite food. A good nurse and no visitors are always desired.

In penumonia, watch the heart carefully, as it is the index to prognosis and treatment, the main point of the latter being to judiciously sustain the heart and treat other factors symptomatically. All cases should not be treated alike. "Individualize your patients, gentlemen."

In malarial hematuria, I believe that quinine is indicated, as in all other malarial diseases, but it should be given intelligently. I often find articles written on the treatment of malarial hematuria wherein the writer is a great advocate of quinine in this disease, but whose views do not conform altogether with mine in its use. I never give quinine until elimination is well under way.

As a vaso-motor stimulant in surgical shock, atrophine is the first thing to use.

The less the doctor knows of aseptic rules in obstetrics, the more cases of puerperal fever he will have. The most common infection is saphrophytic, or the germs of decomposition. As a general thing the patient seems to do well for forty-eight hours after labor, then becomes somewhat restless, with slight elevation of temperature. In a few hours it runs up to 104° or 105° F., with swelling and tenderness of the abdomen. Under gross carelessness, as a general thing, you have let your patient get into this condition. Now what are you going to do? As for my part I would treat her the same as I would infection of a wound from any other cause. Clean out the vagina and uterus thoroughly, with dull curette, and thoroughly irrigate with a hot solution of permanganate of potash, hot as tissues will bear; give chlorate potash internally, and apply turpentine stupes over bowels.

In these so-called "congestive chills give calomel in small doses, to elimi waste matter, and to prevent a subseq chill after elimination is sufficiently vanced, as shown by the tongue, skin mental condition, begin with quinin solution, with diluted hydrochloric If you will keep your patient under influence of hypodermics of atropine the first forty-eight hours, until you get in your quinine, he will not ha second chill.

Atropine will stop a chill and is on our best hemostatics.

"Bed wetting," the diagnosis of in tinence of urine, is not a difficult ma but to determine the precise cause of incontinence is often far from easy. the treatment by far the most succes drug I can use is belladonna. A dos five to ten drops of the tincture may given to a child three times a day. remarkable how resistant children to the action of belladonna. In dribb of urine, in the aged, as well as in tinence in children, I have found following prescription to be excellent

℞ Thuja Oc. Fld..... 1½ drac
Tinct. Belladonna .....30 drop
Aquæ.....q. s. ..... 4 ounc
M. Sig.: Teaspoonful three or four times a

Pain extending over the entire abd inal region and tympanites is very c acteristic of peritonitis. Now, as reg treatment: As a local application I rec mend turpentine stupes. As an inte remedy I prescribe some good prepara of opium.

I am opposed to treating cancer by knife, when seventy or eighty per die. Here is a remedy I have been u in my practice when a case presented self for treatment, and I do not rem ber of a single instance where it faile cure. It is this: Take galangal root, g to fine powder—sufficient to make sev plasters—then take zinc chloride, ad little water, and allow the zinc to bec thin by heating in warm water; then the zinc chloride to the pulverized ga gal root; make plaster and apply to cancer. Renew every day for three four days, until the cancer begins to br loose all around, then discontinue plaster of the galangal and apply

good salve until healed up, which will be in the course of ten or fifteen days. I have cured somewhere near fifty cases with this treatment. There is no danger in it.

Drug Habit.—I am permanently (satisfactorily) curing all that come (and there are many) with the hyoscine treatment. I have them ready to return home inside of eight days. I have them often that take one hundred grains of morphine per day.

The Sex Question.

BY SILAS HUBBARD, M. D.,
East Aurora, N. Y.

I see by recent numbers of the BRIEF that G. W. Bowen, M. D., and T. E. Reed, M. D., are each respectively advocating new theories of the sex question. Their views join, and I will endeavor to make their theories join and will endeavor to show how they may both be right to a limited degree, although neither of them know how or why they are so. To help them out better, I will say that in 1850 and '51 and '55, I published for the first time, in the *Buffalo Medical Journal*, that ova of the human subject, if impregnated while recent or immature, developed into males, and if impregnated while mature or old developed into females.

Dr. Bowen says children begotten in the fore part of the night, till midnight, are females, and those towards morning are males. There is a shade of truth in this, because the weakly and cross women will generally submit to intercourse only in the fore part of the night before sleep has overtaken them, and that class of women are they who have the most girls. They do not allow their ova to become impregnated till they have come down into the uteri and have become mature or old, while the healthy, vigorous women, if they do not initiate proceedings, at least will not object to being awakened in the morning, and thus with them a fresh or immature ovum is more likely to be impregnated, consequently such women are more likely to produce a majority of males. They give more than two chances for the impregnation of a fresh or immature ovum to the weakly woman's one. I will here say that the very great majority of the human race are begotten during these two periods, viz., the fore part of night and the morning.

Now, as regards Dr. Reed's theory about males being begotten during the flow of the tide, and girls during the ebb of the tide, I will say that the perfection of the flow of the tide is in the daytime under the attraction of the sun. I will say that in general only vigorous, healthy women will initiate or submit willingly to intercourse during the day or under the influence of the sun and consequently they give more than twice as many chances for immature ova to be impregnated, consequently they produce more males. The vast majority of mankind are born without any design or intention of the parents what the sex shall be.

The strong, active women abort more of the impregnated ova which would have developed into females, because the ova are low down in the uterus, and her wide-awake activity causes the abortion, while they retain the fresh or new ova which were impregnated in the tubes, and had acquired attaching powers by the time they entered the uterus, while the weakly women, in consequence of their sedentary, slow habits, are more likely to retain old ova, which have been impregnated while in the uterus, consequently they produce more females than males. I will here remark that very many more girls in general are aborted than boys, which I will not now explain.

The weakly, or cross women, lack encouraging psychological and physical effects to the male, and thus they do not give one-half the chance of new ova being impregnated, consequently they produce a majority of females, while the healthy, active, amiable women have an encouraging psychological and physical effect on the males. Consequently more new ova are impregnated, consequently they have more births of males.

There is not in general very much anxiety through the United States and France to know how to beget boys or girls at will. There is in general much more anxiety to know how not to beget either.

I will repeat my former sayings that boys are generally begotten shortly before menstruation, and girls shortly after menstruation. That the ova shortly before menstruation are fresh or new, and shortly after menstruation they are mature or old.

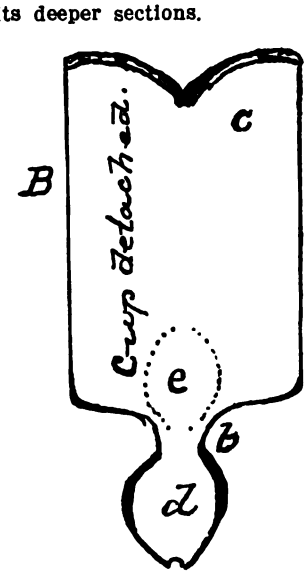
[Written for the MEDICAL BRIEF.]

An Improved Syringe and Urethral Irrigating Nozzle.

BY FERDINAND KING, M. D.,
New York City.

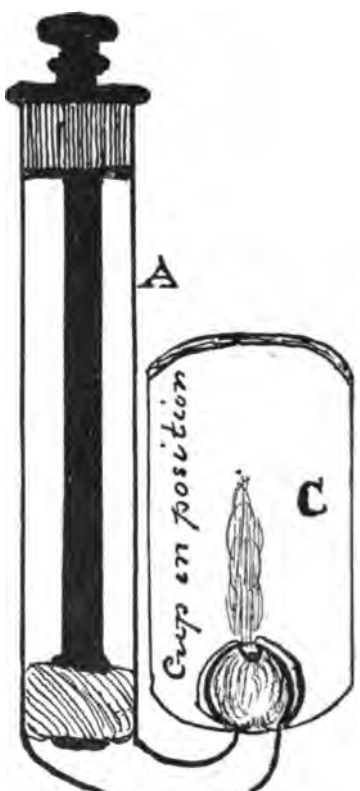
A careful study of about one hundred cases of gonorrhea treated by the irrigation method during the past year, has convinced me that the gonococcus, if left alone, will not invade the urethra to a greater depth than its first bend, which may be said to be at a point corresponding to the peno-scrotal notch, or between the cruræ, when the penis is at rest.

It therefore occurred to me that this organ should not be lifted upward (and thus straightened) during the process of injecting or irrigating the urethral canal, if we would avoid forcing the gonococci into its deeper sections.



To inject or irrigate the urethral canal in accordance with this idea, I devised the syringe and cup here shown and described.

The syringe, as to barrel and pistol plunger, is similar to those already use, but its distal or pointed end is like a shepherd's crook, and looks up



when held in a line with the opera body and with the plunger pointed d wards.

The barrel of the syringe may be m of hard rubber or glass. The soft ru cup (C and B) is slipped over the n of the syringe by self-invagination, by pushing its point (a-B) upw through its own neck (b-B) into space within the cup (e-B). The tip therefore, supplies a rubber cover fo nozzle of the syringe or irrigator (e-

The cup, which is made in three s fits snugly over the glans penis, and penses with the necessity of the pati fingers coming in contact with the o thereby removing a fruitful source o fection.

In like manner the cup may be fitt the nozzle of the ordinary wall irrig

Enteric Fever Jugulated.

BY JOHN T. DE MUND, M. D.,
Ridgewood, N. J.

Cui Bono.—Progressive therapeutics always enlivens the interest to make pathology subservient to physiology.

In the treatment of fever, be ever careful not to harm the delicate mechanism of the human system. The solution of the electric enigma has been solved, making it an epoch in the wholesome advancement in medicine.

Medicine the writer looks upon as nothing more and nothing less than "chaos confounded."

In the healing art, the *pros et cons* enameling the *Pev Sceintiæ et Aete* of the present day are as the quicksands of tentative tautology, which so often beggars description. The inexactness of medicine as a science is irrefutable.

When we think, but for the life of us we do not know, Common Sense politely invites us to go way back and sit down; for as there is life in medicine, there is also death in disease.

The simplicity of the best treatment, with its flush of success, far outweighs the complicity of incomprehensible custom and usage. Custom so often so metaphrastic, usage so repeatedly paraphrastic, that the pessimistic optimists—the survival of the fittest—is like sounding brass and a tinkling cymbal.

Cold and caloric, fruitful factors, though one the antithesis of the other. Note the shiver of the physiologist, and the blush of the pathologist; also, the nidus and the germ, pet prerogatives of assailments. It seems a hard matter to get the physiologist to admit that cold contracts in *statu quo*, while heat expands and eliminates—this we know. The practical part of theory is almost always at swords' points.

The radical or enforced reductions of temperature by the cooling process, centefebric, wholly by the use of selected drugs, thus signaling the downward drop in the scale of caloric—making a "minimum of the fever curse"—to its normal condition in the human system is as attractive as it is instructive.

Fever, so-called pyrexia, is nothing more or nothing less than a morbid increase of vitalized caloric. It may be termed an acute affection of the system, characterized by increased heat of skin, increased frequency of pulse, with a general derangement of the whole system.

Defervescence, lysis, recrudescence crises, if not nipped in the bud must undergo the procrastinating process toward recovery. From all of which the good Lord deliver us. These are facts.

The late Professor George B. Wood, of Philadelphia, the author of "Enteric Fever," with his lucid interpretation of enteric fever, proved himself to be a true clinician, the enteritician of his day. Wood with his terebinthinate treatment in this fever, could well afford to say, "What do I teach?" I am not aware the cold tea preparations were in vogue in his day. Turpentine and acetanilid, in combination, when called for, give the eureka of satisfaction.

On the other hand, the late Professor Louis, of France, Woods' contemporary, with his hybrid typhoid, evidently a devotee of typhoidal illusion, gave to the profession the "Signal Points," "The Right and the Wrong." The acuteness of the former and the sub-acuteness of the latter, speak for itself. It is hardly necessary to dispute the neologico-nosological part of this matter-of-fact statement.

If you ask a person for a crowbar and the individual hands you a monkey-wrench, would it enable you to make the crowbar of disease the monkey-wrench of health? Absurd, indeed! A step farther, "Trying to Teach Ducks to Swim," "The Tall Treatment," well meant, but by no means backed by physiology, is superlatively preposterous!

Take him up tenderly, lift him with care;
Purgatorial Probation—he is getting it, for fair.

Call you this scientific? Yes, "*sigh*-entific!"

The hybrid treatment for a hybrid disease; its analogue is, "onology." It is but human to fight the disease, as it is inhuman to fight or toy with the victim of circumstances.

Enteric fever is a fever *sui generis, per se*, its "countersign," the abdomen. Prodrome—week or two, more or less. Habitude, cephalalgic epistaxis, rose-colored

spots, "little jokes," meteorism, portal derangement (for as is the portal circulation so is the individual), "and all the doctors in the land" will find it so.

On applying both hands over the abdomen one can almost cover the nidus of this fever. The catarrhal complications and the enteric erosions of enteric fever are best combated by pillowing the patient's head, strictly enforcing the horizontal position, thus as it were "splinting" the bowels, thereby getting an early metabolism, instead of the tedious meteoric perverted cell action so characteristic of this fever.

Glands of Lieberkühn and of Brunners, solitary glands, agminated glands, or Peyer's patches. Herein lies the infected nidus, and the sparks that kindleth.

If retrograde advancement is anywhere to be found it is in the healing art. It droppeth as a thunderclap from a cloudless sky. The wherefore and the why is history.

To jugulate, nip in the bud, or abort, is all very nice in print, but it takes a very nice and level-headed clinician to accomplish the wished-for result. Close observation, years of experience, and a natural predilection has much, every way, to make the effort a success.

In medicine we are all prone to vex the question. Be fair; let us agree to differ, for by so doing the patient may get the benefit.

The epitome of nutshell conciseness, in my humble opinion, far outweigh the plagiaristic platitudes of Greek and Latin nomenclature so frequently and so fearfully distorted that there is often no sane resemblance to the mooted object in view.

Is it not unfair for our children to be allowed or encouraged to follow in the wake of our inexcusable ignorance or plausible perverseness?

The jugulating treatment which has given the most satisfactory results, is as follows: Put your patient in bed, and keep the patient in bed until the patient obtains the consent of the physician to leave it—out of all danger. A good and safe plan. To unload the *primæ via*, a fair dose of calomel, followed in two hours with a seidlitz powder. To increase peristalsis, soapsuds enemata as occasion requires. Note the temperature carefu yourself; visit your patient four time day for the first three days. If there no rise in temperature, so far so go *cæteris paribus*, you may look for early defervescence. This will test ability of the medical attendant. Spo ing with warm water or alcohol is tional, flannels steeped in warm camph ated oil and applied over the abdon have a two-fold effect. As a rule, patie should have a good supply of pure wa Small pieces of cracked ice in the mo is a harmless luxury. Lithia, about tw ty-four grains in twenty-four hours, w diluted, flushing the kidneys, as it w imperatively. The diet should be sim nutritious and of easy assimilation. uid diet for six weeks is the safest. M and liquid peptonoids, as a rule, chime beautifully. Be ever mindful of the valescent stage.

The two following formulæ merit sideration:

℞ Acetanilid.....1 scrup
Spts. Terebinthinæ.....2 drach
Tinct. Opii.....2 drach
Tinct. Acoine.....½ drach
Syr. Acaciæ.....3 drach
Aquæ Dest.....q. s.....4 ounc

M. Shake well. Sig.: Teaspoonful every t or four hours, day and night.

℞ Acetanilid.....1 scrup
Quin. Sulph.....1 drach
Spts. Nitre Dulcis.....1 ounc
Tinct. Acoine.....½ drac
Aquæ Dest.....q. s.....4 ounc

M. Shake well. Sig.: Teaspoonful or two required, every four to eight hours.

Each dose goes to the spot, as your tient will often tell you.

P. S.—An eye to the splenetic compl tions.

Once more, pin-head doses of calome the tongue, to tone down the derangen of the portal circulation. This should be neglected.

I have learned a little by experie and have made as big mistakes as man living—it seems a part of the fession. In some cases, the medical tendant may be inclined to doubt the rectness of the diagnosis. The drop in temperature and the continued drop i interesting as it is instructive. The j lating part is doing its work. For m years I entertained a very different of this matter. But none so blind as t that will not see.

If under the canopy of heaven ther a line of treatment with its quick

satisfactory results superior—as given in the weak outline of this paper—why delay the opportune moment for its publication?

Citation of three cases, to avoid the prolixity of unnecessary repetition: Young man of plebeian poverty, not even a bed, only an apology of a lounge; no change of raiment; no nurse, only a woman in the hovel to hand him his scant diet. Recovery very satisfactory. I made twelve visits.

The other two cases in comfortable compartments, both large men, one an M. D. graduate of Cornell; the other a layman. Enteric fever stamped each victim with all its iridescence. The M. D. had been complaining for two weeks. After taking to his bed his fever left him on the "fifth day." The layman on the ninth day. Loss of flesh and emaciation, whether due to the nip in the bad treatment, or the result of the disease vexes the question. Their recoveries O. K. A gain of about thirty per cent. Now for the incredulity of opposing ostracism:

ENTERIC VERSUS TYPHOID.

Enteric is generic, how much in a name!
Typhoid from τμφὸς—stupor, hard to explain,
Let the mistake be corrected,
Let the right be interpreted,
The public will thank you,
Your conscience will bless you,
One among many or none.
Let the scholars "en classe"
Go for their instructors "en masse"
As a beau and his lassies,
May the quarrels prove fun,
Let your children be taught
O'er the length of the land,
What is classical is classical,
Onology—so Jackassical.

Typhoid is One.

[Written for the MEDICAL BRIEF.]

Hydrophobia Versus Madstone.

BY WM. H. TATE, M. D.,
Tackett's Mill, Va.

Since we are just passing through an excitement of hydrophobia among dogs, with a possibility of witnessing, perhaps, a case or two in the human family, consequently, I am inclined to write a short article on that disease, with a few comments on the madstone.

That hydrophobia is a disease caused by inoculation with the saliva of a rabid animal, and characterized by intermitting spasms of the muscles of respiration, together with a peculiar irritability of the body and disturbance of mind, is an indisputable fact, and as prevention is better than cure, it is very necessary that every physician should know the symptoms in the dog, and most especially the earliest symptoms. First we have unusual sullenness, fidgeting and shifting of posture. Sometimes the animal will retreat to his bed, where he will lie curled up with his face between his paws.

Then he becomes fidgety, continually changing his resting place; he appears clouded and suspicious in his countenance, and gazes strangely about him as he lies on his bed. A peculiar delirium is also an early symptom: The dog sometimes springing up and giving an angry bark at some imaginary object, but if his master speaks to him, every fancied object will disappear, and he will crawl toward him with his usual expression of attachment. Sometimes it seems as if his feet would give way and he would fall, when suddenly he springs up again, every object of terror seeming to surround him; gazing wildly around, he snaps and barks and rushes again to the end of his chain to meet his imaginary foe.

The amount of ferocity displayed by rabid dogs varies considerably. Some there are whose fury knows no bounds, and, if loose, rush about biting every man or beast in their way. Others, on the contrary, can not be made to bite, but in the earliest of the disease show an increased fondness for their master; hence some persons have been poisoned simply by having the dog to lick the hand, if perchance there is an abrasion about the parts.

Change of voice in the dog is an early symptom, such as a hoarse inward bark with a slight elevation of tone, and another most peculiar characteristic combination of a perfect bark, ending in an abrupt and singular howl.

According to the best authorities, there is no known specific for this disease. As soon as possible after the bite the wound should be sucked, and at the earliest possible convenience the whole wound should be excised, or cauterized, or both.

In stating that there is no specific for hydrophobia known to the medical pro-

fession, I would like to add that there is a traditional remedy which among the populace is regarded as not only specific, but infallible; that is the wonderful madstone, of which I suppose every boy and girl on the American continent have heard.

I have known several who, after having been bitten, have visited the madstone, and had it applied to wounds inflicted by dogs, and who claim to have been benefited by the application, but I have never seen or heard anything about it that had any tendency to increase my faith in any such superstition.

About three weeks ago my hired hand was bitten by my dog on attempting to chain him, and about two or three days after he received the wound he was influenced by his friends to visit the madstone, after I had cauterized the wound, and, as usual, he claimed to have derived all the benefit from the wonderful madstone.

Always having my conscience susceptible to conviction, though as yet not having been converted to the madstone theory, I would like to call the attention of the BRIEF readers, and the profession generally, to search for all the facts that may throw some light upon the efficacy of the venerable madstone, if there is any known, and by so doing might convert some one, and save a soul from death.

[Written for the MEDICAL BRIEF.]

Abnormal Eyesight—Responsibility for Its Correction.

BY WILMOT P. BRUSH, OPH. D.,

Fredonia, Pa.

Being a regular reader of the MEDICAL BRIEF with other periodicals pertaining to ophthalmology, and especially the branch known as optometry, the position of the glasses as shown in the frontispiece in the July issue of the BRIEF, Doctors Carmalt and Waldo, is, I think, of sufficient importance for some practical observations on eyesight work. All modern optometrists recognize the necessity of properly placing the lenses before the eye that comfortable, or easy vision, may be secured. The visual axes of the two eyes, the optical center of the lenses, and t angle at which the lens sets before t eye should be considered carefully, a if possible, adapted to the needs of t user. The optical center, when t glasses are used exclusively for eitl distance or near work, can be quite eas set, so as to avoid prismatic effects, b when the single lens is used for both d and near work, if set for distant objec and then the eyes directed to an obj at the usual working distance, say fo teen inches, the eyes turn down and the visual axis, instead of passing throu the optical center of the lens passes from the center horizontally,and do from the center vertically. If the le used is a plus or converging one, it thickest in the center, hence when t visual axis is turned in from the cen it is affected as though passing throu a prism base out, and if it passes do from the center it results in a prisma effect base up. In case that the lens us is a minus or diverging one, then t prismatic conditions are reversed, becau this form of a lens is thinnest in t middle or center. A prism bends or fracts rays towards its base, which in t case horizontally deflects the rays th enters the eye from the object to te poral or outer side of the macula, there compelling the brain to turn the eyeb outwards in order to bring the mac within the area of the displaced focus avoid double vision or diplopia. In c that the lenses are set so as to center near vision, and the eyes directed to so distant object, it results in the opti centers of the lenses being within t inter-pupiliary distance, too close, wh results in the rays from the object look at passing through prisms base in, a deflecting the rays from the obj towards the nasal side of the fundus, macula, thereby compelling the brain turn the eyeball inwards in order that t focused rays from the object may fall the macula and distinct and easy visi be secured, though at the expense of extra amount of nerve force to the ex ocular muscles concerned, and some d association of accommodation and conv gence. It is true, however, that where lens is properly set for either near distance vision the eye is directed

liquely, producing prismatic effects, but it returns and looks through the optical center of the lens, thus relieving the brain in its extra supply of nerve force used in overcoming the prismatic effects. Then, in case that one pair of lenses are to be used for both far and near, we divide the distance of the pupils apart when in the near vision, and the distant positions, using a focal point distant about twenty-four inches from the eyes of the patient. Now, the point that I wish to make, if point it is, is that however exact the refraction found and the lenses conform thereto, in order to have easy and comfortable vision the lenses should be properly set before the eyes.

The position of the eye-glasses shown in the photographic picture of Dr. Carmalt, shows him to be engaged in reading or near work, and undoubtedly looking more than half way between the optical center of the lens and its lower peripheral border, resulting in the effect of a prism base, up or down, as the case may be. In either case an undue effort of muscular action, or nerve impulse, is required. Thus far we have only referred to or supposed to be using spherical lenses, but when compound lenses are to be used the question becomes more complicated and requires even more care in the proper setting and the results to be attained. If strong and vigorous, which the Doctor looks to be, but little or no nervous trouble may be aroused, but in the case of one more susceptible or less vigorous, every modern optometrist knows the inevitable and sure result. On turning over a page in the BRIEF we note the position of the lenses before the eyes of Doctor Waldo. The right eye is looking about two-fifths of the distance outward from the optical center of the lens, whilst the left lens seems to droop downward, causing the visual axis of the left eye to be about two-fifths of the distance upwards from the optical center of the lens. The lenses may be, it is true, simple sphericals and of low power, and the wearer physically able, which he looks to be, to overcome the displacement of the focus of the two eyes without noticeable muscular trouble, or resultant eye-strain. On the other hand, the condition of the eyes may have been that they required the apparent decentration of the optical centers of these lenses, but every up-to-date eye man at once recognizes that if that were the case that such decentration could and should have been made before the lens was cut and edge ground, if for no other reason than that of having the frame set right for a better appearance. The main point that I desire to make is that the wearer of a correction should always be instructed how his glasses are intended to be adjusted, and it seems to me that all those engaged in the fitting of glasses should take pride in knowing not only how to refract, to diagnose disease, gain a thorough knowledge of the anatomy, and reflex nervous troubles, but be competent to measure for a frame, and see that it properly sets the lenses before the eye of the wearer. If the reader will but take the time and note the number of misfit frames that he may chance to see in a single day, he will, doubtless, if he have an ambition to do unto his fellow as he would be done by, resolve to become proficient in correctly fitting his patients with a frame affording the best possible vision within the purview of modern optometry. One has but to note the rapid advance made within the past few years in the art of correcting abnormal vision with lenses, and no single observation contributes more towards the conformation of this fact than does a perusal of the questions used by the California State Board at its last meeting, held in May, where but seven of the seventeen candidates successfully passed the examination.

[Written for the MEDICAL BRIEF.]

Blood Conditions in Rheumatism.

BY IRA B. BARTLE, M. D.,
Carmen, Okla.

There is a wide difference of opinion in regard to the exact blood condition encountered in rheumatism. In fact, almost as many different opinions as there are different observers. As to what condition these blood changes can be ascribed, is still a matter of doubt, as many of the blood conditions noted in both acute and chronic rheumatism, are nearly identical to those encountered in other acute and

chronic conditions; consequently, to base the diagnosis upon blood conditions alone, would be impossible. However, a close study of the blood in several cases of both acute and chronic articular rheumatism, convinces me that the causative factor of these diseases may be traced to conditions existing in the blood itself, and not, primarily, to deposits in the affected joints or muscles.

The average condition found in my blood observations were alkalinity, always present, gradually diminishing as the disease progresses, until, in a few instances, almost a neutral reaction was obtained. Increased fibrine, the time limit of coagulation is about normal. A diminution of erythrocytes, especially in the chronic cases; this diminution may amount even to a mild enema. Almost invariably there is an increase of leucocytes, especially in the earlier stages of the disease. The hemoglobin estimate is slightly higher than would be expected from the red blood count. Consequently, there is a disproportion between the hemoglobin estimate and the red cell count. The average count is four million two hundred thousand erythrocytes, with a maximum of four million five hundred and eighty thousand, and a minimum of two million eight hundred thousand.

The average hemoglobin per cent is sixty-five, with a maximum of eighty-four and a minimum of fifty-six. Some writers record much lower per cents and red cell counts, but these are the average in my experience, and it includes some very severe and protracted cases. Rheumatism, as a rule, attacks the full-blooded, gouty patient; consequently, prior to the attack, the blood count would naturally be at its maximum limit, and without having had opportunity to make a count prior to the attack, it would be impossible to know the exact amount of cellular destruction. There is a tendency, always, in these cases, to resume their original high-blood standard very shortly after recovery.

The theory of crystal infiltration or deposits in the myolema or muscular inter-spaces or the joints, is, I think, to be discredited, only as the secondary condition and not as a primary factor. Neither do I think rheumatism due to any specific, single micro-organism or plasmo
When the blood seems to be in a cer
condition, there is a predisposition tow
these crystalline deposits, and any distu
ance of the normal equilibrium may
cipitate an attack of rheumatism. I beli
that there are several micro-organis
which can bring about these blood co
tions favorable to crystalline depos
namely: Kleb's-Loeffler bacillus, strep
coccic, gonococcic, staphylococcic (t
limited extent), pneumococcic, bacil
associatus, influenza bacillus, etc.

The analogy between the disease cau
by this micro-organism and a post-rh
matic affliction, has been observed fo
great number of years. We expect rh
matism to follow diphtheria, and are
surprised to find it after scarlatina,
it has been observed that followin
grippal epidemic, we will have an unus
high number of cases of rheumatism.
observation in 1901, was that about tw
per cent of the cases of la grippe w
followed within two months with a n
attack of rheumatism. The epidemic
1903 showed a still larger percent
while the recent epidemic of 1905
not, up-to-date, shown so marked a t
ency toward this rheumatic condit
However, the blood picture in the att
of la grippe this year has been diffe
to that in the years before mentioned,
impoverishment being much more
found than heretofore, and our la gri
cases were of a much more acute type

It is my belief that, in the dis
caused by these germs there is an a
toxine elaborated, which is curative to
acute infection, although it brings ab
blood conditions which favor rheumati
I am strengthened in this belief on
count of my experience in the admi
trating of the various anti-toxines. In
use of anti-streptococcic serum in mi
tubercular conditions, I have always
attacks of acute articular rheumatism
lowing in from nine to twenty days f
the beginning of the administration of
serum, and the severity of the attack
not seem to be affected greatly by
amount of serum used. In writing
other physicians for their experience al
these lines, I find that they have enc
tered the same complication, with the
ception of Dr. J. T. Walles, of Portl

Ore., who reports to me one case in which he used four hundred and seventy cubic centimeters of serum with no rheumatic reaction whatever. We invariably look for some rheumatic symptoms following the administration of anti-diphtheric serum, and I think that the same is true of the use of all of our serums. I therefore believe that the anti-toxine, whether elaborated in the system of the patient himself, or whether introduced thereto by artificial means, seems to bring on that peculiar blood condition which is favorable to rheumatic attacks.

In our *post-mortem* work we often find heart changes in diphtheria, scarlatina, septicemia, pneumonia and la grippe cases that are identical to those found in rheumatism cases. Whether those heart changes are due purely to toxines, elaborated by the causative organisms, or to antitoxines elaborated by the system, or to lowered vitality, is a question which would be hard to answer. Even under the old theory of uric acid deposits, the heart changes encountered were poorly explained, and the fact that they followed rheumatism was more of a clinical observation than a scientific deduction. That these same heart conditions are encountered after acute infectious diseases, caused by the germs before mentioned, would indicate, to my mind, that they play an important role in these heart changes.

This year's grippal epidemic seemed to be secretive in its attack upon the heart muscle. Not only, in our experience in this locality, but in talking with physicians from over the entire middle South, they have encountered the same experience. The attack of la grippe was often heralded in by an attack of pericarditis, accompanied by great irregularity; especially was this true of the aged. In a good many cases death occurred from heart failure within the first three to five days, with apparently little trouble elsewhere, and yet they were distinctive cases of la grippe, the influenza bacillus being found in the sputum in every case, and sometimes in the circulating media, just before death, at least such was found in two of our cases. We were not permitted to make a *post-mortem* examination in either of these cases, consequently, we do not know the exact condition of the heart. One, however, had a previous mitral regurgitation, but within a few days from the beginning of the attack, murmurs were distinctly heard over the entire cardiac area.

Mitral regurgitation very commonly develops in even mild cases of pneumonia, where the tissue waste and the severity of the attack would scarcely warrant an anemia murmur. Both diphtheria and scarlatina have a very selective tendency toward the mitral valve, and in this case it must certainly come from direct influence through the circulating media of the micro-organism itself. Consequently, it seems to me more feasible to accredit many of the muscular and valvular changes, heretofore ascribed to rheumatism, to an attack of some germ disease.

I think in some cases of rheumatism, you can, by delving thoroughly into the family and personal history, find where the original rheumatic nidus was located. The reason that some persons are predisposed to rheumatism is very readily explained, because when these peculiar blood conditions once exist, there seems to be never an entire return to normal. The same as in an attack of small-pox, there is an immunity found, though we have never been able to find any difference in the blood examination before or after the attack. Yet this peculiar immunity remains, and in nearly every disease of germ origin there is left after the acute attack, either an immunity, or a predisposition, consequently, the same rule will hold good in these cases of recurrent rheumatism. Therefore, discover the secret of immunity and predisposition, find what an anti-toxine truly is, and you will undoubtedly discover the cause of rheumatism. Find a remedy that will put the circulating media in exactly the same condition that it was prior to the attack of an infectious disease, and you will have discovered the cure for rheumatism.

Enclosed find one dollar, for which send me the MEDICAL BRIEF for 1905. I can not do without the BRIEF. Keep pegging along for liberal medicine.—J. L. CARTER, M. D., Maxwell, Ky.

[Written for the MEDICAL BRIEF.]

Commonplace Remedies—Turpentine.

BY W. T. MARRS, M. D.,
Jewett, Ill.

It would be well for every physician to familiarize himself with the therapeutic possibilities of the remedies usually found in homes. One frequently finds himself in an isolated place without the very thing he most needs, when some homely remedy or appliance must be called into requisition. Again, many poor people, not able to pay the doctor's fee, to say nothing of a druggist's bill, may often obtain good and serviceable treatment from remedies regarded as valueless, simply by reason of their cheapness.

In this short article I wish to call attention to a drug which is cheap, valuable and nearly always at hand.

Turpentine, divested of its homely name, frequently comes under our notice in some form of derivative or analogue. Among these are the oils of succini and thujæ, terebene, terepine, sanitas, etc. All of which are good remedies for their separate indications.

The dose of turpentine is from five to fifteen drops in pearls, capsules, or emulsion. Given as an emulsion with glycerine, the taste is, in a measure, disguised. The dose as an anthelmintic is from a teaspoonful to a tablespoonful. When thus given in large doses it should be combined with castor oil, in order to hasten its elimination from the system. Large doses irritate the kidneys and irreparable damage may, possibly, ensue. In Bright's disease, or any abnormal state of the urinary tract, turpentine should never be given in doses beyond the minimum. Strangury, hematuria and other untoward symptoms may be produced. The normal urinary tract, however, usually tolerates large doses of this drug. One girl under my observation stated that she drank a half pint of turpentine with abortive intent, not to get the desired result, nor any unpleasant symptoms.

The vapors produce in susceptible persons a nasal and renal irritation. The writer always observes his urine to have the characteristic odor after having only poured turpentine from one bottl another. From this and other facts I upon it as being a two-edged sword.

Turpentine, in goodly-sized doses, stimulant to the vaso-motor system, ing for a time increased arterial ten Years ago the old backwoods doctor finding his patient nearly moribund, a teaspoonful of turpentine. Being a fusible stimulant and quick in action results were often gratifying.

In typhoid fever, after eliminants, pentine holds a conspicuous place, is likely to come in good play cally or internally, or both, during stage of the disease. It possesses gre antiseptic properties than many ag used for that purpose. It controls me ism and stays intestinal hemorrhage relieves chest symptoms and acts the secretions in a way not easy to plain. A dry, cracked, brown tongue "turpentine tongue," as our homeo friends would say. In such a conditi is usually indicated, both locally an ternally.

Pneumonia, with symptoms simul typhoid, also suggests turpentine. wise many other fevers or low states

In puerperal fever turpentine is a able remedy used internally and, als stupes. A septic uterus, when swa out with turpentine and glycerine, parts, loses much of its bad odor, microbic action correspondingly less A tampon of this mixture will co *post-partum* hemorrhage.

Dr. Bevill, in the *Medical Sum* states that turpentine will remove odors from the hands, such as result handling decayed placentæ, uterine cer, etc.

Turpentine when taken into the m causes heat, burning and a flow of s From this fact one would think it co indicated in mercurial ptyalism—si adding fire to the flame, but among laity, where it is used for this pur I find that it very materially cuts this troublesome condition.

Turpentine when exposed to the a comes somewhat ozonized by abso oxygen, which it retains tenaciously, increasing its efficiency in the treat of wounds. Nail thrusts and other ture wounds, when cleaned and tr

with turpentine, to which a little carbolic acid has been added, seldom give trouble.

Acne rosacea usually improve under inunctions of turpentine. It is also a good remedy in chronic eczema, with thickened epidermis.

Turpentine and ether make an allround anodyne and anti-spasmodic.

An ounce each of turpentine, aqua ammonia and vinegar in a quart of boiling water produce vapors which relieve asthma, croup and other forms of dyspnea.

Young infants, with anuria, are invariably relieved by the application of cloths wrung out of a quart of hot water, to which has been added a drachm or two of turpentine.

Physical Treatment of Heart Disease.

BY EPHRAIM CUTTER, M. D.,
New York City.

A strong, stalwart policeman with heart disease came into our office, panting, with a pulse of one hundred and sixty. He was put into a chair specially made so that his heels were higher than his head. In ten minutes his pulse was eighty, a reduction of one-half. The writer knows of no physic that would do this—that was done by physics alone.

Briefly, the physical signs were dullness on percussion over twice the normal cardiac area; palpation showed impulse spread over said area; auscultation showed heart's sounds almost normal over said area. Some months later the man died suddenly, after he had done both day and night duty in his profession!

A feeble young man, with physical signs of enlarged heart and valvular disease, came up stairs one flight, too fast, and entered our office breathless with palpitation, with increased impulse over an enlarged area and signs of immediate death. He was accorded the same treatment as the other, and in ten minutes he came down to his normal condition. A few weeks later he was talking with his mother at home, and the butcher coming along in his cart he jokingly told her to go and buy the things he ought not to eat. When she returned he was dead.

A middle-aged lady had attacks of pain in her enlarged heart (with mitral murmur) that ran up to the left shoulder and down the left arm, dyspnea, a feeling as if a giant hand was squeezing her to immediate death. At the outset these anginas were relieved by Hoffman's anodyne, brandy or whisky. But the frequency increasing she was put on the same invalid chair (to be seen, not for sale) at offices. When the anginas came on she would be lowered as to her head and raised as to her feet and the attacks would cease physicless. She lived twenty-two and one-half years after this, to die of another complaint, but for years before her death the mitral murmur disappeared, and a physician from a foreign country coming in was asked to examine her heart and tell what the matter was with it. He did so, and said he could find nothing wrong.

Of course, Nature naturally, all the time trying to cure, did these cures, because said supine posture, acting according to Nature's physical laws, aided. When we stand erect the heart has to pump against the capillaries in the feet with a pressure of blood (sanguinostatic) the height of our crowns. Completely reversing this posture it is evident that the heart would send the blood through the arteries and capillaries readily, and the blood would return by its own weight to fill the void in the heart. In other words, the physical work of the heart would be lessened by having no weight of venous blood to lift, and by the addition of said weight to propel itself downward. Of course, such patients as these named could not be stood on their heads in this posture, though medical gymnasts hang people up by their toes and report good results. But in the postures named in the above cases there was a partial operation of said physics that certainly did much good as a medicine.

The condition of the blood stream, when filled with ropy, adhesive corpuscles, with fibrin filaments, manifest in enlargements, in threads single and in skeins, and thrombi, with crystals of uric acid, urate of soda, triple phosphate, oxalate of lime, cystin, cholesterine, stellin, etc., as pointed out by American observers, or as heart-stones, referred to in German medi-

cine in 1729 A. D., makes most important and interesting physics for treatment. If hydrant water runs through pipes freely because it is not dense as molasses; because it is filled with masses of algæ or flora, or aggregated fauna (animal parasites are found in the blood stream); because it is not clogged with gravel stones. (The above-named crystals exist in solution in the blood and in the writer's opinion never would be found in the blood if the patient had drunk water enough to furnish the menstruum for their solution, and because crystals of cholesterine roughen the inside of the arteries, as in atheroma.) It is easy to see how such like physics in the blood stream increase the work of the heart, to name nothing more.

The writer testifies as a secondary witness that blood abnormal as the above has been made normal by the plans of the American authority who first pointed out these physical obstacles, in full, in the blood stream. In fact, it should be stated that the three cases above all had some of the said physics of blood obstruction, and that the latter was removed by treatment which the present limits forbid explaining, save to say that if the urine is kept at a specific gravity of 1015-1020 by drinking enough water, hot or cold, then the said crystals, at least, would not form in the blood, and when formed are more or less removed thereby. Indeed, if you have but one medicine to treat a case of this kind with, use water and stick to it (dictum by the master).

Cerebro-Spinal Meningitis.

BY JOHN MAYFIELD, M. D.,
Denison, Texas.

I notice in the June number of the MEDICAL BRIEF you wish some information from any physician who has had some experience in that terrible disease cerebro-spinal meningitis.

I will give you the cases of two boys in same family. Sons of Mr. Thomas Grundy, of near Springfield, Ky. I had seen some cases before I saw those boys, but all died. This was in the sprin 1874. The oldest boy, about thirteen, taken very suddenly with all the promi symptoms of cerebro-spinal menin head thrown back, muscles very r soon coma supervened, soon became conscious. All the usual remedies been used to quiet the nervous syste valerian and the bromides—and he on the sixth day after he was taken The next day another boy, eleven y old, was taken with all the same s toms as the first boy; never were two more alike. Dr. Green, of Spring Ky., was in consultaton. We infor Mr. Grundy that we were fearful that boy would die also. Being a wea man, we suggested sending to L ville for Dr. D. W. Yandell (now de He came on the first train, had Grundy send to the pasture for a sh had it brought near the house, and dered the hide taken off as soon as p ble, while hot; had the boy strippe his clothing, hide spread out on mattress, and the boy wrapped up in it. three or four hours his nervous sy was so relaxed that his head relaxed nearly its normal position, and the recovered rapidly.

Up to that time I had seen a few and this one was the first I had ever recover. I thought several times I w report this treatment, but such cases so rare that physicians soon forget a them.

Doctor, I know you understand the *dus operandi* of this treatment, somet to relax the system as soon as poss Yes, Doctor, this disease and the grip very much alike. You know the musc system is controlled by the nervous tem, and when you quiet the nerves quiet the muscles, and in these cases capillary circulation is cut off, so you by this treatment that is also restore

The reason I say this disease and are so much alike is that the treatm for one is good for both.

The worst case of grip (influenza) cured in one night. A kettle was f with water, and corn on the cob was in and boiled until very hot, and placed around the patient, and covere in bed. A fellow feels like he is in a nace.

The Effect of Vaccination on Small-Pox.

BY P. S. AYERS, A. B., M. D.,

Paola, Kans.

I have just read and re-read the article on page 548, April BRIEF, written by Dr. Strickland, entitled, "Chicken-Pox." It fixes an impression which has been growing upon me for some time so strongly that I wish to answer this article.

Based upon an experience of twenty-five years the Doctor makes the declaration that unless there is a large death rate—ninety per cent among children and fifty per cent of all the afflicted—small-pox does not obtain, but that the malady is chicken-pox.

I would like to exhibit here some clinical statistics and close this article with a theory, so far as I know, of my own weaving.

During the past winter we have had a siege of the "chick-o-small-pox." In my position as health warden of our city, I have seen and investigated two hundred and forty-five cases of, as one of our older physicians, who has been averse to calling it small-pox, said, "This—this—this 'breaking out.'" The victims have ranged in ages from babes six months old to people of sixty years. With a number of exceptions, the premonitory symptoms were as follows: A feeling of lassitude for a day, chilly sensations, furred tongue, loss of appetite, fever (about 103° F.), headache, backache, aching all over for two days. The attending physician invariably diagnosing malarial fever; third to fourth day feeling all right and physician dismissing the case. About the fifth day, small, bright red spots, size of a pin-head, would appear on forehead, wrists and back. About five days after the eruption appeared they had increased in size and became filled with a semi-viscid, milky fluid. The eruption would continue to grow until the eighth or tenth day, when they would be filled with pus, the base being bright red in a circle, and exceedingly painful, or as the patient would say, "Awful sore." After coming into "full bloom," which was invariably eight to ten days, they would dry down very rapidly into a hard, dry, dark-colored knot, which in three or four days would drop off; then would commence a series of desquamations of thin, white, dry scales, requiring from start to finish from twenty-one to thirty days to leave the skin smooth and clean.

In all the cases where it was possible to determine the exact period of inoculation, the incubation period was fourteen days. In all the cases where one member of a family was stricken first, the other members came down just fourteen days from the beginning of the desquamation. In some instances some members of the family escaped entirely.

One family, consisting of parents and four children, will be given to illustrate. In November the children had an eruptive disease. The attending physician diagnosed chicken-pox. The neighbors protested, and another physician was called. He said chicken-pox. I, as health officer, was called and was satisfied the diagnosis was correct. On January 28 I was called to this same family and found the father sick, having had the premonitory history cited above, and now the small, red spots were appearing. I placed the family under quarantine. Just fourteen days from the date of beginning desquamation of the father, all four of the children took sick. Two of them had the eruption, thick and large, from the crown of the head to the palms of the hands and soles of the feet. The pain was excruciating for three days. The mother escaped entirely. She had been vaccinated. The quarantine was raised March 9. What did this family have?

I am told by the county health officer that there has been in the county, outside of our city, about three hundred cases, making a total of about five hundred and fifty cases, with only one death reported, none among children. If Dr. Strickland's mortality test must be applied, we have not had small-pox. People who had had chicken-pox two months previous had it in confluent form. What was it?

I admit that I have not been in the harness as long as most men of my age. Preparing for the practice I took a four years' academic course, a four years' clas-

sic collegiate course, then a three years' medical course, entering the actual ranks at thirty-three years of age and, consequently, have been in the active practice but seven years. I have noticed that many men who have been in the practice for twenty years or more demand the same clinical picture for positive diagnosis that was demanded fifty to one hundred years ago. If we demand the same for small-pox, why have we all these years been indulging in the barbarous superstition of vaccination?

My experience with several hundred cases in the past six years has been that people who were vaccinated had this eruptive disease very light; many not having it at all. Others who were not vaccinated, but whose parents and grandparents had been, had it light. Those who had not been vaccinated nor had their ancestors for generations back, had it very severe, were delirious, and the eruptions appeared in a mass from head to foot, and in many places were confluent.

It is certainly time physicians quit teaching the laity that vaccination renders one immune for a given period; the popular belief is that it "runs out" in seven years. If an attack of genuine small-pox renders one immune from contagion, the same result can certainly be had from vaccination. When the virus is put into the human system and we have "a take," this certainly carries the work of burning out the fuel of conflagration completely to a given point, the point depending upon the degree of susceptibility to the small-pox contagion, and will not "run out" during the life time of the individual. The conflagration started by once vaccinating may render one individual entirely immune and another only partially so. Then the course to pursue in the case of partial immunity is to revaccinate repeatedly, until it is impossible to get "a take." Then and not till then can we consider the individual immune.

It is certainly a bigoted assumption of superior intelligence for a physician to flatly and decisively say that this one or that one is immune for seven years or more who has had one successful "take." There is but one way to know and it can be known to a certainty. "Prove things" is certainly mandatory in t matter of vaccination. If vaccinati will "take," however light, small-pox w "take." It is possible to produce absolu immunity by repeated vaccinations. I peated vaccinations after immunity h been established causes no inconvenien whatever and proves susceptibility to t contagion. If a little renders an atta of small-pox light, then more—enough will prevent it, rendering the individu immune.

By repeated vaccinations, small-p can certainly be annihilated and driv from the country. Then we will ha done with this protracted controver among physicians as to whether we ha modified small-pox or severe chicken-p My own opinion as to the epidemic Kansas the past winter is that it is ger ine small-pox, with few exceptions, mo fied by several generations of vaccinati My theory is that by repeated vaccinati we can render any individual immune small-pox, and by repeating the proce sufficiently often prove a state of imm nity. My teaching shall be vaccina *vaccinate*, VACCINATE, revaccinate, *rev cinate*, REVACCINATE, and yet again vacc ate and revaccinate.

[Written for the MEDICAL BRIEF.]

Poison Ivy.

BY W. L. HUGHSTON, M. D.,
Red Banks, Miss.

In a country practice we often hav deal with a most troublesome affection the skin, caused by coming in cont with a vine commonly known as pois ivy, or, as it is called by most persons this section of the country, "poison oa

It causes a violent erythema, with mu swelling, intense burning and itching, e Until about seven or eight years ago had tried a great many remedies, witho much success. But about that time I s in some medical periodical a prescripti which, in my hands, has worked li magic, only a few applications being n essary for a complete cure.

I have seen some very severe cases lieved by two or three applications. T

simple prescription which I came across and have used with unvarying success, is as follows:

℞ Plumbi Acetat.....10 grains
Spts. Aetheris Nitrosi..... 1 ounce
M. Sig.: Apply on parts affected.

This simple prescription has been so successful in my hands that I hope it will benefit those physicians who have heretofore been unsuccessful in the treatment of this simple affection, as I have found that it is in the treatment of these simple affections that our text-books have given us little satisfaction.

[Written for the MEDICAL BRIEF.]

Reminiscences of a Country Practice.

BY J. W. BARKMAN, M. D.,
Hooks, Tex.

About twelve months past I wrote a short article for the BRIEF upon the treatment of dysentery, and closed by observing that I was disgusted by the many medical fads. And as for horse serum, I begged to be excused, and thought a man who would inject horse serum into the anatomy of man, woman or child, should be prohibited by law from practicing medicine. That I was nearly seventy-nine years old, and had been practicing medicine for fifty-six years; and that during the civil war between the States, diphtheria prevailed as an epidemic, in the location where I practiced. I treated a large number of cases and lost but one patient, and that was many years before horse serum had ever been thought of.

A very short time after my article appeared in the BRIEF, a postal card was mailed to my address without date or signature, saying a man who had practiced medicine fifty-six years, and would not use serum therapy, must be suffering from atrophy of the brain, and should leave earth and soar to heaven.

For the benefit of my critic I will give a short summary of my past experience, which extends over fifty-six years of country practice in the wilds of Arkansas. I practiced medicine for twelve months and while there I was sent for one evening to go twenty miles to amputate a negro boy's leg, who had shot himself through the ankle joint, and mortification had set in. I went, but it was night when I reached there. I examined the boy and saw that immediate amputation was imperative, and began to operate immediately.

My only light was sperm candles, held by negroes. That was before we knew anything about antiseptics, but I had been taught the importance of cleanliness. I chose from ten or twelve young negro men, a boy named Jake, who was an intelligent youth, with steady nerves. I instructed Jake how to administer the chloroform. I went to work, and amputated the limb. And when I would pull down an artery I called upon some one to hold the tenaculum until I could tie the vessel, but no one responded. I turned to a girl, fifteen years old, to hold the instrument until I could tie the artery, which she did with a nicety that was surprising. In less than four weeks my patient was going around on crutches.

I would like to know what my critic would have done, under similar circumstances, with no help, but ignorant, uneducated negroes. I believe he would have let the boy die, rather than operate, without the assistance of one or more doctors.

It was a case that called for immediate action. Delay might have resulted in the death of the patient. Having done most of my practice in the country, where I could not procure consultation, I had learned to depend upon my own resources.

Let me tell my critic, who thinks I should leave earth and soar to heaven, what I did on the coldest night we had last winter. I was sent for, at nine p. m., to go south, three miles, to wait upon a lady in labor. I went and delivered her of a ten-pound boy. I stayed with the lady one hour after the birth of the child. I then started for home. Before I had been in bed fifteen minutes I was called up again, to go east four miles, to wait upon another lady. I got up and pulled out, and got there just as aurora showed her first blush in the east, and delivered the lady of a fine girl. And as my critic

thinks I am so ignorant, in not using horse serum, that I should leave the earth and soar to heaven, let me tell him that during my fifty-six years of country practice I have waited upon hundreds of women in childbirth, and have never lost a case.

Of course country women are different from city ladies, but I have had to contend with some very critical cases, with abnormal presentations of all sorts and kinds, but I have never failed to turn the child, so it could pass to the light of day without the aid of instruments.

I have never had to use forceps, and I believe thousands of women have been ruined for life by their use, that could have been delivered in a natural way by trusting to the powers of nature, and by the judicious use of stimulants and relaxing remedies.

A few years ago I was sent for to assist a brother doctor in an obstetrical case. When I arrived he told me he had been in attendance for twelve or fourteen hours, and he did not believe she could be delivered without the use of forceps. He had already sent back to his office for forceps and had them sterilized, ready for use, and was only waiting for a consultation with myself.

I told him I would make a careful examination of the lady and then tell him what I thought best to do.

The lady was young (about nineteen years of age), stout and in perfect health.

Upon examination I found a large and perfectly-formed pelvis, with a natural presentation, but the os hard and rigid, but had commenced to dilate to the extent of a quarter dollar. Having finished the examination I told him I thought we might manage the case without their use, and that if he would turn the case over to me for one or two hours I thought the trouble would be over. He consented. I commenced by giving chloroform by inhalation in a moderate way, and in forty minutes I had her perspiring freely, and the muscles thoroughly relaxed. I then gave a whopping dose of the fluid extract of ergot, and in less than thirty minutes she had strong bearing-down pains, and in a very short time I delivered her of a live, healthy nine-pound child.

I believe in antiseptics, but I have seen doctors who thought it murder in the first degree not to scrub the hands with sterilized water and green soap, and then in a solution of carbolic acid, finishing off with chloride solution.

Before I examine a woman in labor I clean my finger nails and wash my hands in pure water and a good toilet soap, and then apply plenty of vaseline or fresh lard. And I have never had a woman who I have waited upon to have child bed, or puerperal fever.

When I find a remedy that has served me well, in critical cases, I never discard it for any other remedy until experience has proven it to be more efficient. By all means make a correct diagnosis of the case, and do not dilly-dally in the choice of remedies, but use such as your sober judgment and experience suggest as best and then persevere in their use.

Then use suggestion, which is a potent factor. Tell your patient you have treated and cured hundreds of cases just like his and that your remedies will cure him and you will save your patient.

Examination Questions of the Indiana State Board of Medical Registration and Examination. Indianapolis, Ind.

M. S. CANFIELD, M. D., President.
W. T. GOTT, M. D., Secretary.

(Continued from page 592.)

MEDICINE (ECLECTIC).

Submitted by M. C. CANFIELD, M. D., May, 1905

1. Give etiology, symptoms and treatment of acute gastritis.
2. Give etiology, symptoms and treatment of acute meningitis.
3. Give etiology, pathology, diagnosis and treatment of tabes mesenterica.
4. Give etiology, pathology and treatment of icterous neonatorum.
5. Give etiology, pathology and treatment of catarrhal laryngitis (croup).
6. Give etiology, pathology and treatment of chronic endocarditis.
7. Give etiology, pathology and treatment of acute adenitis.
8. Give etiology, pathology and treatment of parotitis (mumps).
9. From what diseases must variola be differentiated?
10. Give diagnosis, sequelæ and treatment of scarlatina.

ATERIA MEDICA AND THERAPEUTICS (ECLECTIC).

1. Give dose and indications for amyl nitris.
2. Give dose and indications for apis melli-ca.
3. Give dose and indications for cactus randiflorus.
4. Give dose and indications for collinsonia anadensis.
5. Give dose and indications for leptandra irginica.
6. Give description and uses of formalde-yde.
7. Give common name, indications, dose and ses of gossypium herb.
8. Give common name, indications, dose and ses of hyoscyamus niger.
9. Name the pathological condition for hich you would give cuprum, digitalis or igeron can.
10. How would you treat a patient who had ken one teaspoonful of specific tincture of elladonna?

GYNECOLOGY.

1. Define: *a*. The left latero-prone posi-on. *b*. The Trendelenburg position. Name me advantages of each position.
2. Give proper method of applying the hot aginal douche.
3. Give principal indications for tamponade.
4. What is your idea of drainage in major perations? Give chief cause of ventral hernia.
5. Give differential diagnosis of normal estation and ovarian cyst.
6. Define Alexander's operation. Give in-cations and contraindications for the opera-on.

OPTHALMOLOGY AND OTOLOGY.

1. Give causes, symptoms, diagnosis and reatment of granular conjuctivitis.
2. Define the field of vision. How may the mits of the visual field be roughly ascertained?
3. Give etiology, symptoms and treatment f acute inflammation of the middle ear.

MEDICINE (HOMEOPATHIC).

ubmitted by W. T. GOTT, M. D., May 2, 1905.

1. What is the specific gravity of normal lood? How may it be obtained?
2. Give etiology and remedies usually in-icated in erysipelas.
3. Define acute articular rheumatism. Name hree agents you consider most useful in the reatment of rheumatism.
4. Give cause and treatment of cerebro-pinal meningitis.
5. State causes, symptoms and treatment of ppendicitis.
6. Define dementia. Name two or more orms, and give treatment for each..
7. Give symptoms of paralysis agitans, rognosis and two agents most commonly in-icated.
8. State causes, symptoms, and remedies in-icated in cerebral anemia.
9. Give treatment and management of chronic gastric catarrh.
10. Give diagnosis and treatment of gastric dilatation.

MATERIA MEDICA AND THERAPEUTICS (HOMEOPATHIC).

1. Differentiate the characteristic symptoms of belladonna, hyoscyamus and stramonium.
2. What drugs are indicated in facial erysipelas with vesiculation?
3. Give the characteristic symptoms indicating the use of (*a*) podophyllum, (*b*) mercurius.
4. What is the general action of bryonia on serous membranes? Differentiate it with other drugs having similar action.
5. Name three drugs most frequently indicated in chronic nephritis.
6. Give the therapeutic individuality of sulphur and phosphorus.
7. State the characteristic action of rhus toxicodendron on the skin and muscular tissue.
8. Give the therapeutic individuality of acidum muriaticum.
9. Give the habitat and principal sphere of action of pulsatilla.
10. Give the therapeutic individuality of nux vomica.

OBSTETRICS.

1. Give physical signs of approaching labor.
2. Describe the mechanism of a natural labor.
3. What is meant by the "bag of waters?" Should it be ruptured? If so, when?
4. Give cause and treatment of prolapse of the cord.
5. What are the dangers to be apprehended to the mother from a miscarriage?
6. Does the death of the unborn child occur simultaneously with death of the mother? What course would you pursue in such a case?
7. What significance would you attach to marked edema of the lower limbs of the enceinte?
8. What changes take place in the heart of the mother during pregnancy?
9. Give technique of asepsis in the management of labor.
10. Give cause and treatment of ophthalmia neonatorum.

PHYSIO-MEDICAL PRACTICE.

1. Mention three distinct varieties of dysentery, giving treatment for each.
2. Give the diagnostic symptoms and correct treatment of diphtheria.
3. Give the pathognomic symptoms and treatment of syphilis.
4. Give the symptoms of locomotor ataxia, with a brief definition.
5. Define interstitial nephritis.
6. Name the forms of laryngitis, with the diagnostic symptoms in each.
7. Give the synonyms and the diagnostic symptoms of chorea.
8. Give the definition, diagnostic symptoms and medical treatment of appendicitis.

9. How would you treat broncho-pneumonia?
10. Name the three pathognomic symptoms of exophthalmic goitre.

PHYSIO-MEDICAL MATERIA MEDICA

1. Give the dose and physiological action of pulsatilla.
2. What is the physiological effect of quinine?
3. Write a compound prescription for a patient afflicted with inflammatory rheumatism.
4. Mention three of the most efficient drugs for the relief of chronic constipation.
5. Give the dose and therapeutic properties of fluid extract of cereus bonplandi.
6. Write a prescription containing apocynin, ieptandrin and podophyllin. State the conditions where this prescription would be applicable, and give directions for its use.
7. Mention three cardiac stimulants and three vaso-constrictors.
8. Name the alkaloids contained in the rhizone of golden seal and give the dose of the various preparations of golden seal.
9. Write a prescription for a patient with hepatic colic.
10. Give the physiological action and therapeutics of valerian.

THEORY AND PRACTICE OF OSTEOPATHY.

Submitted by J. E. P. HOLLAND, D. O., May, 1905.

1. Give etiology, prognosis, symptoms and treatment of hay fever.
2. Give etiology, symptoms and treatment of lobar pneumonia.
3. Give diagnosis and treatment of parenchymatous nephritis.
4. Give symptoms and treatment of the first stage of pulmonary tuberculosis.
5. Give symptoms, prognosis and treatment of chronic constipation.
6. Give pathology, symptoms and treatment of acute articular rheumatism.
7. Give prognosis and treatment of (*a*) writers' paralysis, (*b*) telegraphers' paralysis.
8. Give etiology, symptoms and treatment of sciatica.
9. Give treatment of paralysis agitans.
10. In what diseases are the following physical signs present: (*a*) barrel-shaped chest, (*b*) sugar in urine, (*c*) viscid, rusty colored sputum, (*d*) fecal vomiting, (*e*) urinous odor from the skin and breath.

SURGERY (OSTEOPATHIC).

1. Give names of four antiseptics in the order of their potency.
2. Give treatment of hydrocele of the testicle.
3. Give treatment of a tubercular abscess.
4. Give treatment of chancre.
5. Give symptoms and treatment of appendicitis.
6. Give symptoms and treatment of fracture of the middle third of the femur.
7. Give symptoms and treatment of a P fracture.
8. Give symptoms and treatment of a location of the femur onto the dorsum of ilium.
9. Differentiate fracture of the outer t of the clavicle and a subcoracoid disloca of the shoulder.
10. Describe (*a*) compound fracture, simple fracture.

PRINCIPLES OF OSTEOPATHY.

1. Describe a lesion and give two ca explaining how.
2. Give technique of correcting an inn nate which is forward and upward.
3. How would you correct an anterior dition of the third, fourth and fifth lu vertebræ?
4. What is the best way of correctin spinal curvature in which the primary cur convex to the right and is at the lower do and upper lumbar region, the secondary c being at the upper dorsal region?
5. Give technique of correcting the fol ing: (*a*) anterior atlas, (*b*) posterior axis, posterior fifth dorsal, (*d*) depressed fifth (*e*) depressed first rib.
6. How would you treat a rotated spin
7. In facial paralysis what nerves affected and how would you treat?
8. Give treatment for torticollis.
9. Name four disorders caused by a pressed fourth rib and explain how.
10. Explain (*a*) stimulation, (*b*) inhibi

GYNECOLOGY (OSTEOPATHIC).

1. Define gynecology.
2. What is meant by (*a*) puberty, menopause.
3. Give causes, symptoms and treatmen (*a*) dysmenorrhea, (*b*) amenorrhea.
4. Define subinvolution, giving causes treatment.
5. Name three kinds of lacerated cervix describe same.
6. When and how would you repair a la ated perineum?
7. Give symptoms, prognosis and treatm of carcinoma of the cervix.

OBSTETRICS (OSTEOPATHIC).

1. What is meant by L. O. A., R. O. L. O. P., R. O. P.?
2. What and how many stages of labor there?
3. What is meant by placenta previa.
4. Of what is the umbilical cord compos
5. Describe fetal circulation.
6. Give the management of the second s of labor.
7. Give treatment for threatened abort
8. Give indications for the use of stetric forceps.
9. Give diameters of the female pelvis
10. Give hygiene of lying-in room.

Editorial.

Mastication.

Unfortunately many people do not understand the importance of proper mastication to digestion. It is not only that the saliva contains a digestive principle, ptyalin, essential to the conversion of foods containing starch, but the mechanical manipulation of the food, reducing it to a soft pulp, makes it set better on the stomach.

Indigestion has, in many instances, been entirely relieved by insisting on deliberate and thorough chewing of the food. Occasionally physicians suggest that the patient chew gum for a few minutes after eating. While this does tend to relieve flatulence to a certain extent, by stimulating a flow of saliva, the food does not get the benefit of the grinding and mixing which takes place when mastication is correctly performed.

Not long since, we prescribed olive oil for a patient who was suffering from recurring colicky pains in the bowels, and losing weight. At the next visit the patient complained that he could not digest the oil. He was told to masticate it well so that it should be thoroughly mixed with saliva. After this he had no further trouble.

We are aware that saliva is supposed to have no effect upon oil, which is digested in the small intestine, but the fact remains that the oil, when well mixed with saliva, gave no trouble to the digestive organs. It is possible that the saliva, aided by the churning which the oil received during the motion of chewing, emulsified it in a degree, thus making it easier of digestion.

Whatever the explanation, the fact remains that olive oil, when masticated, usually causes no trouble, and it will be well for doctors to instruct patients on this point when prescribing the oil.

Medical Liberty.

Every man owes it to his country, his children and himself to do what he can in the cause of liberty. The medical profession has not escaped the tendency of the

times to use organizations to bind and tie the hands of individuals. Yet to make the medical profession great, the individual doctor must be great, and this, in turn, necessitates the fullest possible measure of liberty.

Class legislation works on the principle of robbing Peter to pay Paul, a precedent which involves no increase of wealth, and, like all injustice, is selfish and short-sighted.

The moment a man is given to understand that he jeopardizes his standing, his future, his interests, by an independent stand, all his energies slacken. He inevitably becomes less straightforward, less sincere and courageous. Instead of asking himself what is the right thing to do, he questions what course is most prudent or politic. He does not hurl himself into the breach in an emergency, he does not rack his brain for ways and means, he consults the precedents established by authority, and exempts himself from responsibility. A machine man follows instructions, whether or not he "makes good." That is a secondary consideration.

If we look around us and see what organizations and political methods have done for commerce, for industry, for government, we can see nothing to be gained from their adoption in medicine. Medicine is in an advanced state in the United States because of the liberty enjoyed for so many years. Since the era of fads and theories set in, and the legislative mills began laying down restrictions, the medical profession has been almost at a standstill.

Would it not be well for us to shake off this appearance of apathy and indifference, which is the political doctor's opportunity, and let it be understood exactly where we stand on this matter. If you believe in medical liberty, say so; do not leave it in doubt. Would you rather be a man than a cog in a big machine? Would you rather think your own thoughts, make your own decisions, carry out your own plans, or would you prefer to take orders as a private in the ranks of a semi-military body?

If you believe, as all history shows, that independence and self-reliance are conditions inseparable from man's best development, then wake up and do your part to preserve those conditions.

Governmental and Municipal Ownership.

Will the fellows who are always s cating governmental and municipal ership of railways, street car lines, gas electric light plants, stop and think a ment what private ownership has actu done for us in the past twenty or th years, bearing all the responsibility, confronting difficulties and problems t unknown. Do you remember the da the tallow dip and kerosene lamp, more expensive as regards illumina than gas is to-day. Carry your mind to the horse car, with no light or h floors covered with straw, six and cent fares.

Illumination is cheaper now tha ever has been in the history of the c try, and transit facilities are better. this has been accomplished by private terprise, the wear and tear of brain ti of men who did not spare themselves cause they were attending to their business.

Compare the flat of to-day in even poorer districts of our great ci equipped with bath, heating appar and other improvements, with the m able, dark, airless tenements of years

Progress is inevitably slow, the q tion of ways, means and cost bring u many problems which must find a p tical solution, but private ownership operation has accomplished wonders w we stop to think about it instead of tal it all for granted, and looking for so thing to grumble about.

Do those who advocate public ow ship ever stop to weigh the meanin the term seriously? Step into the p office and look at the dirt and smell air while you wait an hour or two fo overworked clerk to attend to you. L at the mail wagons, with their decr horses, and reflect upon the inadeq mailing facilities. Then ask yoursel private management would not ac plish better results.

Talk about graft! Does any thinl man really want to swap the governn of our forefathers for a political brick in the shape of public ownershi

Suppose, for instance, the governn did own the railways, and you were t eling on a fast train to catch a shi

to consummate a business deal, or to be present at a medical consultation, and some government official should telegraph to hold the train half a day for him, how would you like it?

There are some people who think that any change is better than what they have, and a politician is always keen to have the government do any and everything, for there are always axes which need grinding, and men looking for office.

The sentimental people who talk about the "good old times" would be the first to object if they had to go back to them. As for public ownership, it would be like jumping from the frying pan to the fire. The best minds can only be enlisted in private enterprises. What would become of progress and routine certainties if the management of practical affairs were committed to the academic mind? The idea of turning the machinery of civilization over to the graftsman on one hand, or the learned child on the other, seems preposterous when you come to think of it. Financial irresponsibility and demoralized service would be the least we could expect. "I" and "mine" have magic power to bring out the most and the best there is in a man, making him responsible in a way nothing else can do. Private ownership is and probably always will be the lever to accomplish practical results of the highest character.

Before we go any further with this idea of government ownership, suppose we do a little thinking. Turn the matter over in your mind as you would a case, Doctor, and see what you can make of it.

Some of the More Commonly Encountered Conditions of the Stomach and Their Diagnosis.

BY LOUIS LEROY, M. D.,

Professor of Histology, Pathology and Bacteriology in the Medical Department of Vanderbilt University.
Nashville, Tenn.

Gastritis.—Perhaps the most common inflammatory condition of the stomach is acute catarrhal gastritis, and this should include all cases of toxic gastritis since both conditions are produced by fermentation products, or some variety of ptomaines. The symptoms vary, and in the cases of greater severity are accentuated, and the time of attack may vary from a few hours to several days. In general, it may be said that in the corrosive cases (poisoning by phosphorus, antimony, arsenic, or mercuric chloride) the symptoms appear quickly, and the pain, vomiting and prostration may be severe. Blood usually appears in the vomitus and urine, and a history of poison-swallowing can be elicited on examination. In the non-corrosive, the symptoms usually appear after eating; there is a sense of fullness, thirst, oppression, headache, sometimes dull pain, eructations and nausea, followed usually by vomiting, which in the milder cases brings relief. The severer cases are followed by an accentuation of these symptoms, and, in addition, there may be a sharp temperature rise, preceded by a chill, and in children there may be an erythematous rash, and in some cases jaundice.

Acute Suppurative Gastritis, or phlegmonous gastritis, resembles the foregoing in the early stages, but the pain and constitutional disturbances usually differ somewhat. The physical signs are not distinctive, but any pressure usually intensifies the pain. Prostration soon passes into a typhoid state, and that frequently into coma. If the vomitus be examined microscopically, blood and pus cells will be found and a leucocytosis will usually be observed, if the disease had progressed for several days.

In Chronic Catarrhal Gastritis the walls of the stomach vary in thickness as to whether an inflammatory deposit of fibrous tissue has occurred or not. In any event, the glands of the mucosa will be found atrophied, and the distinction between acid and parietal cells nearly if not completely lost. The pyloric end of the stomach usually suffers most, and may contain eroded areas closely bordering upon ulceration. The stomach is usually coated heavily with viscid, tenacious mucus, which shows desquamated epithelium upon microscopical examination. The amount of hydrochloric acid is diminished so that fermentation changes more easily occur, and the motor function is decreased to a considerable extent.

Among the more important subjective symptoms are, distress after eating, epi-

gastric pain, frequently palpitation of the heart, a bitter taste, which is persistent, excessive thirst, nausea. Among the reflex nervous symptoms are headache, either frontal or occipital, tending to occur before meals, and which may be associated with some nausea, vertigo, depression, amounting in some cases almost to melancholia, or an inability for concentrated attention, or disinclination to any activity. Insomnia, or drowsiness after meals. Urine is abundant, pale, of low specific gravity, and tends to deposit large amounts of urates and phosphates. This condition may resemble or be associated with the more immediate dangerous gastric lesions, but the diagnosis must be based upon the absence of the characteristic physical signs of the lesions, and upon the large amount of alkaline mucus, motor deficiency, and small percentage of HCl.

Gastric Ulcer, by which I mean the round or simple ulcer of the stomach, is easy of diagnosis, but when associated with other conditions (as it usually is) it taxes the diagnostic acumen of the physician. The three cardinal symptoms are pain, vomiting and hematemesis. More or less periodic attacks of gastralgia may be complained of; any food usually intensifies the pain; emesis tends to relieve. The posture which causes the greatest pain or relief may be of diagnostic value in locating the ulcer. Vomiting occurs two hours after meals, and is frequent. The vomitus contains an excessive amount of HCl.

When blood is present, it is of significance, but this sign is frequently absent. When it is present in small amounts, the circular character of the corpuscles may be destroyed by digestion, in which case it is necessary to recognize it by laboratory tests. When a large vessel is eroded there is no trouble in recognizing it, as hemorrhage may be so severe as to cause collapse and death in a short time.

In Gastralgia the pain is frequent when the stomach is empty, and may be relieved by eating. Tenderness upon deep pressure is usually absent, whereas hyperesthesia of the skin may be present. There is usually no disturbance between attacks. Hematemesis is absent, though this may also be absent for a time in ulcer also. The diet has little or no effect, and the general health may be good. Signs of tumor or dilatation are absent, and ne thenia and hysterical tendencies are ally manifest. In females, the peri life near or during the menopause i quently a predisposing cause.

Gastric Carcinoma when it occurs an old ulcer, and develops insidio may be impossible of diagnosis for a A constant endeavor should be ma this direction, however, as many of cases can be cured if operated in The onset may be abrupt. Anorexia but little pain is the rule in the stages. When there is much pain, it a lancinating character, and not o boring or burning nature usually able to ulcer. The pain is not as st localized, as a rule, and may be ref to the back, arms or shoulders, or of the abdomen, sometimes suggestin pendicitis. Vomiting is less frequent in ulcer or dilatation. The vomitus contain some blood if erosion has red, but is more frequently free fro A chemical examination of the stoma of great value, although not of abs certainty. When HCl is present in cinoma, the former may be said with fidence to be secondary to an ulcer. tic acid is usually present if HCl sent, and is due to fermentation, the HCl normally restricts. In add the microscope may reveal epithelial from the growth and certain charac tic bacteria.

While no one of these points singly may safely be used basis for a diagnosis, all of them together form a symptom complex can not be considered second to the ical picture, but neither the clinica laboratory findings should ever be c ered apart from the other in this more than in any other diagnosis.

Incipient Insanity.

BY T. OUTTERSON WOOD, M. D., F. R. C. P. (EDIN)., M. R. C. P. (LOND.),
Senior Physician to the West End Hospital for Nervous Diseases, Welbeck Street, and President-Elect of the Medico-Psychological Association of Great Britain and Ireland.
London, England.

In the present article it will be my endeavor to give an account of a group of cases which we meet with in the earlier stages of incipient insanity, before the mental manifestations are pronounced, but in which we can clearly see the signs of an impending nervous breakdown. We are frequently consulted by the parents of young people over the age of puberty who have developed symptoms of restlessness, unnatural sensitiveness and self-consciousness, who have become what the parents call "strange in their manner," who at times seem momentarily forgetful of themselves and their surroundings, and at other times positively stupid. The usual history is that during school life the child has always been sensitive, emotional, and though quick at learning, never what one would call robust, but at the same time equal to entering into and enjoying the games and physical exercises of his fellows.

On leaving school to enter college, or to commence some business, his self-confidence fails him, and he develops the symptoms above enumerated. His attention is found to waver, and he can not concentrate his thoughts upon the work he has in hand. He will sit with a book before him, but after reading a page or two, you will find him gazing into space, "lost in thought," as it is termed, but really thinking about nothing, for there is a complete temporary arrest of mentation.

This is followed by a coming back to consciousness, and an effort to remember the subject matter of the book, a failure to do so, and a commencement to read the subject over again, with a similar result, until, wearied out with repeated endeavors, he either sinks into sleep, or, closing the book, throws it on one side, and proceeds to take up some physical exercise. And so, day by day, the same thing happens, till the youth lags behind his fellows, and his tutors or employers begin to entertain doubts as to his ability, and, wrongly attributing his mental weariness to laziness or want of interest in his work, endeavor by a course of increased severity of discipline to "make him attend to his studies," or his business, with the usual result that the wearied brain becomes more and more incapable of responding to the calls made upon it, until the unfortunate youth becomes morbidly sensitive, or reduced to a condition of actual stupor. It is generally at this

stage we are consulted about him. We are told he can not study, that he has no application, and that they can make nothing out of him, and we are asked to advise as to what should be done with him.

Let us consider a fairly typical case, one of this group. We find our patient a pleasant, easy-going youth, who converses with us in a nervous, fidgety way, gazing furtively about him, and answering our questions almost mechanically, while his hands are restless, seeking with his fingers for the arms of the chair on which he is seated, running his fingers along the contours of the woodwork, and interposing between his replies a silly, senseless laugh; the expression of his face is meaningless and he seems to be looking at something far away. We recognize that we have before us a case of mental exhaustion and we proceed to inquire into the history and as to what may be the probable causes that have led to this condition of mental weakness so evident in the manner and appearance of our patient. We will find that in all probability there is a history of a predisposition to mental disorder in the family of one or other of the parents, the symptoms complained of are of comparatively recent development and that it was not until he was about to leave school that anything was noticed to be wrong with regard to his health, also that he always seemed better when engaged in any outdoor occupation, and that it was only on his attempting to do any brain-work that the mental weakness became apparent. His memory was defective, and he could not add up a column of figures correctly without considerable difficulty, or remember the substance of more than a page or two of a book.

We find, also, on careful examination that there is a tendency to exaggerate his self-importance, and although you prove to him his want of mental attainments, he will still be inclined to consider himself better than his position warrants. This exaggerated self-importance is often the result of his too fond parents encouraging the too precocious ideas and mental inflation of their favorite or only child, and in failing to check the running over of childish day-dreams, and the building of castles in the air, which can only end in "vanity and vexation of spirit," for "that way madness lies," as we too of find, and it is only by ruthlessly digg up these weeds of misguided educat that we can hope to rescue our pati from the development of those grandi ideas which end in the mental disas of mania and dementia.

In thus briefly endeavoring to ske the leading symptoms in cases of the cl under consideration, we must not l sight of the fact that the symptoms, though present and distinctly observa are still by no means strongly marked, that they do not as yet constitute a inite condition of mental unsoundn These cases are still on the sane side the line, though they are gradually proaching the opposite condition, and less arrested, may ultimately become tifiable.

With regard to *causation*, I have m tioned the family history, which sh predisposition to mental irritability. T there is the effect upon the growing m of defective social surroundings, the quiring of bad habits from companic and the tendency to over-education, wh acts so disastrously upon those who h a hereditary tendency to mental derar ment.

It would be difficult to enforce strongly the observance of the princi that the school-life of this neurotic cl is the most critical time of moral and p sical development; it is the period wh the most careful and discriminating pervision must be exercised. I would pecially emphasize the moral aspect education, because I have through a l experience but too often seen the sad sults of carelessness, or want of kno edge, on the part of those who have committed to their care the training education of the young. It is a fact, yond all shadow of controversy, that m turbation is largely prevalent in scho for both sexes, and it is especially among the highly-strung, sensitive spring of the neurotic. Any head o school, male or female, who would ture to say otherwise would display amount of ignorance which should qualify for such a position. In the patients' room of our hospital, the nu ber of young people, of both sexes, are brought for advice and treatment

disorders which can be clearly traced to the habit, are too numerous to be disregarded, and they carry conviction.

There can be no doubt that education properly conducted upon lines based upon the elements of physical and mental physiology is a potent factor in warding off insane developments in those predisposed to them by neurotic heredity; and so, on the other hand, we find that when the education has been faulty, either by reason of deficient moral supervision and training, or from disregard of the physical and mental strength, ability, and idiosyncrasies of the pupil, the foundation is laid for the development of the symptoms which we so often find make their appearance among the young adolescents on leaving school to enter upon the battle of life, and maintain their individuality in the world.

I would say, with regard to masturbation, that although it exists largely where numbers of boys and girls are collected together, as in schools, in which the habit is taught by one to another, and so indulged in to great excess (unless checked by that watchful supervision which should always be in force, yet exercised in such a manner as to be almost unobserved), yet the habit is also now and then acquired accidentally by very young children without any teaching from without.

It is especially so among the neurotic children which come under observation for all the various nervous disorders, such as those we see at a special hospital for nervous diseases. Among the children admitted as in-patients of even three or four years of age, the habit appears, and it is not difficult to imagine how in the later years of school life and adolescence, the pernicious habit may be fostered and encouraged by vicious associates.

It is needless to point out the serious results which are bound to follow the long-continued recurrence of conditions of high nervous excitement and shock which the frequent indulgence in the habit must engender, but the fact can not be too frequently stated, in the hope that by frequent repetition attention may be kept alive, and watchfulness stimulated to check it.

In thus dealing with the question of masturbation as a cause of incipient insanity, I would repeat that it must always be borne in mind that it is frequently met with in both sexes as a symptom of mental and nervous instability brought about by other causes, in which heredity plays a leading part.

Treatment.—This resolves itself into rest for the brain, and improvement of the moral and physical health generally. It is useless endeavoring to encourage mental work when the brain and nervous system are in a state of weakness and exhaustion. It is far better that study or business should at once be given up for a time, and that the patient should be encouraged to engage in some healthy physical occupation, but it must be under a kind yet vigilant supervision, for without it the treatment is sure to fail. It is extremely satisfactory to observe the effect of a few weeks of farm, say, or garden work upon the mental condition of the patient, work which puts the muscular system into good training and condition, and brings the physical health generally up to a high standard of excellence. The mental processes should be allowed, to a great extent, to "lie fallow," and no greater strain put upon the attention than that which the simple operations of mechanical labor demand.

Meanwhile, pure air, cheerful companionship, with a good healthy moral tone, combined with sympathy and kindness, all tend to relieve monotony, and the result is soon seen in the increasing strength of the body, and the awakening activity of the mental processes which will ere long commence to assert themselves.

The general appearance and conduct of the patient soon betokens the return of nervous stability and mental vigor; the vacillating uncertainty and morbid shyness, the furtive glance, and the shuffling gait, are replaced by directness of purpose, and an upright bearing, while the patient slowly and surely recovers. If possible, the period of recuperation should never be less than three months, so that the improvement may be continued and confirmed.

Much, of course, depends upon the nature of the case, and the temperament of the patient, but we should certainly err on the side of caution, and discourage any

attempt at mental work until the tone of the brain and nervous system has been thoroughly restored. When we are satisfied upon this point we may commence a course of mind-training, gradually and carefully enlarging the scope of the mental work until we find our patient able to calculate, concentrate his attention, and exercise forethought and discrimination in work which a few months before had been completely beyond his powers.

In all these cases of youthful breakdown we have to act promptly and decisively. There is nothing to be gained by allowing the patient to struggle on with mental work when the brain is out of gear. The only hope of recovery lies in mental rest, and such physical training as is suitable to the age, sex, and nature of the case, and when once it is diagnosed, the sooner the treatment is commenced the better.

I have said nothing about medical treatment, for, beyond the ordinary medicines necessary for keeping the various excretions in order, but little is required. A little bromide judiciously administered (when there is a tendency to over-excitement, or extreme restlessness), combined with extract salix nigra liquid, if the sexual system is too active will, as a rule, be all that is necessary. Beyond this, "medicine out of the bottle" is not required, and the less the drugging of these cases is resorted to, the better it will be for the ultimate and permanent recovery of the patient.

[Written for the MEDICAL BRIEF.]

The Relation of the Unobliterated Funicular or Vaginal Process to the Production of Inguinal Hernia and Certain Forms of Hydrocele.

BY ARCH. YOUNG, M. B., C. M., B. SC.,
Dispensary Surgeon, Western Infirmary, Glasgow; Extra Honorary Surgeon Royal Hospital for Sick Children, Glasgow; Late Senior Assistant to the Regius Professor of Surgery, University of Glasgow, etc. Glasgow, Scotland.

While the role of the funicular process in the production of what is generally recognized as, and termed, congenital hernia is probably sufficiently understood, it may be found of use to the general practition to draw up something like a consiste scheme embodying the chief variations its closure, and the bearing of each up the production not only of hernia, but al of the several forms of hydrocele.

The student of surgery is apt to form somewhat imperfect idea of the impo ance of the process, and at any rate the close relation between its part in t development of hernia and the role may equally play in the production hydrocele. He usually reads the two su jects at different times; he looks on the as widely different lesions—as from son points of view they no doubt are; he s dom takes them up together, as he ough The result generally is that he finds hi self in considerable confusion, when, p haps, unaided, he suddenly realizes th they have between them the same co mon factor, viz., that process of peri neum which may, from whatever cau in whole or in part, at one level or at s other, fail to accomplish its normal obl eration.

After some considerable experience the teaching of surgery, I have found worth while to work the subject into more or less consistent scheme, embr ing the chief variations in the closure, obliteration, of the funicular process, dicating for each the possible patholo ical results in the production of hernia hydrocele.

This scheme has been so well receiv by my students, and seems to answer purpose so satisfactorily with them, th it is put forward here in somewhat conc form, and presented for the considerati of the student of a larger growth—t brother practitioner.

The accompanying diagrams will ser to illustrate the successive points in t scheme.

The Vaginal or Funicular Process is funnel-shaped sac of peritoneum, c nected at first with the general cavity the peritoneum, which at, or shortly aft birth should undergo obliteration, exc at its lower part, where it persists as covering to the testicle, viz., the *Tun Vaginalis Testis.* (Fig. A1.)

Suppose, then, that this normal p cess of obliteration has occurred, wh are the possibilities as regards both h

nia and hydrocele? Clearly, any hernia which may form will be of the type termed *acquired*, an entirely new peritoneal protrusion, being necessary for the formation of the sac, such sac descending along the inguinal canal into the scrotum, and in time reaching the testicle below, but shut off from this by the tunica vaginalis, which ensheathes it. (Fig. A3.)

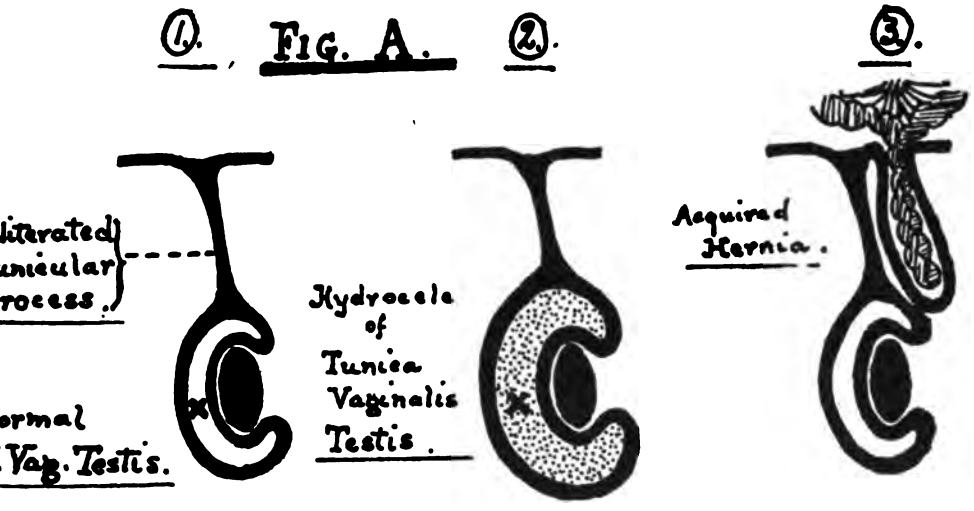
Or, on the other hand, a *hydrocele of the tunica vaginalis testis* may develop (Fig. A2). In the former, the cord will be, to some extent at least, concealed by the neck of the hernia; in the other it will be entirely free up to the point to which the bulging tunica vaginalis reaches.

The two conditions are distinct enough clinically, as they are anatomically, but

I. The funicular process may remain patent throughout its whole extent. (Fig. B1.)

II. *That portion of the process from the testicle up may remain patent*, and directly continuous with the general peritoneum, *occlusion taking place close to the testicle*, and tunica vaginalis testis being formed in the usual way. (Fig. C1.)

III. *The process may close at its upper (abdominal) end, remaining entirely patent from about the internal inguinal ring down*, the cavity of the tunica vaginalis testis being continued up along the cord in a funnel-shaped canal shut off from the general peritoneal cavity by the occluding diaphragm above. (Fig. D1.)



both are associated with the normal complete closure of the funicular process.

They may occur together, but confusion in diagnosis need seldom arise even then, for the hydrocele remains when the hernia has been reduced, and there are abundant means of clinical differentiation in addition, into which, however, it is no part of the object of this paper to enter.

So much, then, for the possibilities associated with normal completeness of obliteration of the funicular process.

Let us summarize the possibilities in the direction of incompleteness, and see what each of these may lead to as regards hernia and hydrocele.

IV. *The process may close above the testicle for a variable distance*, the tunica vaginalis testis being quite normally developed, *and obliteration also occur close to the internal inguinal ring, but some portion between these two points continue patent*, this patent part of the process being shut off above from the general peritoneal cavity, and below from the tunica vaginalis testis. (Fig. E1.)

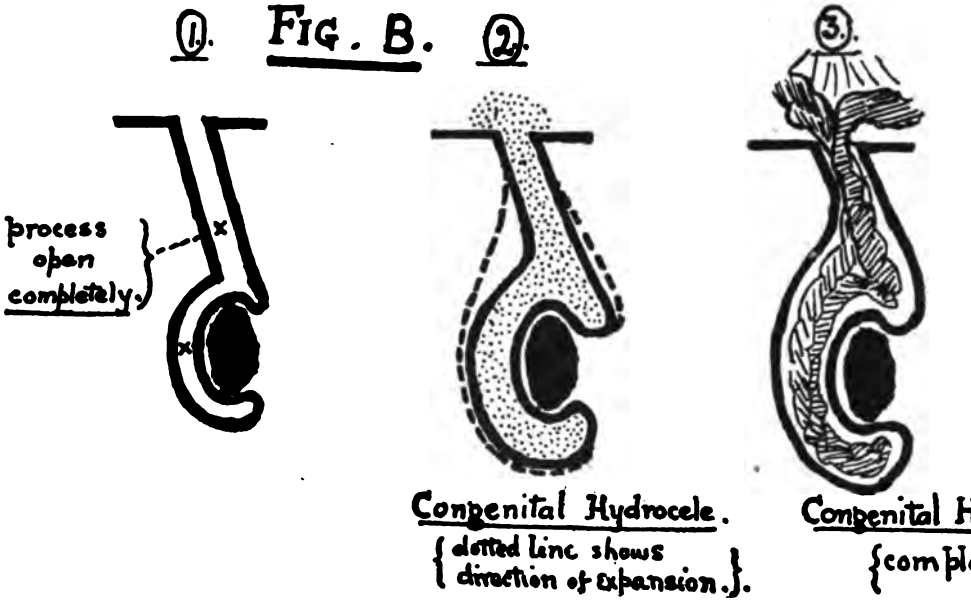
I. *The Funicular Process Remains Patent Throughout.* (Fig. B1.)

With a condition of this kind it is clear that any fluid collection in the peritoneal cavity will have free access to the whole canal, and may come to greatly distend

it. There is no separate tunica vaginalis testis, the whole cavity being unbroken. Hence, fluid may as readily flow up into the abdomen from the distal part of the sac when the recumbent posture is assumed, as it will certainly gravitate downwards again whenever the erect posture is adopted. A hydrocele of this type is generally known as a *congenital hydrocele*, though, looked at purely from the developmental point of view, the term "congenital" might with perfect justice be applied to hydroceles occurring under the other heads, II, III and IV. (Fig. B2.)

Similarly, if an hernial protrusion occurs along an entirely unobliterated process, the bowel finds its way down to the

track, potential or actual, which can demonstrated to have a definite devel mental role. That view may possil enough be correct, but for the present need not further concern us. The o point of importance seems to be that would probably be more satisfactory term this particular form of hernia simply "congenital," but *"complete c genital,"* the complete absence of ob eration allowing of the sac being occup throughout its entire extent by an truded viscus, not that this occupati need from the first be complete, but t from the first its potential value is t of a *"complete congenital" hernia.* (F B3.)



testicle, but, unlike "acquired hernia," is not checked there by the tunica vaginalis testis. The cavity of the tunica is not shut off above, hence the bowel finds its way free, and may ere long come to almost entirely embrace and conceal the testis.

That is the best recognized form of *congenital inguinal hernia.*

Apart from the fact that the other forms of hernia still to be mentioned might quite justifiably be termed "congenital," there is, of course, the further fact that not a few observers believe every hernia to be due to congenital deficiency, or, at least, to take place only along some

It is obvious that in the one case th may be present at the same time both c genital hydrocele and congenital hern Indeed, it is probable that where cong ital hydrocele of the complete variety present, the corresponding form of h nia must at some time appear, unl either the upper opening of the process somewhat narrowed, or the bowel is hu unusually high, its mesentery not bei long enough to allow of protrusion i a patent sac, a possibility of somewh remote nature.

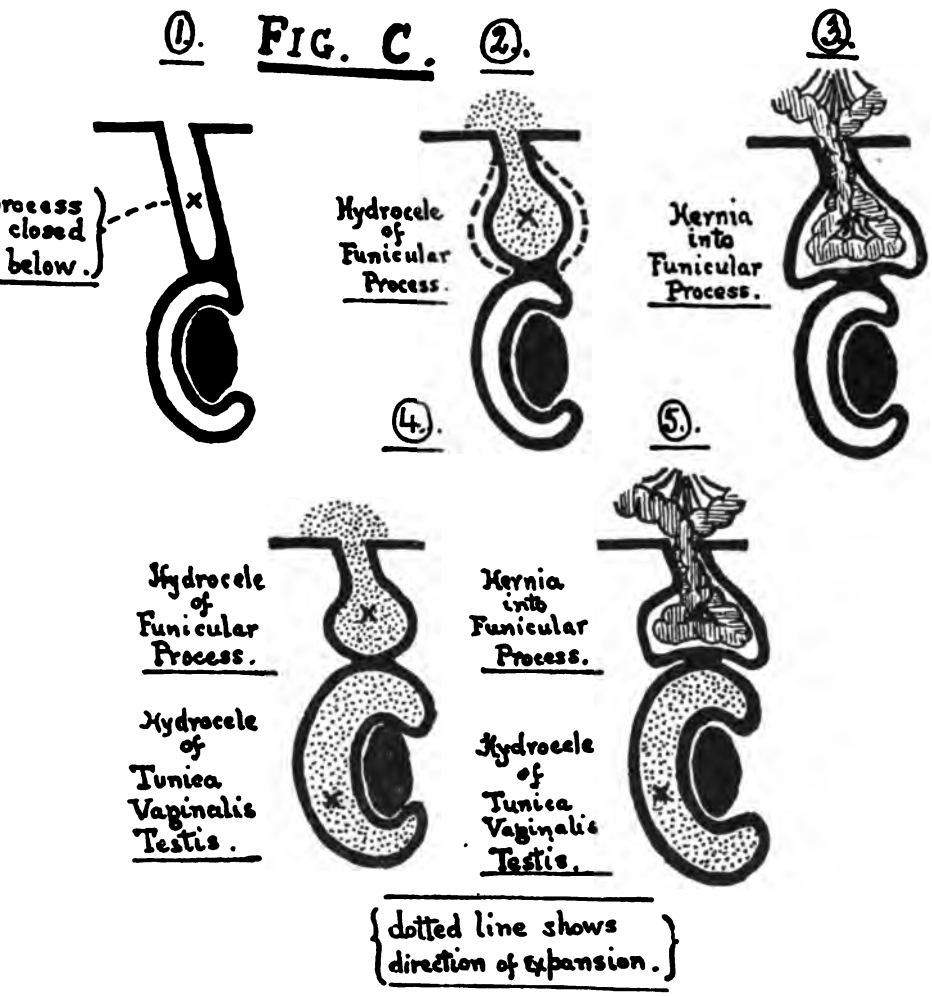
To illustrate the combination of her and hydrocele in this form would requ

merely a simple adaptation or composite arrangement of Figs. B2 and 3.

II. *The funicular process remains patent as far down as the testicle, but the tunica vaginalis testis is shut off below from the general cavity of the peritoneum above.* (Fig. C1.)

In this the possibilities are not unlike what we have just described under Class

Hydrocele of the upper unobliterated portion might quite reasonably be termed *"incomplete congenital" hydrocele*, and hernia into the same might be described as *"incomplete congenital" hernia.* As a matter of fact, the terms in common use regarding each are, *hydrocele of the funicular process, and hernia into the funicular process.* (Figs. C2 and 3.)



, with this difference, however, that the unica vaginalis testis is completely shut off below, and, consequently, fluid in the upper part of the funicular process does not communicate with any in the tunica vaginalis testis, neither does any bowel protruded from the abdomen along the upper patent channel reach further than the upper end of the testicle.

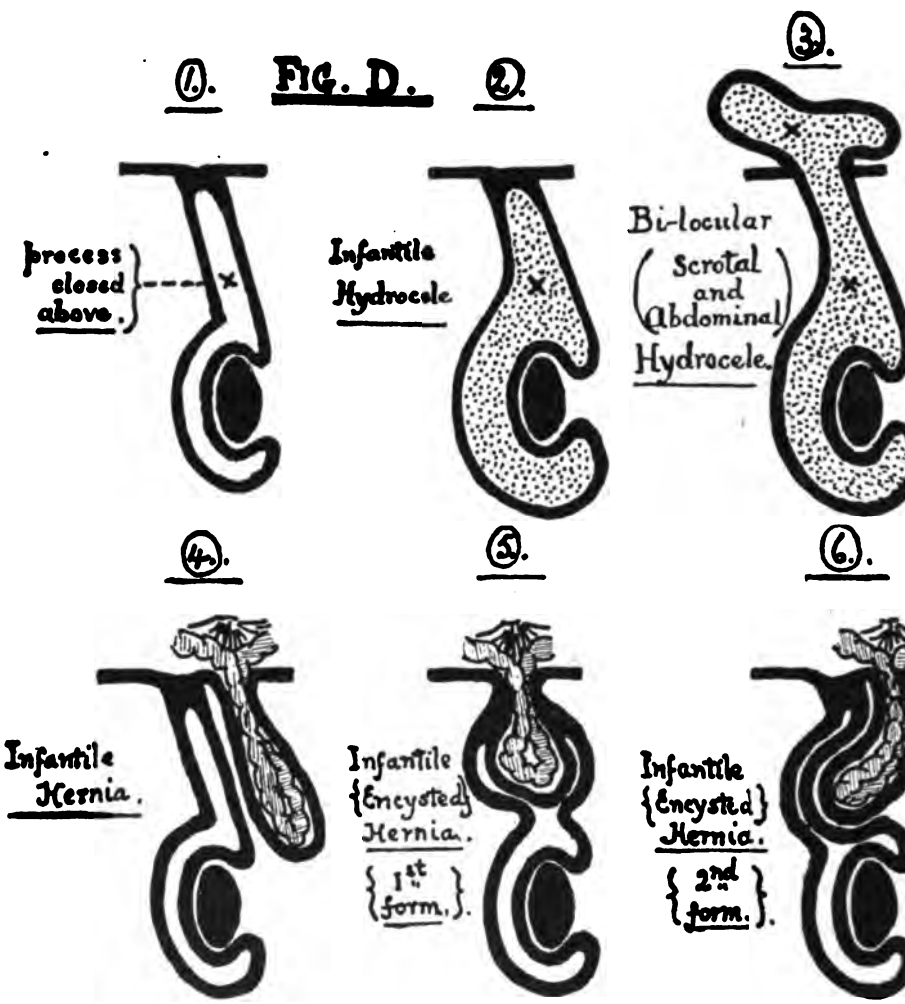
Further, not only may these exist together in the same case, but they may be present along with, though anatomically quite independent of, a hydrocele of the tunica vaginalis testis, a possibility illustrated by Figs. C4 and 5.

III. *The process becomes obliterated at its upper (abdominal) end, but remains patent below, so that the cavity of the*

tunica vaginalis testis is not normally shut off at the upper end of the testicle, but is continuous with the open funnel shaped canal passing upwards along the cord, perhaps as high as the internal inguinal ring. (Fig. D1.)

Where hydrocele develops in such a condition as this, the sac is formed from the whole distended process, as far up as the level of the obliteration, say at the internal inguinal ring. Although, strictly, such a condition is a congenital one, the term usually applied is that of *infantile hydrocele.* (Fig. D2.) If of considerable size, there is a large oval swelling below, continued upwards along the cord as far as the internal ring as a tense funnel-shaped process. If the tension be great,

the elements of the cord may not be d tinguishable from it, a marked point difference between it and ordinary hyd cele of the tunica vaginalis, above wh the cord can be easily isolated, as a ru From the ordinary or complete congeni hydrocele it differs in not emptying or laxing in tension with the adoption of recumbent posture.



A somewhat rare form of this hydroc is seen in the so-called bilocular, or sc tal and abdominal hydrocele.

In this it may be supposed that the t sion is great enough to distend the ob eration septum at the upper end, so th the hydrocele sac extends upwards to almost indefinite degree, forming some cases a huge intra-abdominal s

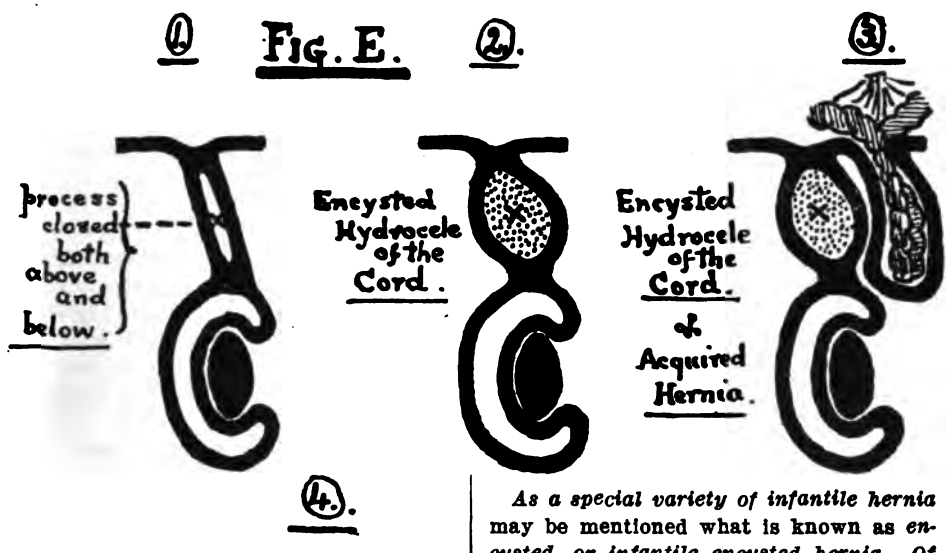
of course outside the cavity of the general peritoneum. Such a possibility is represented in Fig. D3.

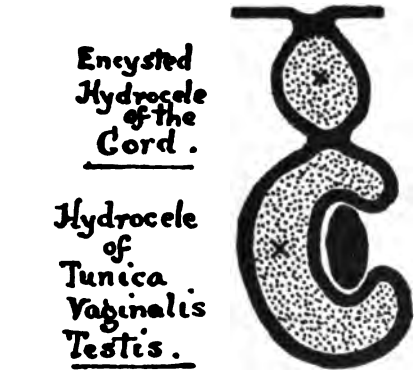
Hernia occurring in association with this state of the funicular process might in some cases be quite justifiably termed an acquired hernia.

The hernial sac is probably to some extent, at least, however, guided in its descent, if not actually encouraged, by the immature condition of things, and at any rate it usually presents certain abnormal anatomical relations.

Very often it emerges quite close to, but behind, the obliterated opening of the funicular process, and, passing downwards in the same relation to it, preserves as additional coverings to itself the two extra layers formed by the anterior and posterior layers of the process, so that, in cutting down upon the hernia, the surgeon's knife goes through (1) the anterior layer of the unobliterated funicular process, (2) the posterior layer of the same, (3) the peritoneal covering of the proper hernial sac, *i. e.*, three layers of peritoneum instead of the customary single layer.

This condition is known as *infantile hernia.* (Fig. D4.)





As a special variety of infantile hernia may be mentioned what is known as *encysted, or infantile encysted hernia. Of this, two forms are met with,* differing in reality only regarding the level at which occurs the process of invagination which characterizes them both.

In the one, the hernial sac is formed by distension, and bulging downwards of the obliteration septum, the hernia passing into the unobliterated funicular process below, carrying in front of it the stretched septum, and adjacent peritoneum. (Fig. D5.)

Here, the surgeon's knife would have to go through only two layers, viz., the anterior layer of the unobliterated funicular process, and the covering formed by the expanded septum and peritoneum drawn down with it.

In the other form the hernia is for some little distance quite behind the unobliterated funicular process, but then invaginates it, so that there are the same three layers as in the simple type of infantile hernia in front of any contained viscus. (Fig. D6.)

It is obvious, of course, that as in Class C, so also here hernia and hydrocele may occur together, but no separate diagramatic representation is necessary.

IV. *The process becomes obliterated both above and below, the tunica vaginalis testis being quite normally formed, but at some part of the canal failure of obliteration occurs.* (Fig. E1.)

In such a case, fluid may collect in, and distend, the unobliterated canal, and there is produced what is known as *encysted hydrocele of the cord* (Fig. E2). This may be quite small, or may distend within wide limits.

It has nothing in common with, though it is at times confused with, encysted hydrocele of the testicle or epididymis—conditions in most cases connected with embryonic or fetal structures (müllerian duct, Wolffian body, etc.).

Hernia occurring here will be of the ordinary acquired variety, though, of course, if the cyst of the cord be of considerable size or extent, it may, strictly speaking, have quite similar relations to the separate hernial sac, as does the unobliterated process in the typical infantile hernia. Surgically, however, this has no practical importance. (Fig. E3.)

A hydrocele of the tunica vaginalis testis may, obviously, be developed in the same case as an encysted hydrocele of the cord, but the two conditions are quite separate and independent. (Fig. E4.)

[Written for the MEDICAL BRIEF.]

The Universities of Scotland.

BY D. J. JONES, M. B., C. M. (EDIN.),
Deputy Coroner for South Breckonshire.
London, England.

As a medical graduate of the University of Edinburgh of many years' standing, and as one who has traveled in most parts of the world, and has had favorable opportunities of studying the educational advantages afforded by the universities of other countries, I gladly avail myself of the invitation of the Editor of the MEDICAL BRIEF to give a short account of university life in Scotland such as may be of practical use to our American confreres who contemplate a visit to the Land of Burns.

There are in Scotland four great versities:

1. The University of Edinburgh.
2. The University of Glasgow.
3. The University of Aberdeen.
4. The University of St. Andrews.

I have not arranged them in chronological order or in the order of their importance. They are all quite distinct and arate; that is to say, each of them has own governing body, and confers its degrees, although they are connected various links. For example, a profe moving from one Scottish University another—and this occurs sometim continues to count his years of ser just as if his whole life were passed one university.

It is curious that although so m American physicians and surgeons London annually, few of them thin worth while to spend a week or two Scotland. It is possible that they are terred by the distance, although tha inconsiderable. Edinburgh is four dred miles from London, and Glasgo mile or two further, but in a somew different direction. Aberdeen is five dred and forty miles, whilst St. Andr is four hundred and forty-four. these distances involve practically no of time, for the train services are so mirably arranged that the journey is peditiously performed at night, and just as easy to sleep in a comfort berth in the car as in one's hotel.

Take Edinburgh, for example: ther a service by four different lines, every evening six or eight trains l London for the northern capital. 11.30 P. M. Great Northern reaches E burgh at 7.15 A. M., and the 11.50 P. M the London & Northwestern arrive 7.50 A. M.

Aberdeen is equally accessible, for 11.50 P. M. from London arrives at its tination at 11.40 the next morning.

These trains, in addition to being comfortable, are run with absolute p tuality, and usually reach their respec destinations on the tick of the clock. is desirable, especially in the heigh the season—August and September—t cure a berth in advance, and this is ea arranged by telephone. On the Lon & Northwestern, and on most of the o

lines, a return ticket, by taking which a considerable saving is effected, is available on the homeward journey via either Edinburgh or Glasgow. Week-end tickets from Friday to Tuesday are also issued at considerably reduced fares; for example, the first-class return from London to Edinburgh, available from Friday to Tuesday, inclusive, is £3, or about fifteen dollars, with an additional charge each way of 7s. 6d., or two dollars, for the sleeper. Hotel accommodation in all these cities is excellent. In Edinburgh there are the North British and the Caledonian, both owned by the railway companies, whilst at Aberdeen the Imperial is a good type of a thoroughly comfortable hotel, long famed for its good cooking, good wines and superb whiskies.

These, however, although not unessential, are somewhat remote considerations, and have little or nothing to do with medical life in Scotland. I will endeavor to be more specific, and give a brief account first of Edinburgh, and then of the other Scottish universities.

Edinburgh, since the time of James IV, has been the capital of Scotland. It is one of the most beautiful cities in the world, and its appellation, "the Modern Athens," is really deserved. The town is built entirely of stone, and the Salisbury Crags, Arthur's Seat, Calton Hill, with the lovely blue of the Firth of Forth, are not easily surpassed. The university itself was founded in 1582, and the celebration of its tercentenary brought together a collection of distinguished men from all parts of the world which has probably never been equalled. I well remember the 17th of April, 1884, when the university conferred its highest honor, the degree of LL. D., on Louis Pasteur, Ferdinand de Lesseps, Pettenkofer of Munich, Wilhelm von Bunsen of Heidelberg, Cremona of Rome, Schmiedeberg of Strasburg, Virchow of Berlin, Jowett of Oxford, Samuel W. Gross of Philadelphia, and last, but not least, on His Excellency James Russell Lowell.

When I entered as a student, William Turner was the Professor of Anatomy, having been appointed to the Chair in 1867. He was not a Scotsman, but came from the north of England, and received his medical education in London. He was an admirable lecturer and demonstrator, and attracted crowds of students, amongst whom were numbered men of all nationalities, and from every quarter of the globe. Sir Wm. Turner is now Principal of the University, and at the head of affairs. A few years ago he was succeeded in his Chair by Professor Cunningham, M. D., LL. D., D. C. L., F. R. S., one of the most distinguished anatomists in the British Kingdom.

In my time, as now, Sir T. R. Fraser, the well-known pharmacologist, was Professor of Materia Medica, having succeeded Sir Robert Christison in 1877.

The present Professor of Medicine in the university is Professor Wyllie, who succeeded Sir Thomas Grainger Stewart.

The Professor of Physiology in my time was William Rutterford, a kindly man, and a good teacher, although of somewhat eccentric habits. He had succeeded Professor Hughes Bennett, and was followed in his turn by the present incumbent of the Chair, Professor Schäfer, an importation from University College, London, and a pupil of Sharpey and Burdon-Sanderson.

John Chiene, the Professor of Surgery, is one of the best exponents of Scotch surgery, and is a typical Scotsman.

The professors in the university have wards in the Royal Infirmary, and devote much time to systematic clinical teaching. One of the best teachers on the staff of the Royal Infirmary is George Gibson, the Editor of the *Edinburgh Medical Journal*. He is an accomplished physician, and commands a large following. Byrom Bramwell is known both as a pathologist and as a writer on diseases of the nervous system.

Another notable man in Edinburgh, although not a university professor, is Sir Patrick Heron Watson. His practice is a large one, and he numbers amongst his patients many distinguished people. The teaching in all branches of the medical faculty is thorough and practical. The classes are large, and the emoluments of the staff, although perhaps not so great as in former days, are still princely. The professors can afford to devote the whole of their time to their official duties, and are, as a rule, free from the cares of active practice. The cost to the student of his curriculum is comparatively small.

and bursaries, prizes, scholarships and fellowships, are freely bestowed. Many of the students in the early days were sons of small crofters, and came to Edinbugh with a bag of oatmeal, and a very small sum of ready cash, which had to suffice until their return home at the end of the session. This is not so common now as in days gone by, but the Scotch universities afford ample opportunities for the training of clever lads of small means.

Glasgow is a city of some seven hundred and sixty thousand inhabitants, and the commercial metropolis of Scotland, is on the Clyde, sixty miles from the sea. It is famous for its shipbuilding, and is a center of industries of all kinds. Although not so romantically situated as Edinburgh, it is surrounded by most beautiful country. The university was founded by Pope Nicholas V, and is a corporate body, with a Chancellor, Rector, Deans of Faculties, Principal, Professors and Students. The Rector is elected by the students, who are careful to choose as their representative some one of note in literature, science or politics. The competition for this honor is keen, and is conducted with all the formalities of a contested election. Glancing down the list of Rectors for the last half century we come across the names of Viscount Palmerston, the Rt. Hon. Benjamin Disraeli (Earl of Beaconsfield), William Ewart Gladstone, Joseph Chamberlain and Lord Roseberry.

That the university is in a prosperous condition is shown by the fact that during the last nine years the income has increased over £10,000 per annum, the sum being almost entirely derived from payments by students whose numbers have, in seven years, increased from one thousand eight hundred and thirty-six to two thousand two hundred and nineteen.

The list of professors at the present day comprises men who have made their mark in their respective specialties. The Professor of Materia Medica is Dr. Ralph Stockman, well known as a writer and lecturer on pharmacology, whilst Sir William Gairdner, Dr. M'Call Anderson, Professor M'Kendrick the physiologist, and Professor Cleland the anatomist, have all done good work. Sir William MacEwen, the Professor of Surgery, is as we known in America as in Scotland. In ad dition to these there are numerou younger men who take their share in th teaching, and many of whom by the influ of time will be incorporated in the un versity body.

The only objection that can be urged t even a temporary residence in Glasgo is that the climate at times leaves muc to be desired. Fog, mist and rain, wit cold bleak winds, prevail during the wi ter months, and even in the height of th summer are not unknown.

Aberdeen, the granite city of the nort is at the mouth of the Dee between it an the Don. The university derives its origi and endowments from two separate, an for a long time, independent foundation One of these, the university founded b William Elphinstone, Bishop of Aberdee dates from 1494-5, and within it was afte wards founded, in 1505, the College of S Mary, subsequently called King's Colleg The other foundation was that of Mari chal College, founded in 1593 by Georg Keith, fifth Earl of Marischal. The tw colleges, or academic corporations, bot exercising university rights and priv leges, co-existed for a long period as ind pendent and rival institutions, but wer finally incorporated in 1860 under th style and title of the University of Abe deen.

Since then it has flourished exceedingl and is now a great center of learnin comprising various faculties, of whic that of medicine is not the least prospe ous. The staff of professors comprise men of the highest reputation, one of th best known being Theodore Cash, M. D F. R. S., the Professor of Materia Medic and a pupil of Lauder Brunton. He is pure pharmacologist in the best sense o the word. Prof. Matthew Hay, formerl demonstrator to T. R. Fraser, of Edi burgh, is the incumbent of the Chair o Forensic Medicine and Medical Jurispr dence, whilst Prof. Hamilton is respons ble for Pathology. Both at Aberdeen an at Glasgow there are ample facilities fo girls to take their degrees in medicin At Glasgow, the men and women, at a events in some subjects, are kept apar but in the University of Aberdeen mixe classes are popular. The introduction o

the female element into the life of the university has given rise to no complications, and the influence of the girls over the young men is said to be beneficial rather than otherwise.

The University of St. Andrews comprises, as regards the Faculty of Medicine, the University College of St. Andrews and University College Dundee. It is, perhaps, less flourishing than the other Scottish universities, but is a good educational center.

Finsbury Park, W.

[Written for the MEDICAL BRIEF.]

Thoughts Regarding Some of Our Cardiac Remedies.

BY FRANK E. WEST, A. M., M. D.,

Professor Materia Medica, Therapeutics and Clinical Medicine Long Island College Hospital; Visiting Physician Long Island College Hospital; Consulting Physician to Brooklyn and Kings County Hospitals; Fellow of the Academy of Medicine; Member of the Kings County, County Medical and Pathological Societies, etc. Brooklyn, N. Y.

From some of the phases presented by acute diseases, and the tendency possibly on the part of many to the use of the class of remedies generally called cardiac remedies, it would seem as though a thought or two regarding their action and indication might be opportune.

This class of remedies seems to be exceedingly popular and quite generally employed, possibly in some instances when others might be more wisely selected. For a clear scientific application of these agents, we ought to bear in mind their physiological action in selecting the remedy to be employed.

Perhaps in no class of cases is it more important to individualize our patient.

General teaching is that such an agent as digitalis is indicated by loss of cardiac power. This loss of power may be occasioned by various causes independently of any weakness inherent to the heart muscle. Where the loss of power is due to the weakness in the heart itself, and there being no other contrary indications, such as degeneration, either cardiac or vascular, digitalis will frequently serve a purpose. But where the loss of power is toxic, or by increased cardiac force through the use of digitalis, there is danger of cardiac strain—as so frequently the case—then its use is certainly unwise, except as this action is overcome by the use of such agents as would reduce resistance to the circulation.

Digitalis at the same time that it increases the force of cardiac systole, produces arterial contraction, hence resistance. And, therefore, in many of our cases, except where there is careful adaptation of dose, is a factor in causing ventricular dilatation, which may eventually lead to cardiac degeneration.

This question of dose is a matter of great importance, and as an effect is gotten from its use, the quantity given should be graduated so as to maintain a uniform effect. That is to say, if when we first employ the drug in case of weak heart, a given quantity is required to accomplish the effect, but that improved circulation, owing to its action, improved absorption occurs *pari pasu*, the effect is increased, hence a smaller dose is needed to maintain the effect which was originally obtained, and by thus graduating our dose, adapting the quantity to the effect, we are able to maintain a more uniform condition, and postpone the time when failure to respond occurs in cases of organic condition where cardiac support must be maintained for an indefinite time.

I am constantly impressed with the lack of wisdom in cases of cardiac disease of giving such an agent as digitalis in considerable quantities for walking patients, and allowing them to go about while taking these large doses, for a quantity which is adequate to maintain free and proper heart action while the patient is active is in excess when the patient is quiet.

The point which I wish to make is this: that with this drug the least possible amount should be used to accomplish the effect desired, and this quantity should be still further modified as the treatment goes on.

Another word of protest I wish to make with regard to the use of caffeine. It is not unusual that this remedy is prescribed for more or less continued use in cardiac weakness. Caffeine increases cardiac force by reason of its action upon the central nervous system. Hence is

what may be termed an exhaustive or an exhausting agent. As a remedy to tide us over a crisis until some other agent may be employed which will increase power by reason of its influence upon the heart muscle, cardiac ganglia, and improve nervous control, it is exceedingly valuable, and undoubtedly when so employed will enable us to save many lives, but as an agent to rely upon as a cardiac support, it is, in my opinion, harmful, and a heart which has been supported by the use of this agent for a considerable time is less susceptible to stimulation from other agents, and hastens the time when we arrive at a condition graphically described as physiological bankruptcy.

A combination of several of the cardiac stimulants is frequently of decided advantage, enabling us, in this way, to use smaller quantities of a given drug with satisfactory results. Yet in cardiac disease simplicity in our therapeutics is of undoubted advantage. By combining such agents as digitalis, strophanthus, cactus, and preparations of nux vomica, we are often able to do what we have alluded to, the use of cactus, to my mind, being especially advantageous in cases of excessive heart action, tachycardia, etc., which we frequently meet. Yet with these combinations, a careful watch should be maintained of the effect obtained, and a graduation and modification of our dosage followed. By reason of the improved heart force minus arterial resistance, these remedies with digitalis are particularly advantageous. Sparteine, as a cardiac stimulant, or perhaps better as a heart tonic, is, to my mind, a useful agent, more especially where there is a rhythmical disturbance. As a pure heart tonic in many of our acute diseases where there is failing heart, its use has been very satisfactory. This seems not to have been the experience of many of our best observers. The suspicion arises in my mind that their failure to get effects from it may possibly have been due to their not using it in sufficient doses. Rarely do I employ less than one-fourth grain, and when occasion requires, do not hesitate to give it in considerably larger doses, even up to one or two grains, and from quite an extended use of it in weak heart my results have been very satisfactory.

One other thought in these cases i importance of attention to elimin Many a heart staggers and is embarr in its action by the burden of waste v it is carrying about. The use of a su cathartic is, in many an instance, a ceedingly beneficial cardiac tonic, by son of its removal of the load wh weak heart has to maintain.

[Written for the MEDICAL BRIEF.]

Remarks on Treatment of Fibr

BY ROBERT HAWTHORNE WYLIE, M.

Professor of Gynecology in the New York clinic; Gynecologist to the Polyclinic pital; Attending Gynecologist to the Patient Department Bellevue Hos Assistant Gynecologist to Bellevue pital; Surgeon to the Hackensack Hos Fellow of the Academy of Medicin New York City.

Fibroids *per se* rarely give actual unless they are wedged in the pelvis cause pain by pressure, or, unless intra-uterine, they are being squeeze or, unless acting more or less like a eign body in the abdomen, they ca certain amount of peritonitis, by me ical irritation. It is safe to say, there that when a fibroid is apparently g pain that it is complicated by salpin or is degenerating.

Hemorrhage as a symptom of fib has been over-rated, as salpingitis ovaritis, with an accompanying endo ritis, much more frequently causes orrhagia and metrorrhagia. You have very large fibroids, which giv increased flow unless they encroach the mucous membrane of the uterus cause hypertrophy of the same.

The method of treatment of fibroid been an evolution. When I began to tice medicine they were treated with ergot, electricity, and the curette, to them over the menopause. Hegar's ation was done to cause an arti menopause. I never saw any real b from ergot in stopping hemorrhag decreasing the tumor.

I went to Paris to see Apostoli, was the great apostle of electricity, after I left Bellevue Hospital. I wa that enthusiastic man for a short

bought his instruments, and on coming home gave electricity a fair trial. I found it a great means for impressing patients, and I had a number of patients who believed it was curing them while I used it, but they were mistaken.

I wish to give Apostoli credit for measuring his electricity, and trying to formulate the method of its use. Where sufficient amperes were used, the intrauterine pole, or the pole thrust into the tumor, would destroy tissue, and, therefore, blood vessels.

It tended to stop hemorrhage, but it was, at best, of little use, and I never could decide that the so-called electrolytic action did any good. We must remember that vascular fibroids, and especially fibromas, naturally vary considerably in size. Electricity was a great means of fooling many patients and doctors.

The sharp curette was and is still a good means of stopping hemorrhage when you can reach the bleeding mucous membrane in cases where radical means are not allowed. Hegar's operation served a good purpose in bringing on the menopause, and also in destroying the ovarian artery, but it properly fell rapidly into disuse as the operation for complete removal was simplified, because we know that the menopause in some cases is not followed by atrophy of the tumor, but that they are prone to degeneration of a more or less malignant type, and may grow rapidly. Even where the degeneration is not malignant, they may calcify and cause pain and discomfort in a mechanical way.

As intimated, it is not necessary to operate on every patient who has a fibroid in order to save her life, but the operation for removal of the fibroids, and leaving the uterus in child-bearing condition, or removing the whole organ, are so simplified and have so little mortality that few patients ought to be allowed to suffer the discomforts caused by fibroids.

31 West Thirty-Fifth Street.

I cheerfully enclose one dollar for continuance of the BRIEF's visits to my office. I have profited much by the perusal of this excellent and scholarly journal.—J. G. A. DAVIES, M. D., Canaseraga, N. Y.

[Written for the MEDICAL BRIEF.]

Curettage of the Uterus.

BY J. M. HUNDLEY, M. D.,

Professor of Diseases of Women in the University of Maryland; Gynecologist to the Hebrew Hospital; Gynecologist to the Emergency Hospital of Frederick, Md.; Member of the Medical and Chirurgical Faculty of Maryland; Fellow of the American Medical Association, etc. Baltimore, Md.

There is no operation in gynecology so frequently done as curettage of the uterus. It has now taken the place in great part of the older method of dealing with pelvic diseases. The older method I refer to is the application of iodine, and the use of boro-glyceride tampons. This method was the routine practice some years back. It was resorted to for the relief of every conceivable ailment which might arise from disease of the pelvic organs in women. As it was with the older method of iodine and tampons, so it is to-day in the use of the curette; both have their limitations.

In properly selected cases the curette in skillful hands is a valuable instrument, but the operation of curettage is not devoid of danger. Even in skillful hands, puncture of the uterus is every now and then reported. I myself have had the mishap twice with no serious results.

My object in this short paper is not to point out the class of cases which call for, or do not call for, curettage. What I wish to emphasize is that the indications calling for the operation should be definite and clear before the operation is undertaken. It appears to me that the average doctor is somewhat hazy in his ideas as to the indications demanding the operation. This is most likely due to the faulty teaching methods of a few years ago. It is only recently that the schools have recognized the necessity of a closer relationship between the student and patient. It is preposterous to expect a student who has had only didactic teaching to be competent to make an accurate diagnosis in any branch of medicine, and especially is this true in gynecology, and so this lack of accuracy in the treatment of a given case is not so much the fault of the man as it is of the teaching methods some years ago. What is incumbent upon us as teachers is to emphasize the value of

painstaking history recording and the necessity to properly interpret what is felt by the examining finger in making a bimanual examination of the pelvic organs, and that the history of the case is of the greatest value in deciding for or against such a simple operation as curettage.

Within the past week I have had two cases at my clinic emphasizing the points set forth. The first case was a white woman, thirty-nine, single; she began to menstruate at fifteen; suffered slight pain at each period until she was twenty-nine years old. At that time the pain began to increase in severity until now it is unbearable. She had undergone medical treatment of one kind and another without benefit, the only thing that brought relief was morphia.

Within a year previous to her entrance in the hospital she had been dilated and curetted twice without benefit. During the menstrual period she was never free from pain. Three small interstitial fibroids were removed from the uterus. The fibroids were the cause of the pain. Curettage could not possibly cure such a condition.

The second case is more interesting: This woman was forty-three years old, the mother of two children, the youngest child fourteen years of age. No miscarriages. Began to menstruate at thirteen; flow lasted two days. Two or three years ago the flow began to last six days, and became freer. In May of this year it lasted ten days; in August, the entire month with no let up. From August to November she had irregular uterine hemorrhages. Such was her condition when I saw her.

After obtaining a careful history of the case, the pelvic organs were examined. The vaginal outlet was greatly relaxed; the veins in each vaginal sulcus were visible and varicosed. The uterus was retroflexed; cervix normal, tubes and ovaries normal. No disease of heart, lungs or kidneys. Curettage was a proper procedure in this case. From scrapings obtained, malignant disease of the uterus was excluded. It could not have been done in any other way. But that was not sufficient in such a case to put a stop to the hemorrhage. The relaxed outlet should have been repaired, and the uterus replaced in its normal position and m tained there, preferably by ventral sus sion. The above operations were don me. On opening the abdomen, large p inent veins were seen crossing over bladder, and the veins of the broad ment were greatly varicosed.

My previous experience with such c warrants me in the belief that this will be permanently relieved of the ute hemorrhage from the above operati Curettage alone would not have cured

My contention is that, however sir the work attempted, be it curettag not, if the work is to be efficient and plete, the man doing it must be cap and have a clear conception of the cas hand.

It is foolish to curette a uterus fo lief of pain at the menstrual period, o the arrest of uterine hemorrhage, wit first ascertaining the cause of the pai hemorrhage.

The Good and Bad Effects of Thought.

BY MARC RAY HUGHES, M. D.,

Professor of Mental and Nervous Dise Barnes University (Medical Department St. Louis, Mo.

Speaking of the changes of chara wrought by thought, it is interestin note the changes of expression of viduals one meets on the street and o public places. The face, as has often said, "is the open door of the soul." can almost read the soul by the fa expressions. If we can not read verba the thoughts in one's mind, we can least read the trend, and where we k the trend of percepts, we can gener determine the thoughts therein, especi if we are acquainted with the person, know from constant observation their dividuality, character and idiosyncra Even as the marks of identity are sh by the lines on the face of the crimi so are the thoughts, both good and shown on the face of the infant or adu good or bad, vicious or humane.

One might say, after reading the ab "that no infants have vicious or

thoughts," which is quite a mistaken idea, for viciousness is inborn and inherited, the same as any other condition to which humanity might fall heir.

Children of criminal parentage are bound to inherit the vicious character of their ancestors. It may never be handed down to them as a direct inheritance, but may follow the law of atavic descent. Although viciousness and crime is inborn in the criminal, its outbreak may be avoided if properly handled, and the mind schooled in such a way as to reduce the tendency of criminal acts to a minimum.

By changing the thought you change the character and the lines of the face. This, of course, is easier to accomplish in the young than those of more mature age, where only the tendency to criminality is present, and not where crime has already asserted itself in the individual's mechanism.

In noticing the growth and development of children, it is interesting to watch particularly those who have the vicious temperament and the ones who have the humane. We notice, as we pass along the street or the playground of a children's school how easy it is to discern which child has the proper home surroundings, for their rearing shows foremost in their dispositions. From these children we pick out the rising generation that will be of service or a detriment to the community. Not only do we stamp them individuals of inborn tendency to degeneracy or viciousness, for viciousness is a form of degeneracy by their actions, but by the lines of inheritance, which is plainly written on their faces, and is the accompaniment which marches hand in hand with the vicious acts of childhood life.

No doubt there are many who will disagree with me when I say that children of vicious temperament whose facial lines show their parentage, may be completely changed for better or worse by their environment. Not only do their dispositions change, but the lines that give expression to the face. If the environment be good, the change of expression will be pleasing, and *vice versa*. It is only necessary for the observer to visit the rescue homes and reform schools to be convinced that what I have said in the foregoing lines is quite true. In the reform school we see boys whose ages have a wide range. Upon the faces of the younger boys we find well-marked lines of degeneracy, according to their class, and as we pass on in our examination to the intermediate and on to the upper classes we find gradually as we ascend a diminution of the lines that mark degeneracy in the young and adolescent stage.

I merely mention the foregoing remarks in passing to show that environment is conducive to thought, good and bad begetting their kind, which is the law of Nature. We notice people who have a careworn expression, whose faces portray a life of trouble, and whose environment is one of gloom, but the lines upon the face that tells us their life's history and sorrows are the thoughts of unhappiness that hold them victims and worshippers at the shrine of discontent.

These people go, day after day, brooding over a trouble (real or imaginary) until the lines of the face that once denoted a cheerful disposition, or one that could at least be made happy, begin to diminish, and finally disappear, and lines of opposite character take their place, becoming fixed lines, and destroying the features of a cheerful countenance, which is the background or foundation of good looks.

You then question whether that is so after having seen the "sad sweet faces" in many walks of life. The secret is this: those "sad sweet faces" are ones whose lines were formerly the accompaniment of a happy life and cheerful disposition upon whom lines of sorrow or sadness were just encroaching, or else it is the other way, a face with the accompanying lines of a life of sadness with a new life of happiness beginning to dawn upon the horizon, and bringing with it or changing the old lines of unhappiness to ones of happiness and content.

The effect thought has upon the lines of the face, as I have already mentioned, is largely dependent upon environment, and it is useless to urge people to make their own surroundings, for that is one of the processes of Nature, and we are put there by the hand of destiny; however, it is quite in our power to aid Nature in bettering our environment. We

can form the habit of cultivating and courting a cheerful disposition by using our natural powers of concentration upon the brighter things in life. Of course, it is a gradual process, like all habits, but finally you will notice in your own face faint lines of a different character than those you noticed before. Of course, they are very faint at first, but soon they become pronounced enough to be noticed by outsiders.

Naturally the cultivation of a pessimistic disposition will show in the face the same as the cultivation of the optimistic. So bear in mind that, no matter which disposition you have, you can change it. Also bear in mind the fact that if you have what we would call the ordinary disposition, neither pessimistic nor optimistic, and the lines of the face are not as becoming as they might be, thought along certain lines will change them. Then remember your face is a mirror, and a reflector of thoughts.

Signs and Symptoms of Gall-Stones.

BY MACK ROGERS, M. D.,

Professor of Anatomy and Clinical Surgery in the Birmingham Medical College; Surgeon to the Hillman Hospital; Member of the Jefferson County Medical Society, of the Medical Association of Alabama, of the American Medical Association and of the Southern Surgical and Gynecological Association. Birmingham, Ala.

The disease known as gall-stones is one of the most frequent of the biliary apparatus. It is assumed that twenty-five per cent of all persons reaching forty years of age develop gall-stones in some form. The condition may be acute or chronic, or it may be acute, superadded to the chronic form. The symptoms are more or less severe, but they are often present without giving rise to any trouble. In an acute attack we find the patient suffering from excruciating pain, referred to the region of the gall bladder. It comes on suddenly, and is usually paroxysmal in type, and radiates to the epigastrium or back to the shoulder blades. This pain does not yield readily to moist heat or internal medication. It may continue for a few minutes only or for several days in spite of opiates. This pain is intense while t stone is pasing from the gall bladder the bowel, and when it escapes the pa is suddenly relieved. Should this pa continue and jaundice ensue, the stone evidently obstructing the common du These attacks are known as hepatic col Pressure from the gall bladder excites aggravates the pain, and produces a na sea, and vomiting is nearly always pr ent in this condition. During a paroxys of pain and nausea, there is usually pr ent profound perspiration, and if co tinued long produces prostration. T pulse rate is usually lowered to fifty a even forty per minute. The temperatu rarely rises above 102° F.

These symptoms may last for a sho time only, and pass off quickly, or ma continue for several days, becoming le and less marked until they finally termi ate in the chronic condition.

I lay more stress on jaundice followi these attacks than most writers on th subject, for I do not believe that we ca have much trouble with the biliary a paratus for any length of time witho some degree of jaundice. The history previous attacks is of more or less di turbance of the gastric intestinal appa atus, such as indigestion, constipation wi chalky colored stools, or even the pre ence of gall-stones themselves. Age, se and physical condition play importa parts. Gall-stones are most frequent b tween forty and sixty years of age. F males are three times more affected tha males, and of these ninety per cent ha borne children. They are usually fou in persons of a robust, full habit, and a rarely found in thin, delicate and nervou persons.

I wish to emphasize the importance diligence and care in these special case in order that we may be able to make positive diagnosis. This is not alway easy, especially so in the first attack th lasts for a short time only and passes o without leaving any jaundice. Howeve the diagnosis can be based on sudden i tense pain, tenderness and rigidity, loca ized over the gall-bladder, accompanied b nausea, vomiting, perspiration, and ofte jaundice, clay colored stools containi gall-stones, together with a distended ga bladder, or a mass in that region. The

signs and symptoms grouped together in a large fleshy person over forty years of age, and especially in a woman that has borne children, will justify a diagnosis of gall-stones.

I have dwelt at length on the signs and symptoms of this condition because I realize how important a diagnosis is in the treatment of these cases. When we feel confident we have gall-stones that are giving trouble of a serious character, we should not hesitate to recommend surgical intervention. This is especially true, since there are no known medicinal remedies that materially affect this condition. When we have made a diagnosis of a condition demanding operation, we should not waste time in delay, but state the condition frankly to the patient or his friends, and in most instances they are amenable to reason. This is especially true with the present prognosis we have to offer them. In the hands of competent, experienced surgeons, I regard this as one of the safest operations in the abdominal cavity. The mortality in all non-malignant cases averages less than one per cent.

Cure of the Drink Habit by Hypno-Suggestion.

BY JOHN D. QUACKENBOS, M. D.,
Fellow of the Academy of Medicine; Member of the American Medical Association; Member of the London Society for Psychical Research; Member of the New Hampshire Medical Society; Member of the American Association for the Advancement of Science; Member of the New York Academy of Sciences. New York City.

The drink habit is singularly amenable to treatment by hypno-suggestion. In fact, some of the popular cures are in reality mere suggestion cures, there being no specific virtues in the drugs administered. Dipsomaniacs, as a rule, are easy subjects, in that they yield readily to hypnotic influence, and accept unconditionally the suggestions communicated by the operator.

Regular drunkards should be treated just before the close of the cycle of sobriety. Regularly recurring debauches have periods of varying length, the longest in my experience being three days, and I have satisfied myself that in most instances a relationship exists between the abuse of tobacco and the oncoming of the irresistible thirst, the depressing effects of the nicotine instinctively suggesting resort to the antidote.

Periodic drink storms are usually forecast by significant symptoms well known to the family and friends of the victim—irritability of temper, unreasonable suspicion, so described "cranky spells," abnormal restlessness, unaccountable depression.

Immediately upon the appearance of these symptoms, the patient should be treated by suggestion. Many such patients recognize their danger, and sincerely wish to be cured. They are hypnotized, and assured that alcohol in any form will disgust them, that they can not take it, that they can not carry the containing glass to their lips; the society of low companions is tabooed, the pleasures associated with drink and the glamor of the bar room are pictured as meretricious; the physical, mental, moral and financial bankruptcy that accompanies dipsomania is held before the view of the sleeper, and he is forced to the conviction that begotten of this apprehension there has come into his soul an abhorrence for drink and all that it stands for.

The supersonal mind is then directed to the vocation or avocation, or both, as circumstances suggest, and a career of wholesome activities and satisfactory successes is imaged as the legitimate consequence of the abandonment of the compromising habit.

A *sine qua non* of success is the consent of the patient, an honest desire on his part to reform. Habitual drunkards do not, as a rule, wish to be cured, and about ninety per cent of them, women as well as men, resent the approaches of those who desire to save them. Sometimes when no other form of appeal is effective, they may be frightened into a realization of the fact that constant use of alcoholic stimulants will result in organic changes in the liver, kidneys and brain, or by lowering the general powers of resistance, and at the same time irritating the bronchial tubes and the lungs, through which the alcohol is in part elim-

inated, markedly predispose to pneumonia and tubercular consumption.

When apprised of their enervated mental condition they honestly desire to cure the habit, but can not of themselves; the craving simulates a mania. Under these circumstances it is comparatively easy to persuade the patient to accept treatment, and a rescue may be effected in a week's time.

These views are based upon an experience with some one hundred cases extending over a period of three years. Of these cases, eighty per cent have been permanently cured. The success of the treatment bears a distinct relation to the amount of injury already inflicted upon the brain cells, and the accompanying mental and moral blight.

Its advantage consists in the rapidity of restoration to self-control without the necessity for effort, without the physical discomfort or suffering that usually attends the abandonment of a habit, most conspicuously without the breaking of family ties and the enforced absence from professional or business duties that are implied in sanitarium treatment.

The Treatment of Cancer.

BY THOMAS BASSETT KEYES, M. D.,

Formerly Professor of Suggestive Therapeutics in Harvey Medical College, and the First to Teach Suggestion in any Medical College in this country. Chicago, Ill.

In the annals of *Gynecology and Pediatry*, June, 1901, Vol. XIV, No. 9, Dr. J. Collins Warren, Professor of Surgery in Harvard University, says regarding cancer, that "In rare cases the degenerative processes, for a time at least, seem to exceed the processes of growth in cancer, and under these circumstances we observe a tendency to spontaneous cure. Such a case occurred recently at the Middlesex Hospital, London. A patient over eighty years of age was admitted to the cancer ward with cancer of the breast, recurring after operation. At the end of a year, although there had been no treatment of any kind, the nodules had disappeared, and she was apparently well. This tendency should be taken into count in estimating the value of drug supposed to have an influence cancer."

Under the heading "Pith of Current erature," *New York Medical Jou* August 29, 1903, page 438, is the fol ing: "*Cancer.*—Bell does not believe cancer is a microbic disease. The elem of cancer are present, according the author, in every one. They are mal cells, which, under the influenc metabolism, undergo malignant proli tion. In the early stages cancer ca cured."

As a predisposing cause he has tioned the following: "The vitiated dition of the blood by prostrating the siological activity of the various or and cellular structures, and paraly the *vis medicatrix naturæ* affords e facility for the new growth to estab its identity, and increase its area at expense of its environment. As to cause of cancer, study seems to poi out as a disease of trophic nerve dist ance. How then would suggestion i ence the operative surgical wound cancer site to healthy nutrition growth?"

In the beginning of these pape pointed out, and it is an absolute that wounds will heal much quicker w suggestion to that effect is made, numerous experiments in the treatm of chronic cases have been made by o observers, to the effect that these s which have resisted all other form treatment have yielded and healed thr the effects of suggestion.

Then, if cancer is a disease of tro nerve disturbance, either in weake the parts or promoting cell growth, only reasonable and rational to use gestion to promote healthy healing o wound, to increase nutrition, and a hea physiological condition, for as has conclusively shown by suggestion, we to a greater or less extent, influence phic nerve disturbances in the wa promoting greater nutrition to part the body, with these well-known fact view, after removal of the cancer.

I use suggestion to prevent its re to influence nutrition, and to restore parts to a healthy condition, but i

case would I attempt to cure cancer by suggestion alone. I do not wish to be understood as saying that all cases which have life that are afflicted with cancer can be cured, but I do say, and firmly believe, that we will obtain better results, and cure a much larger percentage of our cases, by using suggestion during and after surgical operation, and that in early cases and in those where the glands have not become greatly involved we will cure cancer. It will not return, for by suggestion we have brought into use the natural forces which the system possesses, and which enable it to counteract the causes of disease.

The body, in order to preserve its integrity, has at its disposal powers which have not been fully investigated, but the more the knowledge of these powers are inquired into the more does one become convinced of the fitness for the particular object for which they exist.

Some seven years ago, in *Surgery, Medicine and Psychology*, I published the following article:

"THE TREATMENT FOR CANCER—SURGERY, THEN SUGGESTION.

"Cancer causes more than four times as many deaths as typhoid fever, but while medical officers of health devote so much attention to their reports of the latter, they give little notice to the former. The continuously progressive increase in the cancer mortality has now been going on for more than a century.

"Having carefully reviewed the entire literature, as listed in the catalogue of the Surgeon-General's office, and the Index Medicus, in all some several hundred articles, I found that the concensus of opinion is, as everybody knows, that cancer can not be cured either by medical treatment or surgical operation, and as to whether cancer can best be treated by medical and local treatment or by surgical operation has received a large share of the physician's attention, and here we have a difference of opinion. Some claim that life is prolonged to a greater extent, and that better results are obtained by medical treatments and the employment of caustics and escharotics, and that the operative treatment shortens life. Others, the surgeons, claim that operative treatment is a more certain palliative; that it relieves the patient to a greater extent, and for a longer period of time, and that if an early operation is performed, a permanent cure will sometimes result. Early operation should be the watchword of every physician.

"If cancer is left to itself, says Jackson, it requires about seventeen months to destroy life, if of the cervix of the uterus, and if of the body, thirty one months. Sims gives the average at eighteen months. Pawlik states that, according to Lebert and West, the average duration from the beginning of the disease is sixteen or seventeen months.

"As to the treatment of uterine cancer, which is the most common, we have three methods, viz.: (1) Chemical or actual cauterization; (2) Amputation or excision of the diseased structure; (3) Extirpation of the entire uterus, and as much of the surrounding tissue and lymphatic glands as possible. Surgical technique has now so far advanced that the latter method is preferable, and should be carried out in properly selected cases. In order to do this, an early diagnosis must be made. This, I am aware, is not always possible, as the early life of cancer is insidious, usually unobservable, and symptomless, and the disease has often become too far advanced before the physician is consulted, for the early treatment by excision, and even in early operation without the aid of suggestion results are discouraging. Fritsch, one of our best operators, has given us the final results of sixty cases, of total extirpation for cancer of the uterus, and he has been honest enough to tell us that at the end of three years he had only two patients alive. Ferrier has given us the results of eighteen operations of total extirpation for cancer of the uterus, and at the end of two years only four patients were alive. The statistics of this day are generally in accord with these, though some are more encouraging as to the primary mortality; what of the remote results? But there is a cure; it is found in properly applied suggestive treatment. After the removal of the cancer we may prevent its return, and promote health.

"Suggestive hypnotism has been recommended as a cure for cancer by a number

of observers. It has been recommended as a palliative by the more conservative, for by suggestion, though there is a number of recorded cases, we will seldom succeed in doing more than relieve the many distressing symptoms, particularly of the digestive and urinary systems in cancer of the uterus, and to relieve pain. In the proper state of hypnosis certain music exercises certain effects upon the nervous organization, and this promotes the effects of suggestion.

"As to the cause of cancer, study has only shown that it is a change of tissue, and it is a trite saying that carcinoma is only a return to the fetal state. It is thus probably due more to failure of the trophic nerves and nutritive conditions than to anything else. From the fact that disease is incompatible with health, it naturally follows that where disease has taken possession of a structure, there must have previously existed an enfeebled condition of the parts affected, *i. e.*, some irritation, which exhausts the ganglionic system from supplying the proper amount of nerve force. Cancer occurs usually in those organs which have passed out of usefulness, as of the uterus at menopause.

"When one observes the perfect automassage that is produced in the hypnotized subject when certain music is played, he will readily appreciate how this will increase the activity of the nerves, tissues, etc., and thus the nutrition of the parts, and also the remarkable aid it lends to the suggestion. And this leads us back to Alsciebiades of Prussia, a man of great natural ability, who in the first century before Christ taught that the body was composed of atoms and corpuscles, and that health arose in consequence of harmony between the atoms and corpuscles, and that disease was the result of a lack of harmony or discord. This is food for thought.

"With suitable music, parts of the body of the hypnotized patient are harmonized. Suggestions are made to the patient to tune himself to the music, to tune every part and organ to the music, and to follow the suggestions.

"This article is not, however, intended to depreciate the operative treatment. In all cases where the disease has not too far advanced, we recommend total extirpation of the part with the surround glands. Suggestive treatment sho then be carried out, with a view of venting the return of the disease. By gestion the wound from the operat may also be made to heal much better firmer and in a much shorter time.

"Thus cancer can be cured, and it with this idea that I first expressed motto as 'Surgery, then Suggestion' in article in the *Char. Medical Journal*, ruary, 1897, entitled 'Surgery, then Sug tion, Especially for Malignant Growth

Now, seven years after the above arti I wish to repeat, Thus cancer can cured.

[Written for the MEDICAL BRIEF.]

Abdominal Section for Adheren Retroflexion of the Uterus.

BY EGBERT H. GRANDIN, M. D.,

Consulting Gynecologist to the French Hosp Gynecologist to Columbus Hospital; Fe of the American Gynecological Soci Fellow of the Academy of Medicine; M ber of the Harvard Medical Society, S Medical Society, Medical Association Greater New York; Ex-President of York County Medical Society; Author Text-Book on Practical Obstetrics, etc. York City.

In considering this topic, it is essent above all, to bear in mind the cau factor of the adhesion of the uterus ba ward. We operate primarily to reli symptoms, and the symptoms are alone dependent on the unnatural fi position of the uterus, but chiefly mainly on the complications. The cau factor is a pelvic peritonitis. Back this, and responsible for it, is the entra of irritating material into the pel This material emanates from tube, fi ovary, from vermiform appendix, poss through lymphatics or veins. No ma whence the outcome of the irritating terial, the result is the same—the glue of the uterus downward and backwa the glueing of tubes and ovaries to the or backward or anteriorly, these org being distorted in every imaginable v Where the causal factor emanates ori ally from the appendix, and this is r tively common, we find this organ ad ent to the uterus or tube or ovary. I ther still, in no mean proportion of

stances, omentum, sigmoid flexure, cecum, even small intestines, are adherent with or to the uterus and appendages.

The symptomatology then of adherent retroflexion is due, in part, to the abnormal position of the uterus, and in part to the complicating or causal factors. The total result of the abnormal position of the uterus and of these distortions and adhesions and disease of adjacent and remote organs, is interference with the pelvic circulation. The uterus becomes enlarged and succulent and heavy, the broad ligaments varicose, the function of bladder and of rectum is interfered with.

We as gynecologists are called on first (and this is the proper function of the gynecologist) to tell by touch just what is present, and then to apply the measure which will best relieve the symptoms. This is where the gynecologist becomes a surgeon. Now those of us who have studied clinically the diseases of women for many years, who have passed through the cycles of multiform treatment, realize the limitations of our sense of touch, and are unwilling in a given case to state definitely just how much lesion is associated with the adherent retroflexed uterus. Our surgical instinct then tells us that where the symptomatology is urgent enough to call for something more than the old-fashioned gynecological tinkering (such as the tampon), we must bring to the aid of touch the sense of sight, and thus arises the justification for abdominal section. The abdomen having been opened, we break up adhesions, and if, in so doing, we injure intestine, we repair the damage. The abdomen open, we can judge with fair exactitude how much work must be done on tubes and ovaries. We may remove the appendix if need be.

Finally, and this is important, we may insure symptomatic cure by lifting the uterus upwards from its sagging situation, and maintain it there, thus, and thus only, restoring, as far as this may be, the equilibrium of the uterine and peri-uterine circulation.

Surgical work of this type is sentient work, because the sight aids touch; to attempt measures such as the above through the vagina is blind work, is imperfect work, is far more dangerous work. I have attempted this work through the posterior fornix, and have broken up adhesions, and have pulled down tubes and ovaries, and have packed in gauze (causing new adhesions to form in so doing), and have injured intestine (unknowingly, of course), and have left in pus pockets, unfortunately, in consequence, being obliged later to resort to abdominal section to repair the lesion made by me, or to break up the new adhesions, and certainly to lift the uterus upward, and to maintain it there.

This statement is far from an extreme one, even though not applicable to every case, but it may be taken as a type. Indeed, as gynecologists become more surgical, I find that the vaginal incision is rarely made except for diagnosis or to evacuate accumulations of pus.

As for attempting this class of surgery through the anterior fornix, I have never deemed it logical. Besides the extensive mutilation of the vagina requisite through such an incision, the work is arduous and is indirect, and is still more blind than that through the posterior fornix. As well reach over a high fence to pick our object from the ground when the hand may reach it more readily from under the fence, for this, putting it in a homely way, is that which is attempted by those who advocate this method of treatment. The uterus is adherent posteriorly, the appendages are glued—the Lord only knows where— the appendix may be adherent to the uterus, tubes or ovaries, other complications may exist, and yet the operator makes a sagittal incision, and next a longitudinal incision, and pushes the bladder away (to which, for all he may know, is attached a pyosalpinx which he may rupture), and then he places his hand over the misplaced fundus of the uterus, and endeavors to drag it down into the vagina together with, often, the diseased tubes and ovaries or (possibly) appendix. This, pardon the term, is not surgery; it is butchery, of which a butcher would be ashamed. Let us face, as gynecological surgeons, the alternatives. I open the abdomen, and sight assists touch. My patient is subjected to a problematic hernia (which, by the way, should it occur, I can heal), and yet I am able to perform sentient, that is to say, knowing work on the woman who has placed her welfare in my

care. On the other hand, I operate through the vagina, a region which can not be sterilized. I open by posterior incision, and I use the exaggerated Trendelenburg posture, and (unforeseen by me) an ovary ruptures, and the pus (most virulent) invades the general peritoneal cavity. I have injured the woman, not helped her. If this does not happen, I pack in gauze, and this causes new adhesions to take the place of those I have liberated. This is not surgery.

Suppose I open by the anterior incision. Aside from the elaborate mutilation of the vagina, and the difficulty of performing sentient (that is to say surgical) work, I necessarily injure the vagina. I cause the vagina to become adhesive to the anterior lower uterine segment, and should it be possible thereafter for the woman to conceive, dystocia is bound to ensue at delivery (thus imperiling two lives).

Finally, neither by posterior section nor by anterior section can the misplaced uterus be lifted upward where, on the line of my argument, it must be, if we aim at symptomatic cure.

Space will not permit my dwelling on the untoward effect on kidneys and lungs of prolonged anesthesia, a sequence which rapid work, and this is yielded by the abdominal route, best avoids.

It has been my endeavor to impress the old adage that he "who runs may read," that is to say, that he who seeks the most direct route to secure a certain result is most likely to win.

[Written for the MEDICAL BRIEF.]

Necessity of Physical Development.

BY H. M. STARKLOFF, M. D.,

Formerly Professor of Orthopedic Surgery in the Marion-Sims-Beaumont Medical College.
St. Louis, Mo.

Every thinking person is bound to admit that physical development has not kept pace with mental progress. Too much attention has been devoted to the mind, and too little to its temple, the body. Exercise depends largely upon occupation —in other words, those whose occupations favor exercise are fortunate, those with sedentary occupations receive little or exercise. This neglect of the body beg at an early age. The mother consid the immediate wants of the inf Fashion, dress, food, receive her car consideration, and the child grows up fitted to resist heat or cold, and or with tastes and cravings which lay foundation for future ill health. Inst of training the little ones in walking running, they are trundled about in riages, and carefully protected from physical exertion. In school this pro is usually continued. Great demand made upon the mental powers of the ch while the body is left to shift for its and very little time is devoted to pro exercise and gymnastic work. The cro ing of school children in unventila rooms, and compelling them to sit still hours at a time, can not but have its fluence.

Parents and educators are equally sponsible for the precociousness of m children, and the mental drill begins l before the child is prepared for s work. It is a well known fact that physically strong child will soon outst the "precocious" one in his studies, e though he may enter school some two three years later than the latter. In higher institutions of learning, the ho of study are so long that but little rema for systematic exercise.

Systematic and scientific gymnastics vate the body to its proper tone, invig ates the lungs, hardens the muscles, se the blood coursing through the blood sels, and sustains the fire of youth. S tematic training physically is the o means of maintaining a perfect equip between mind and body, an equip which was so beautifully illustrated in lives of the ancient Greeks.

Weak action of the heart, irritability the nervous system, impaired digest rheumatism, consumption, dizziness, spi curvatures, and a host of other afflicti are the result of sedentary habits, with sufficient exercise and weak muscular velopment.

While it is true that the average du tion of human life is higher at the p ent age than formerly, it is by no me attributable to our mode of living, bu simply due to the progress in medic

and surgery which enables us to save many lives which formerly would have perished.

In our times, many a feeble life is maintained from year to year merely to bequeath, in many instances, this impaired constitution to children and grandchildren, and thus the gradual deterioration of the human race goes on.

To counteract these evils, every physician should exert his influence to the utmost for the introduction of regular gymnastics among all classes of people; they should join forces with enlightened teachers in laboring for the establishment of gymnasiums. It should be remembered that all physical training, be it gymnastics, horseback riding, swimming, rowing, or fencing, are also a training of the central nervous system of the brain and the spinal cord. Even the power of memory is augmented by systematic physical exercise. Together with gymnastics, massage should also be practised, in order to keep the body strong and healthy. History teaches us that since the time of Homer and Hippocrates, massage was advocated by the foremost men of Greece, philosophers, poets and historians. Among the Grecian women, massage was resorted to for the purpose of increasing the beauty of the skin and figure.

But beyond the healing of various affections, massage is also a great preventative of disease, as most diseases spring from disturbances of circulation and functional disorders, which can readily be forestalled by systematic hygienic massage. In orthopedic practice, massage is simply indispensable. Physical exercise, therefore, combined with massage; are powerful factors in the destruction and prevention of serious diseases, which are the natural product of our strenuous mode of life.

While the ancient Greeks and Romans should stand as our models, they should also be to us a warning example. In Greece, as well as in Rome, gymnastic sports formed the basis of mental and physical, personal and general welfare, and the glorious success they attained gave proof of the soundness and correctness of their views. However, as soon as the Romans grew indolent, leaving their physical sports to professionals, their ultimate decline and downfall was sealed.

It is true that gymnastics, massage nor physical sports will eradicate all the mental and physical troubles which flesh is heir to, but they will add materially to the strengthening and beautifying of humanity, and endowing it with the power of resistance.

Some Remarks on Æstivo-Autumnal Malarial Fever.

BY CHAS. A. MOHR, M. D.,
Professor of Chemistry and Medical Jurisprudence in the Medical Department of the University of Alabama.
Mobile, Ala.

The occurrence of æstivo-autumnal fever in the latter part of the summer and early in the fall months offers a puzzling problem to those inexperienced with the various malarial types. This form of malaria is responsible for frequent mistakes in diagnosis, being sometimes mistaken for typhoid fever, or other infections characterized by fever of a more or less intermittent type. A prompt and positive diagnosis is imperative for successful treatment. Periodicity and the quinine test alone will not always lead to positive results. Frequently, however, the microscope test and the finding of a malarial hematozoa makes positive the diagnosis, and leaves nothing to be desired. However, when the latter is negative we may still be left in doubt.

The finding of the malarial organism in the æstivo-autumnal form is not as easily accomplished as in the other forms of malaria, since the peripheral blood seems to be entirely free from the organism, and unless oft repeated examinations are made the existence of these bodies are overlooked. The writer believes that positive results can be more frequently obtained if bedside blood examinations were more frequently made, removing thereby all doubt as to the condition, and insure correct treatment from the beginning.

While the sovereign treatment of malaria is conceded to be quinine, the mode of administration and dosage in cases of æstivo-autumnal fever must be different from those followed in other types, and a proper classification of the fever is abso-

lutely essential to successful treatment, and efforts to cure this type of malarial fever by the same means as in other summer types will be met with failure. But should it be a case in which the parasite has not been found, and the ordinary use of quinine followed by no results, the temptation will be strong to induce the physician to believe that it is a case of malaria, and to relax anti-malarial treatment with, perhaps, disastrous results, as many of these cases require immediate and prompt treatment, not even offering time to confirm the diagnosis made upon the clinical aspects of the case; quinine must be promptly given without the loss of a moment's time. Most patients presenting themselves for treatment, having suffered for some time, have taken more or less quinine, and under such circumstances the parasite will not be found in the peripheral blood.

Of the two forms of æstivo-autumnal fever, the cerebral type seems to be of more frequent occurrence in our experience, and the patient being seen for the first time, is found in a comatose condition, and often without a history obtainable. The prevalence of malaria in the environment of the patient and clinical picture alone can guide us.

If at all possible, examination of the blood should be made before instituting treatment; quinine should be given quite boldly, and preferably hypodermically. The dose should be not less than fifteen to twenty grains, and if the diagnosis is confirmed by a blood examination, a hypodermic injection of from fifteen to twenty grains of quinine should be repeated within two to three hours after the first. To give small doses of quinine is to lose valuable time. Where the patient can take quinine by the mouth, our rule is to give thirty grains of quinine in a solution, and repeat within eighteen hours. Should the patient show any subjective symptoms of the influence of the drug, it should be given hypodermically. Intolerance to quinine is not so common as is usually supposed. People will often claim that they are unable to take the drug, but when it is given without their knowledge, no bad results follow.

The secret of success in the treatment of æstivo-autumnal fever is large doses of quinine, and repeated as the conditi may demand. No cases should be d charged as cured until the organism is tirely disappeared from the blood.

The most unyielding of all types to t influence of quinine are those in wh the crescentic bodies appear in the blo of the patient. After subsidence of acute symptoms and temperature broug to the normal, these patients should kept under active anti-malarial treatme preferably quinine and arsenic, until t crescents have actually disappeared. U less such disappearance is effected af the treatment is withdrawn, and in sp of a normal temperature, and a feeli on the part of the patient of being p fectly well, there is certain to be a rec rence sooner or later.

There is no choice as to what prepa tion of quinine, if it be in acid soluti Our preference is for the hydrochlora because it is quite soluble in water. fact, for hypodermic use, the hydrochl ate, dissolved in water, acidulated w one or two drops of lactic acid, the do can be taken up in one ordinary syrin ful. Another useful salt for hypoderm medication is the hydrochlora sulpha fifteen grains of which must be dissolv in sufficient water to fill the barrel of ordinary hypodermic syringe. If prop surgical cleanliness is observed, above a clean needle, no abscess will be form

A Few Suggestions in the Treatme of Fractures of the Leg.

BY E. DENEGRE MARTIN, M. D.,

Professor of Minor and Clinical Surgery in New Orleans Polyclinic; Visiting Surg to the Charity Hospital; Member of Southern Surgical and Gynecological A ciation; Fellow of the American Medi Association, Etc. New Orleans, La.

The question of fractures is too exhau ive to be treated as one subject, but a f practical points to the general prac tioner might possibly be of assistance, n only to one of little experience in su matters, but to the comfort of the pati as well.

How many young physicians, or ev men of long experience, are called upon

treat fractures of the leg, having at their command no better preparation than a few didactic lectures upon the subject. It is not a question of text-book knowledge, but rather a matter of common sense, and a fair knowledge of the anatomy of the parts.

First, what do we wish to accomplish? Simply to restore the limb to its normal condition so that ossification will take place with the least amount of deformity. It is, therefore, necessary to ascertain first the character of the fracture, and whether due to trauma or muscular action. If the fracture is transverse, the bones are easily held in position when once replaced, and this in itself simplifies the treatment, but an oblique fracture would require a more accurate adjustment of the splint.

The first thing to ascertain then is the nature of the fracture. Next, its reduction and replacement, and, third, the best plan to accomplish the end. The first is not always an easy matter, if the limb is much swollen. When such is the case, a temporary splint is best, and at the end of ten days, when the swelling is reduced, the deformity can always be recognized and corrected.

The best method of reducing a fracture is by bending it out at right angles to the abdomen, and the leg at right angles to the thigh. This relaxes the powerful muscles of the calf, makes manipulation more easy for the physician, and less painful for the patient. Once set, the leg is straightened, and the splint applied.

Temporary splints are best made from cardboard, and this should either be so shapen or padded as to fit the contour of the leg, so as to prevent sagging at the point of fracture, especially if it be at the lower third. The best permanent splint is made of plaster of paris, properly adjusted —nor can this be done without some practical knowledge in the art.

One of the most important points in regard to treatment of fractures is suspension of the leg. The old method of treating these injuries in the fracture box, by putting them in a temporary splint anchored between two sand boxes, was unquestionably the cause of so many deformities, and likewise the result of great inconvenience and suffering to the patient. Imagine a poor individual anchored to his leg, rather than his leg anchored to him, who dared not move from his position for fear of causing pain to his leg.

The advantage, therefore, of suspension is that it allows the leg to lie comfortably in the splint which will follow the movement of the body without causing the slightest inconvenience or pain to the patient or disturbing the bones at the seat of fracture.

All simple fractures of the lower third can be treated in an ambulatory splint just as soon as the swelling disappears, allowing the patient to pursue his daily avocation within two weeks from the time of injury. Think what this means to the reputation of a physician, as well as to the comfort of the patient, and how much larger fee one would be justified in charging if the patient be released in one-third of the time that was formerly required.

A Satisfactory Operation for Harelip.

BY L. B. GRADDY, M. D.,
Professor of Diseases of the Eye, Ear, Nose and Throat, in the Medical Department of the University of Nashville.
Nashville, Tenn.

A harelip is the result of imperfect development, no matter by what particular name it is called. The cleft in the lip may be only partial or it may be complete, always a little to one side of the median line, and generally extending into the nostril. It may be associated with cleft in the hard palate, or it may be confined to the lip. It may be single or double. In such cases we have always more or less deformity of the teeth, particularly of the central incisors, one or the other projecting outward, and perhaps turned edgewise, giving to the mouth an extremely unpleasant appearance. The teeth appear excessively long, one of the central incisors being turned edgewise, gives to the arch of the teeth a gothic appearance if turned front side up, instead of the natural smooth curve. This unsightly deformity should be corrected as early in life as possible. The amount of ingenuity which has been expended in this effort is surprising; vari-

ous means have been resorted to for correcting the deformity with at best only partial success. An interesting feature, found in nearly every case is the absence of one or more teeth. That is, they do not show. But in all cases of harelip, and in all cases of cleft palate where there is an absent tooth, you may rest assured that that tooth is somewhere in the upper portion of the face, in the antrum of Highmore, or in the nose, possibly high up, even above the middle turbinate. I have taken several teeth from the nasal cavity which required considerable force for their removal.

But the most important matter is the correction of the deformity. How can we restore the lip to an appearance approximating the normal? This is a matter of mechanics pure and simple, a matter of ingenuity. The lengthening or shortening of a definite line already established. It is necessary to call attention to what has been done by almost every surgeon previous to the operation which I devised several years ago, and which I have demonstrated repeatedly. What is usually done in such a case is to freshen the edges of either side of the cleft by means of curved scissors, beginning at the lower edge, cutting upward, bring the raw edges together, which as can readily be seen, leaves a gap in the lip where there should be a projection. Of course, the gap will remain. If we can do away with the gap and establish a normal projection at or near the center of the lip, and restore the lip to an approximately normal appearance, we shall have succeeded in curing a deformity that has been the terror of mothers, and the ridicule of many heartless persons for all time.

Examining one of these cases we will find there is a lack of tissue. By lifting the side of the lip only a trifle, we find strong traction established between the external portion of the lip and the mucous membrane of the gums. The mucous membrane, in other words, presents the appearance of having formed a band or flap. So far as that band extends, the deformity will extend.

Hence, any operation beginning at the inferior edge, and ending at the upper portion of the cleft, will leave a gap in the lip. It goes without saying that notwithstanding the curved line lengthens t raw surfaces which are to be brought gether, it does not interfere with th band, and the gap when the edges un will remain.

Having met with the same difficul which confronted others in proceeding this manner, I saw that there was son thing lacking. How could it be treated as to correct the error? I devised t following operation, which is not difficu of performance, and the cosmetic effect which leaves but little to be desired. troducing up under the lip as far as pos ble one blade of clamp, some distan from the edge of the cleft, the op ation is practically bloodless. Then dra ing up the side of the cleft, and putti strong traction upon it, I loosen all of t mucous bands until the lip is freely mo able in every direction.

Passing to the other side, the same p cedure is gone through with, the clam being allowed to remain on the first si to which it was attached. After detachi the mucous bands entirely, the upp portion of one side of the cleft is seiz with toothed forceps, and held firm while it is transfixed with a strong kn near the upper end of the cleft, a little the outside, cutting downward, and ma ing a curved line outward and downwa to the pink of the lip, stopping at th point. Doing the same thing on the oth side, cutting downward instead of upwa as is usual. The upper ends of the t flaps are detached, both being allowed hang down over the mouth side by si Then closing the wound by through a through sutures of No. 6 silk. Bringi the flaps together down to the pink tiss of the lip, then the lip is everted, and few small fine silk sutures placed in t mucous surfaces. The two flaps are tured at a point where after contracti of the tissue they will still leave a noti able projection in the lip. The whole supported by strong adhesive strips tending entirely across the face.

Wilcox Building.

[Written for the MEDICAL BRIEF.]

Remarks on the Causes of Mortality in Intussusception and on the Advantages of Prompt Operative Interference in the Treatment of this Condition.

BY RUDOLPH MATAS, M. D.,

Professor of General and Clinical Surgery in Tulane University.
New Orleans, La.

The memories of past experiences which vividly emphasize the disasters consequent upon expectancy and so-called conservative modes of practice, and the gratifying contrast offered at the present time by the results of prompt and unhesitating intervention have convinced me that the only sure and safe way to reduce the mortality of acute intussusception is by operation. That the great and unnecessary sacrifice of infant life caused by this disease can be prevented has been eloquently demonstrated by almost every surgeon of experience who has written on the subject. That the results of modern teaching and experience are beginning to tell favorably on the mass of the profession, and on the public, is shown by the increasing number of cases that are now brought to the surgeon in an operable condition, comparing most favorably with the experience of the past when the surgeon was only summoned to the bedside as a last resort, when the patient was in a moribund condition, to give, as it were, a *coup de grace*, often expediting a fatal exit which every one foresaw was inevitable. Yet, in spite of the encouraging tendencies everywhere displayed, there are still too many practitioners who, for one reason or another, cling to the traditions of the past, or who, ignoring the possibilities of modern surgery, are still blind to the light of progress. Some of these practitioners cannot, or will not, think anatomically; they will not keep before their mental vision the picture of a pathologic process outlined before them by the clinical phenomena, but simply think pharmacologically; and thus, in the guise of a so-called conservatism, persist in applying traditional and worn-out methods of treatment which are not only irrational, but pernicious, in the mere fact that they rob the patient of his best, if not the only, opportunity for recovery.

The oft quoted dictum of Nussbaum, in reference to military surgery: "That the fate of the wounded lies in the hands of the surgeon who applies the first dressing," is applicable with equal force in the successful treatment of all acute abdominal conditions such as acute intestinal obstruction, strangulated hernia, acute appendicitis, perforating ulcer of the stomach, acute cholecystitis, etc., in which there is a variable period of comparative safety when the injured or diseased area is still small, the focus of infection still limited and well-defined, the peritoneum still clean and quiescent, and when the mechanic disturbances (as in intussusception) if existant, can be easily corrected by direct, gentle manipulation. It is in these early stages of abdominal disease, when the evil is still purely local and circumscribed, that the general condition of the patient is surgically good, and will permit a thorough and profitable intervention with almost absolute safety. This golden opportunity is, unfortunately, not given to the trained surgeon who devotes himself exclusively to his specialty, and who is most familiar with the physiognomy of abdominal disease, unless it be when the general practitioner who is first summoned to the field of action is quick to see the opportune moment, and calls upon his more experienced colleague for his assistance.

The conditions found in intussusception are, however, so simple, in the early stages before gangrene has occurred, that it is possible for any one who is familiar with the technic of aseptic surgery, to open the abdomen, to reduce successfully an invagination with greater ease and even less risk than is involved in reducing a strangulated hernia.

Ideally simple as these conditions are when the bowel is simply incarcerated, they become most difficult, complex and grave when strangulation and gangrene have occurred. Then the whole aspect of the case is changed, and even the man of greatest experience and technical dexterity must prepare for failure and defeat. In summing up the factors in the mortality of intussusception, we would mention, first, delay in the recognition of the con-

dition, *i. e.*, tardy diagnosis, precious time lost while waiting for the diagnosis to clear up in the presence of manifestly grave, menacing abdominal symptoms. Too often, when the diagnosis does clear up, gangrene and intestino-peritoneal sepsis have set in, and the precious opportunity for simple, safe and sure surgery has passed.

Nevertheless, the diagnosis of acute intussusception is one of the most characteristic and readily established of all the acute abdominal obstructions. Acute, sharp, intermittent abdominal pain, usually well-defined, and circumscribed in the start, accompanied by vomiting in paroxysms, and soon followed by tormina and tenesmus, with frequent small mucous, blood-stained stools, which rapidly lose all fecal character,—all coming on suddenly with progressive signs of distress and exhaustion, unexpectedly, in an otherwise healthy child,—justify the administration of a general anesthetic sufficiently to relax the abdominal muscles, and facilitate the search for the characteristic sausage-like tumor.

This important sign can be felt in fully fifty per cent of the cases without a general anesthetic, but, in my experience, is much more constantly recognized, and made far more accessible to the touch when the patient is completely relaxed by a general anesthetic.

In four consecutive operative cases of ileo-cecal invagination I failed to find a distinctly recognizable tumor until the patient was brought to the operating table, and was thoroughly relaxed by the anesthetic.

The foregoing group of symptoms: pain, vomiting, tormina and tenesmus, with frequent, small, mucous, blood-stained, stools, coming on suddenly in an otherwise healthy child, justify an exploratory laparotomy; more especially if signs of shock or collapse are apparent and progressive. If the characteristic tumor is recognized, then the laparotomy becomes immediately imperative. But even if the diagnosis is not absolutely complete, and there is an element of doubt as to the exact cause of the acute and persistent symptoms, the patient, especially if an infant, should be given the benefit of the doubt, and a direct exploration of the abdominal contents, by laparotomy, is undertaken. It is an error to believe infants do not stand surgery well, c they are especially liable to the sh abdominal manipulations. My expe directly contradicts this view. A paratively small incision is requi permit of a very thorough explorat the abdominal cavity, and its con organs; and in view of the fact tha ducibility with fatal sepsis are mo quent in the early periods of infanti there is still greater reason why th geon should avail himself of the g technical simplicity of a direct ex tion in this class of patients at the e possible moment after the onset of c teristic symptoms.

After a long and varied experie never hesitate, in the presence of grave abdominal symptoms, especial sistent pain, to advise and urge p operative intervention. I thor agree with F. W. Wiggin when he "Many lives will be saved, and thou of others made comfortable when cians generally come to recognize t all cases of persistent abdominal p obscure origin, exploratory ope should be performed, for it has be experience that a cause always does when such a pain is present (esp in children), and that it is usually with ease when looked for."

Another cause of mortality in int ception is an unfounded trust and dence in the value of pharmacologic mechanical methods of treatment, s purgatives and anti-spasmodics donna, atropia, tobacco poultices), sage, enteroclysmata, intestinal i tion, etc., which are not only unre but pernicious, as previously stated, majority of cases, because they inv loss of time in their application, which the patient rapidly drifts pa line of safety, from the domain o *aseptic* to fatal *septic* surgery.

In the chronic and sub-acute for intussusception, it may be permiss temporize and resort to rectal inje or enteroclysmata, but, even in cases, it is evident that the chances cessful surgical intervention are greater than in the acute cases, in all attempts at reduction by such me

pecially in infants, should not be prac-
ed or even taught. In the acute and
per-acute cases, there is no time limit
thin which operation may be delayed
th safety. The aim of the surgeon
ould be to operate before the intussus-
ption has become irreducible, and the
l for intervention is proportionally ur-
nt with the acuteness and violence of
e symptoms, regardless of the time in-
rval. Gibson has shown that the per-
ntage of reducible cases was ninety-four
r cent on the first day of the disease,
ghty-three per cent on the second, sixty-
e per cent on the third, and forty per
nt on the fourth day, etc., the mortality
creasing progressively with the irredu-
ility of the intussusception, and with
e number of days that elapsed after the
pearance of the first symptoms.

A third element of failure in the treat-
ent of intussusception is undue confi-
nce in the unaided efforts of Nature to
cure the spontaneous elimination of the
ughed bowel. It would appear from
chtenstern's classical statistics that out
every one hundred cases of intussuscep-
n of all kinds, some fifteen patients
ay be expected to recover, in conse-
ence of spontaneous elimination of the
vaginated bowel. But, as Treves crit-
lly remarks, this estimated proportion
recoveries is far too high. "Cases of
ontaneous elimination ending in cure
e more certainly reported than are cases
ding in death, and I would incline to
ink that the prospects of recovery in in-
ssusception depending upon spontaneous
mination is represented by considerably
s than ten per cent of the total mortal-
."

In confirmation of this view, I would
ote the following instance which occur-
d in my own practice: On February
, 1902, a bright lad of fifteen years was
ought to me for treatment from one of
e neighboring towns of Mississippi. He
as enjoying the best of health when he
as stricken, while at school, with all the
mptoms of acute intussusception,—sud-
n, violent and agonizing pain, which he
calized distinctly in the left umbilical
gion, about two inches to the left and
e inch below the umbilicus. From this
int of maximum intensity, the pain
diated and spread rapidly to the entire abdomen with greatest acuteness in the original spot. With this pain came vomiting, accompanied by tormina, and a frequent desire to go to stool, and with this tenesmus the boy passed frequent small, fluid and mucous stools. The pulse rose rapidly to one hundred and twenty, but the thermometer registered only 99° F. The diagnosis of intussusception was promptly made by the attending physician, but owing to unavoidable delays, the patient was not able to reach the infirmary until after the first fifty-two hours had elapsed. The general condition of the patient had grown so much worse by this time, and the stools were of such a character that I felt confident that gangrene had occurred.

I was then convinced that the chances of survival after operation were scant, and that his prospects for recovery, if any, would be just as good without operation as with it. He appeared to be thoroughly septic and exhausted. In view of my somber prognosis, the parents decided against the operation, and nothing was done except to stimulate the boy with hypodermics of strychnia and digitalin, and occasional small doses of morphia and atropin. He was allowed to drink ice water *ad. lib.*, so that he might vomit and wash his stomach without effort. This he did frequently, and apparently with great relief. Stimulating enemata containing turpentine, assafetida, and glycerine were resorted to at intervals, to favor the expulsion of gases, and wash out the extremely offensive ("carrion-like") stools which accumulated in the rectum. In the intervals between these enemata he was supplied with small quantities of whisky in saline solution, administered per rectum.

In the beginning, hot stupes were applied to the abdomen, as they appeared to give comfort to the poor sufferer. The patient remained in a doubtful and critical condition until the ninth day, when vomiting ceased, and other signs of improvement were noted.

On the fourteenth day he passed a slough of small bowel (probably a part of the jejunum) measuring thirteen inches in length.

On the eighteenth day after the onset of the attack, he appeared to have recov-

ered completely, and returned to his home. He appeared to be perfectly well while at home, until the thirtieth day after his arrival, when, without any premonition, he was suddenly seized, a few hours after a hearty meal, with all the signs of acute intestinal perforation, and died quickly of overwhelming peritoneal sepsis before any operation for his relief could be undertaken. In this case, death occurred forty-nine days after the appearance of the first symptoms of the invagination, thirty-five days after the expulsion of the slough, and thirty days after the patient's apparently complete recovery.

The conclusions that we gather from this experience are: first, that if it had been practicable to perform an exploratory laparatomy immediately after a diagnosis of intussusception had been established, reduction would, in all probability, have been easily effected, and the boy would have permanently recovered; second, that after apparent recovery had taken place, by the elimination of the sloughed bowel, it would have been justifiable, in the light of subsequent events to have made an exploratory laparotomy for preventive purposes.

In the course of this exploration, the exact conditions existing at the neck of the intussusception would have been ascertained, and, in all probability, a lateral implantation of the bowel or simple anastomosis would have been made at a point below the seat of the intussusception, in order to guard against the possibility of a stricture and secondary rupture of the intestine.

While it is very easy to reason *a posteriori* in such a case, we must realize that, no matter how much a preventive operation of this kind would have been indicated and justifiable, it would have been difficult to convince the parents of this boy of the need of such an intervention, especially when he appeared to have escaped so completely and miraculously from the first attack.

In pleasant contrast with this unfortunate case, I have before me the notes of three consecutive cases of intussusception, all of the ileo-cecal type, in which reduction was effected by operation:

One, a male infant, of seven months, operated upon, and successfully reduced by laparotomy, fifty-two hours aft onset of the first symptoms; the a male infant, fifteen months old ated upon on the seventh day (su type), and readily reduced by int toneal manipulation; and the th boy of eight years, operated upon t ond day, also successfully redu operation.

In all these cases, a part of the the appendix, caput coli and asc colon, had been invaginated in transverse and descending colon. first case, the intussuscipiens could as a polypoid mass in the rectu none of these cases could the cha istic sausage-like tumor be recogni til the abdominal walls had bee oughly relaxed by general anesthe median incision, varying from 2. inches in length was made in the diate supra or infra umbilical The invagination was at once rapi ognized and brought to the line of cision, and a reduction of the in cipiens was at once attempted by pressure and massage of the sheath tussusceptum. While the neck of tussusception was steadied, no t was made upon the intussuscipiens

In all the cases the invaginate was soon extruded and forced o various parts of the incarcerated appearing in anatomical order. A duction, the appendix was found and edematous, and was removed cases. The caput coli was ancho suture to the iliac fossa by attach mesentery to the iliac fossa. Th done with the hope of preventin currence of the invagination at t cecal junction, and while it is evid this fixation of the caput coli ca prevent invagination of the large is also plain that it would not pre entero-colic intussusception.

It is a question yet to be whether any effective procedure ca vised which will prevent a recurr an invagination. It is fortunate t lapses are comparatively rare af duction. In all the cases the il coil was provided with a complete tery, which gave the cecum and ing colon a great range of motion.

the patients, relief was immediate, and recovery uneventful.

The question may now be asked, what course would have been pursued in case of irreducibility with or without strangulation and gangrene? Past experience, always disastrous in such cases, has convinced me of the great danger of all radical operations which will expose the peritoneum to infection from the escape of the septic and intensely virulent contents of the bowel.

I am, therefore, not in favor of the Barker operation, which is usually advocated in such cases, because in opening the sheath of the intussusception, to excise the gangrenous intussuscipiens, the contamination of the peritoneum is almost unavoidable. In the majority of the gangrenous cases, the patients are unfit to stand an extensive radical operation which would include the resection of the entire invaginated gut with its sheath. In fact, in some cases, such a procedure would be technically impracticable. No operation such as an anastomosis, or a simple artificial anus, which will give issue to the feces above the obstruction, but leave the gangrenous or strangulated bowel *in situ*, is rational or likely to give relief. Therefore, to avoid the pitfalls of septic peritonitis from intestinal contamination on the one hand, and the risks of auto-intoxication from the retention of the gangrenous gut, there are but two alternatives: First, to make an artificial anus, which shall include the neck of the invagination, with a part of the intussuscipiens and of its sheath; then this is to be extraperitonealized by suture of the parietal serosa to the gut, after which the neck of the invagination is to be resected, the vessels of the mesentery ligated, and the incarcerated or gangrenous intussuscipiens extracted. The artificial anus, which is thus left open, permitting a free drainage of the septic intestinal contents.

Second, the operation recently suggested by v. Miculicz may be adopted. This operation, as performed successfully by v. Miculicz in two cases, was described by him in a contribution to the Transactions of the American Surgical Association for 1903, and may be summarized as follows: "The intussusception is drawn to the abdominal incision, and stitched there, so as to prevent infection of the peritoneal cavity. The wall of this gut is then incised longitudinally for a sufficient distance (12 cm.) in a case of ileo-colic invagination. This exposes the intussusception, which is composed of two tubes of intestine, one inside of the other. If their vitality is destroyed, they must be resected, and as their serous surfaces are in contact, the peritoneal cavity must be here protected from infection. This is accomplished by cutting through both intestinal tubes little by little, and stitching them together as fast as cut, by catgut sutures which penetrate all the coats. The mesentery will require multiple ligation. The invaginated intestine can then be extracted. The opening in the intussuscepiens should not be sutured, but should form an outlet for the feces. This artificial anus can be closed some weeks later." (See synopsis by Coley, *Progressive Medicine*, June, 1904, p. 73.) By adopting this procedure it is possible that the terrible mortality of resection (thirty to sixty per cent) will be greatly reduced, at least in those cases in which the sheath itself (intussusceptum) has not become gangrenous, and intestino-peritoneal sepsis has not already overwhelmed the patient.

My object, however, in writing these brief remarks is not to discuss the modern contributions to the technic and operative surgery of intussusception, when it has reached the stage of irreducibility, strangulation and gangrene, but simply to urge the family physician who first sees these cases to act promptly, decisively and confidently in advising an immediate resort to direct, open surgical methods of treatment at a time when these measures can be applied quickly, surely and safely in rescuing the lives of those placed in jeopardy by this formidable disorder.

[Written for the MEDICAL BRIEF.]

Enteralgia and Colic.

BY F. L. RATTERMANN, M. D.,

Professor of Gastro-Intestinal Diseases in the Cincinnati Polyclinic and Post-Graduate Medical School.
Cincinnati, Ohio.

Probably intestinal pain is one of the most frequent symptoms complained of during the years of childhood. The tendency of children to eat too much, when opportunity offers, of rich food, as of cake and candy, or unripe fruit, is too well known to need more than passing mention. We have all had the experience of treating these conditions. Even mothers taught by former experiences, or informed by the experience of others, realize the relationship of cause and effect, and without further consultation apply the usual cathartic remedy.

Max Buch, Helsingfors, Finland, in a long treatise on enteralgia and colic, in the Archiv. für VerdaungsKrankheiten, Vol. No. 12, book 4 and 5, believes that intestinal pain is generally due to a neuralgic condition of the lumbar sympathetic, only occasionally could he locate the cause of pain in a tonic spasmodic contraction of the muscles of the intestines. It is with a view of ascertaining, by the analysis of the ordinary cases that come to the physician, the probability of the truth of either one or both of these hypothesis that this paper is written.

In intestinal pain consequent to digestion of improper food, the muscles of the abdomen are generally, if not always, tense, while the gurgling sounds of the quickly moving intestinal contents reveal the increased peristalsis of the intestinal coil. In favorable cases the abdominal wall can be seen successively to rise and fall with the peristalsis of the underlying gut.

These peristaltic movements are frequently followed by pain, demonstrating the relationship in these cases of peristaltic action of the bowel to pain.

In contradistinction to this form of intestinal pain, Buch, as above stated, has isolated another form, and, in his opinion, a more frequent type, which he separated from the violent muscular intestinal contractions of the former in that the abdominal sympathetic system alone is att producing a typical neuralgia in plexuses of nerves. These pains ar ally of a numb, heavy character, b assume the sticking, cutting chara the cerebro-spinal system.

The whole abdomen can be inclu the range of pain; that is, the might feel the pain diffusely over t domen, but only the region of the di tion of the filaments and ganglia sympathetic around or near the a sensitive to touch. Pressure made tain spots along the aorta can eli pain if at that time it be quiescent, aggravate it if present. Pressur where else, as in the lumbar, ingui hypochondriac region, is not follov pain. Slight intestinal fermentatio mal to digestion, can by dilating t press upon the underlying symp nerves surrounding the aorta, ar duce the pain which is occasiona perienced either immediately, or el eral hours after eating.

Buch asserts by the intensity o elicited on pressure at certain spots the abdominal aorta (whether ab below the umbilicus) that we ar from our anatomical knowledge of t tribution of the abdominal sympa to diagnosticate the branch affected know that the abdominal aorta i mally sensitive to pressure, and tients not complaining of intestina in whom the abdominal muscles a enough to follow the palpating aorta sure upon it, particularly if wedg tween the finger and the vertebral c will generally elicit pain.

Head's phenomenon of a sensitiv to light pressure, and absence to he frequently present in disturbance abdominal sympathetic, but this sy can be present in the skin of other of the body when any underlying or tissue is affected. Pressure at c spots along the direction of the abdo aorta, without reaching the pulsatin sel, is followed in these cases eith eliciting severe pain if quiescent, o aggravating it if present.

These neuralgic attacks occur sud and are neither affected or aggravat a rule, by improper food. Increased talsis should not be characteristic o

picture of enteralgia. The pain is frequently lasting, and abates often as rapidly as it came on. The intestinal crises of locomotor ataxia is believed by many to be a form of enteralgia.

Nothnagel, Vienna, in a very interesting article on colic (Archiv. für Verdaung-Krankheiten, Vol. 11, Bk. No. 2, page 124), in defense of his position against the attack of Buch, emphatically states that neuralgia of the lumbar sympathetic is decidedly less frequent than colic. Colic he defines as a painful irritation of the intestinal nerves associated either with a strong tonic contraction of the intestinal coil, or else produced by it, the ordinary traumatic or mechanical irritations of the bowels not being severe enough of themselves to awaken these painful irritations. He believes that the anemia of the gut, consequent to a long lasting spasmodic contraction of the intestinal coil is the real cause which awakens in the sensory nerves these painful stimuli which are perceived as colicky pains. The nerves, in other words, are denied under these conditions the nutrition of the arterial blood, and respond accordingly by sending out painful irritations. He substantiates his position by stating that cephalic pains are generally present after ligating one of the carotid arteries, and only gradually passes away after the collateral circulation has overcome the temporary anemia.

The headache in ordinary anemia as well as the intestinal pain in the beginning of embolism in the superior mesentery artery, is due, he believes, to the temporary anemia of the nerves in these organs. If this theory is correct, it would then seem equally true that wherever anemia exists, or is temporarily produced, pain must be the necessary sequence. But is this true? Does pain, for instance, follow the anemic condition of the mucous membrane of the nose after the application of the proper remedy, or in the finger, toe, arm or leg, when the blood is forced out, and kept so by tying a compress around the extremity? It appears the reverse anesthesia results, not hyperesthesia or pain. It seems difficult to admit the probability of this theory when one can demonstrate its absence by these experiments. The physiological law of contrary innervation, I believe, offers the best theory for the explanation of colic.

The law of contrary innervation means that sympathetic to contraction of any portion of the intestines, relaxation follows of the portion continuous with it below. Immaterial how hard the intestinal coil contracts, as long as this law is not violated the individual is free of pain, but if the intestine below the contracted area contracts instead of relaxes, we have a violation of this law, and pain results.

Meltzer, of New York, was the first to offer this theory, and, I believe, it is the most rational theory for the explanation of colic. The theory of Wilms (*Munchener Med. Woch.*, 1904, No. 31) that colic is the result of stretching of the mesentery, or of Lennander (Grenzgebiete der Medizin und Chirurgie Bd, 10), that it is due to a stretching of the parietal peritoneum by the contraction of the pathologically formed peritonitic bands between the intestine and the parietal wall is more than doubtful. For if Wilms' theory is correct, then why the intermittence of pain in cases of intussusception of the bowel when the greatest possible stretching of the gut exists? And if Lennander's theory is true, then why the frequency of pain in flatulent, rheumatic or stercoral colic where we know that peritonitic adhesions usually do not exist between the intestine and the peritoneal wall?

Willis, two hundred years ago, assured the medical world that colic was a disease and not a symptom, but gradully observers noted the fallacy of his statement, and formed other theories which in turn gave way to still others, until now the multitude of confusing theories are such as to preclude the possibility of even their mention within the limits of this short paper.

In conclusion, let me rapidly sum up the main thoughts of this article:

1. That enteralgia and colic are not synonymous terms, but are affections distinctly separate in pathology, etiology, and symptomatology.

2. That enteralgia is not more frequent than colic, as is assumed by Buch, but, on the contrary, I believe enteralgia to be much less frequent.

3. That colic is produced by disturbance in the law of contrary innervation in

the sense of Meltzer, and as above explained.

4. That enteralgia is probably a neuralgic condition of the plexuses of the sympathetic nerves and ganglia surrounding the aorta.

The Cigarette Evil.

BY A. H. BRADLEY, M. D.,

Professor Hygiene and Sanitary Science, Barnes Medical College. St. Louis. Mo.

Anyone condemning a practice or habit indulged in by a large number of people is apt to secure for them the name of being an extremist; however, I contend that the prevalent habit of cigarette smoking which shows a tendency of becoming general is a thing we, especially as physicians, should call to public notice as regards its baneful effects.

The use of tobacco has become deeply rooted among most nations, and, no doubt, it will take a long time to teach the people its harmful effects, and cause them to give it up. One reason is, because it has become a commercial factor, and is a source of revenue, and the means of providing a livelihood for a great number of persons. Again, the habit has been formed by so many that it has become looked upon as a thing to be expected of all men, and most boys look forward to the time when they can use it and "become a man."

Most schools at the present time teach the effect of nicotine in their books of hygiene, but regardless of this fact the use of tobacco in all its forms seems to be on the increase. No doubt that tobacco in any form, especially if used to excess, is deleterious, but it is of the "coffin nail" form that is, to my mind, the most hurtful. One can seldom board a crowded car in our cities without being able to count a half dozen or more "cigarette dudes," or fiends, on the back platform puffing out volumes of the offensive fumes through their nostrils, and a non-user can readily detect the odor of the same as soon as he enters a car, which emanates from the clothes of the sap-headed gentry. I call them that name because, to my mind, they must be lacking in brain caliber, or t would know enough to abstain.

I once heard an eminent member of medical profession in St. Louis rem that he could find an excuse for a smoking a cigar, but when he sav man (?) smoking a cigarette, he felt sc for him. He felt that he did not h enough brain matter to guide his acti in the right channel.

One might here bring forward the gument that many doctors and educa persons are cigarette smokers. I gr that to be a fact, and we also have to mit that many of them are also vict of alcoholic and other excesses, but t does not prove that their use is benefic It is easy for me to recall to mind sev physicians that are cigarette fiends. of these, I am told, quite frequently to rush through a surgical operation order to get a smoke—a relished "nail that his cravings may be gratified. other one, now dead, a noted alienist, sisted in convicting a medical stud who was a noted fiend for cigarettes, t had killed his wife and child, yet he h self was a victim of the same vice, finally lost his own life from dise brought on by nicotine poison, toget with kindred indulgences, no doubt su induced by the cigarette poison.

I have had opportunity of observin great many patients that I am sure heart, liver, kidney, nose and throat nervous diseases that could only be counted for through the use of tobacco excess in this form.

Having been an examiner for over n years for a leading life insurance c pany, it has been my privilege of not the effect upon the heart of hundreds cigarette users, and I can say that, w out doubt, in at least eighty per cent them, their pulse rate will average beats more than normal. Common se would cause us to conclude that ex work thrown upon the heart to this tent, can not but be injurious to the he itself, as well as to favor congestion other organs of the body, due to its effe on the circulatory system.

It is gratifying to know that many porations, like railroad companies, h put the ban on cigarette users, recogn ing the danger from fires as well as

fact that those using them are not so reliable as non-users.

In countries like Spain and some southern lands that are known to have degenerated, it is not unusual to also see women addicted to this filthy habit, and I have little doubt but that to this cause can be attributed, in a great measure, the fact that the peoples inhabiting these countries are not up to the standard of those other countries in mentality that have not been users for a great length of time.

In the United States, at present, we seldom see a member of the gentler sex indulging except she be a prostitute or a woman of so-called "society" that has become a user through a desire to be called "game," or that does it to "quiet her nerves" after late hours, or to combat temporarily the strain on her nerves, the excitement incident to revelry. Prostitutes are always given to adding other vices as they present themselves, and to this fact alone we can readily attribute this habit to be a vice, and a vicious influence to be combated.

It is a filthy habit from an esthetic standpoint as well, and I can not imagine anything so obnoxious as the odor emitted from the breath and clothes of a cigarette fiend, and the discoloration of the hands is anything but sightly.

In view of all these things I have enumerated, it seems high time for the medical profession, which can not but know the evil effects of this growing habit, to take upon themselves the good work of teaching their patients and friends the harm wrought by this deadly and unclean habit, and also to urge legislation against it, and the enforcement of the laws that are made.

Nervousness.

BY W. T. MARRS, M. D.,
Jewett, Ill.

Often due to autoxemia, by which the blood is not sufficiently oxygenated. Calomel and soda, one grain of each, at bedtime for a few nights, often works wonders. If a nerve sedative is indicated, a preparation of celery in proper doses will be found the least harmful.

Etiology of Prostitution.

BY ALFRED DE ROULET, M. D.,
Chicago, Ill.
Formerly Professor of Diseases of Women, Medical Department of Trinity University.

Few subjects have been more widely discussed with less benefit in the way of results than the various phases of the so-called social evil problem. The principal reason for this barrenness of results lies in the fact that the great majority of the participants in the discussion either have no actual knowledge of the subject, or they are swayed to such an extent by prejudice and preconceived theories as to be incapable of appreciating existing conditions. Until conditions are thoroughly understood, attempts at remedial measures are futile.

In studying this subject, a broad and sympathetic knowledge of the frailties of human nature, combined with keen power of observation and analysis, is essential.

The causes which would lead a previously reputable woman to become a wanton are numerous, but not, as a rule, complex. These causes vary widely with the subject's training, social condition, surroundings, and associates. The causes which would lead to the downfall of a society girl would be inexplicable to her sister in the shop, while factors which would be irresistible in the working girl would not be appreciable to the wealthy butterfly. Certain factors operate to a greater or less degree in all cases, while others are operative only in certain limited classes.

As a rule, the descent into the demi-monde is not accomplished at a single step, and there is a vast difference between the young woman whose kindness occasionally exceeds her discretion and the common prostitute. Neither does it follow that because a woman is subject to occasional lapses of virtue that she will develop into a demirep. In fact, in a generous proportion, if not a majority of cases, she does not; neither is it permissible to assume that the causes which would lead a girl into indiscretions are the same as those which would lead her into the demi-monde. While all prosti-

tutes were originally guilty of indiscretions, all indiscreet girls do not become prostitutes. Except in a certain rather limited group of women who become wantons voluntarily, as the result of peculiar temperamental conditions, there is usually present a well defined element of compulsion.

Among the causes which would lead a girl to take the first step, ignorance of possible consequences, associated, probably, with deficient moral instruction and stamina, when combined with sufficient temptation and suitable opportunity, is easily entitled to first place.

American young women are either entirely ignorant of sexual matters or they are fully instructed in things of which they should know nothing. A girl of the first class does not realize the consequences of her act; one of the second class thinks she can avoid them. With many, if not most, women, a wholesome fear of consequences is a great incentive to virtue, and as our Puritanic notions place the mother of an illegitimate child beyond the pale of human forgiveness, and regards complacently the murderer of an unborn child, one great incentive to chastity is nullified.

Abortion is now practiced to so great an extent that there are men in every town whose reputations for this kind of work have made their names household words in their respective communities. Presumably reputable publications do not hesitate to print their advertisements. On actual count the advertising columns of a certain well-known Sunday paper which boasts its ultra-respectability revealed the presence of the advertisements of thirty abortionists and of eighteen drugs or preparations "guaranteed to correct any irregularity regardless of the cause." If one-fourth of the energy wasted in persecuting prostitutes was expended in prosecuting abortionists, much good might be accomplished.

On the theory that it is impossible for the American young woman to slip a moral cog, the young of both sexes are allowed to mingle freely at all times without supervision or restraint.

We are accustomed to scoff at continental chaperone systems, and pride ourselves on our own superiority. We brag that "the American girls do not need watching." The continentals, however, realize that most young men do need watching, and, knowing that propinquity is the mother of iniquity, they guard against temptation by eliminating the possibility of falling.

In America many of our customs seem designed to facilitate temptation and opportunity. The American parlor after dark has probably been the scene of more mislaid virtue than the much condemned wine rooms of our cities, while our public schools and co-educational academies and colleges have a more widespread and deleterious influence on morals than immoral books and plays. Mingling young people promiscuously at an age when passions are easily aroused, physical impulse at its strongest, and moral and ethical restraints at their weakest, is certainly more dangerous than the mental effect of bad reading or immoral plays with no opportunity for physical gratification.

Among the leisure classes, idleness, vanity and curiosity are the important factors. A girl of this class, as a result of her mode of life, has her normal craving for admiration enormously stimulated. To attract attention, which she often mistakes for admiration, she combines in her costumes, as far as possible, the scenic advantages of the dinner gown and the bathing suit. She tells risque stories to increase her popularity, and drinks and smokes with her male friends to show what a jolly good fellow she is, and before she realizes she has carried good fellowship a little farther than she intended.

Among the poor the surroundings and associates are not altogether conducive to high standards of morality. Few are aware of the extent to which even the respectable poor are compelled to associate with the vicious, both at home and in the shop, and the girl who, by hard work, is enabled to earn only a bare living, is not encouraged to persevere in the paths of righteousness when she sees her less virtuous acquaintance wearing fine clothes and living apparently a life of luxurious idleness.

The entrance of woman into the industrial world has also added to the dangers which surround her. The promiscuous mingling of the sexes while at work, often

on wages insufficient for decent support, with low moral and hygienic surroundings, is not conducive to chastity. And since she is now a competitor, there is developing a tendency on the part of the male to drop his chivalric attitude toward women. In the great industrial centers, this respect for women, which at one time was an important factor in the promotion of social purity, is rapidly becoming a tradition.

The exploitation of licentiousness in the newspapers, the publication of every nauseating detail of the more notorious divorce cases, with alleged pictures of all concerned, lengthy accounts of the liaisons, real and imaginary, of famous personages, detailed accounts of sexual crimes, books idealizing adultery, plays dealing with the so-called "sex problems," a polite term for clandestine prostitution, all tend to excite the passions and arouse the curiosity of those least able to withstand either. Ungratified curiosity has long been recognized as a potent cause of feminine troubles.

As to the factors which would lead a woman to become a public character, believing that data of considerable interest could be obtained from the women themselves, I questioned one hundred and eight declasse patients, with the following results:

Fourteen attributed their downfall to ignorance, and became prostitutes because they thought there was nothing else for them to do. Nine of these were country girls who came to the city to find work.

Ten were accidentals who drifted into the professional class as the result of discovery, scandal, etc.

Thirty-six were out of work, and, unable to find employment, they had no other way to support themselves.

Twenty-three became prostitutes voluntarily, because they thought it would be a good way to make an easy living, because they were too lazy to work, or because they wished to wear finer clothes and have more good times than they could if employed regularly.

Nineteen were employed in offices, stores, or factories, and were unable to support themselves on their regular wages.

Six attributed their downfall to domestic difficulties. Of this six, five were kept women, and one the proprietor of a fashionable assignation house.

These women form a fairly representative group. Five were proprietors of either brothels or assignation houses, forty-four were inmates of disorderly houses, eight were kept women,* ten were street walkers, and thirty-one were clandestines. No account is taken in this group of a very large class of women who, while not technically prostitutes, distribute their favors among a more or less extended circle of friends. For convenience, these women are termed accidentals. A small proportion of them gradually drift into the professional class.

A Physiological View of Death.

BY WM. R. FRISBEE, M. D.,
Medical Examiner, Bureau of Pensions, Washington, D. C.

The rest of mankind is under sentence of death no less truly than is the convicted criminal awaiting execution. One essential difference in the two cases is that the latter knows how, where and when his earthly existence will probably terminate. The others are left in the dark on that point. No avenue of ultimate escape is possible in either case. There may be reprieve and delay, but a fatal termination is inevitable. Our brief expectancy of life is fixed by fate and reduced by insurance statisticians to a mathematical proposition.

It is a matter of surprise that so momentous a fact, which concerns every human being so deeply, and which of necessity obtrudes itself so often and so persistently upon every adult mind, should, by tacit and almost universal consent, be tabooed as a subject of discussion, and so seldom be even hinted at in ordinary conversation.

*By a kept woman is meant the mistress of (presumably) one man. A street walker is a prostitute who, living in a single room, goes out on the streets in search of business. A clandestine is a prostitute who lives in a hotel or boarding house, and who, while pretending to be decent, meets her friends at various places for a cash consideration.

We need not go far to find explanation. Men, in this respect, are not unlike the ostrich, which, finding escape from a supposed enemy to be impossible, ignores the inevitable, and hides its head in the sand.

And death, regarded as the last great enemy, is designated in ordinary speech as a "grim monster," and "king of terrors." The average lips blanch with pallid fear when brought unexpectedly face to face with the possibility of its near approach. Avoiding the very name, we substitute for it such expressions as "a passing away," "a going to rest," and, in most instances such euphemisms are merely obvious attempts at disguising an unwelcome reality.

An essential difference between man and the lower animals is that the former knows and can realize the certainty of death. All animals alike, including man, cling tenaciously to life, as is especially noticeable in time of peril. This instinctive and universal impulse is implanted for the obvious purpose of protection from injury and for self-preservation. The knowledge that existence must terminate at a more or less remote period, and that it has a definite limitation, is probably confined to man, who alone has faculties sufficiently developed to enable him to deduce general and certain conclusions from observation and experience. An avoidance of causes endangering life is based upon reason as well as instinct. In the case of man this useful provision of Nature often degenerates into such a horror of dissolution as to overshadow and eclipse much of the enjoyment and satisfaction which rightfully belong to living. Men are but children of a larger growth. The child, put to bed in the dark, though surrounded by every possible safeguard of home and parental love, yields to senseless terror and unreasoning fear of imaginary conditions. A crowded audience, composed largely of men who would readily face real danger in a good cause, is stampeded by a causeless panic. Groundless fear makes cowards, even of the brave.

Nor is the dread, or fear, of death based generally upon imagined condition of a future existence. In most cases it seems to relate chiefly to the act of dying, which is popularly conceived to be one of agony or suffering. The average mind is apt to confuse the fact of death with the condition of disease or injury and attendant suffering which often precede it. For this reason such expressions as "pangs of dissolution," and "death agony" are misnomers and misleading. Then, too, the disposition which may be made of the corpse is a prominent and not uncommon factor in this dread. The habiliments of mourning, the shroud, the casket, the grave, the cemetery, conjure up a picture of revolting horror to the average mind. Much, too, chargeable to adventitious surroundings, is often accentuated and aggravated by suggestions of bigotry and superstition.

It seems strange as well as pitiful that dread of its ending should so largely lessen the enjoyment of living. As a matter of fact, there are many good and well-supported reasons for a contrary view. Such reasons are based upon science as well as common experience.

The oft-reiterated truism holds good here that we apprehend more trouble than ever materializes, and, as Shakespeare says, "the sense of death is most in apprehension."

Under a strict analysis it must be admitted that death is nothing more than a negation. It has no distinctive characteristics, and is merely a convenient term for expressing our mental conception of the ending of physical life.

What life itself is and the real nature of vital processes, is a problem of problems, ever baffling solution, and which need not be considered in this connection. That it should have an ending is involved in the very fact of its beginning, and the beginning of this ending dates from the moment of birth. It is a generally recognized physiological fact that at least as often as every seven years the body is wholly renewed in all its parts. Thus a man who has lived his three score years and ten, has changed his body, or, in other words, passed out of it, ten times. The final passing out is simply an accomplishment, by a single physiological process, of that which has so often occurred by a gradual and piece-meal dissolution. In each instance the process is a natural one, and no more to be dreaded, as to the method of occurrence, in the once case than in the other.

Nature never inflicts pain needlessly. Pain is intended as a danger signal, warning us to avoid conditions causing it. When no purpose could be served by it, Nature spares us the infliction. Hence, it may be fairly assumed that when life ends at a normal period, from natural causes, such ending is painless. We are, in fact, no more conscious of the precise moment when the final change occurs than we are of the moment of dropping to sleep. All of us have unsuccessfully tried to realize the latter moment.

In the economy of Nature, suicide, accident, and even disease, are not contemplated as causes which should terminate existence, and circumstances attending such a termination are too numerous and varied to admit of such classification as is partially possible under normal conditions.

Strictly speaking, we should regard death from old age as the only normal or natural ending of life, and when, in conformity with this obvious intention of Nature, we leave the worn-out body, much as ripe fruit drops from a tree, the change is effected without physical pain, and probably often accompanied by a sense of relief. The manner of occurrence, as well as the immediate cause, have a bearing on this point.

In the aged, life ends most frequently from a rupture of a cerebral artery, or interruption of the heart's action, and in such cases, whether occurring suddenly or gradually, there is no more consciousness of life ending than there was of its beginning. It is essential to consciousness and sensation that the brain and nervous system should receive that full supply of blood upon which their functional activity depends.

In sleep, in fainting, in catalepsy, and as the result of certain accidents, the vital functions are temporarily suspended, and meanwhile consciousness and susceptibility to pain disappear. We may regard death, whether chargeable to violence, disease or senile changes, as a permanent continuance of similar conditions. The cause may operate either directly, upon parts immediately concerned in the performance of vital functions, or indirectly, by an interruption of essential nervous stimulus. The various organs are so closely allied in their mutual relations that any interference with the functions of one necessarily involves others. Whatever the immediate cause of death, it is almost invariably ushered in by coma. The word itself literally signifies sleep, and implies an absence of conscious sensation.

Prof. Metchnikoff, of the Pasteur Institute, in a recent work entitled "The Nature of Man," advances the theory that if we live as long as Nature intended, we develop what he styles an "instinct of death," and eventually lose desire to live longer. This view is corroborated by general experience. It is observed of very old men that, having largely outlived their capacity for physical enjoyment, they lose that dread of dissolution for which there is no longer any occasion, and face the thought of dying, as well as its actual occurrence, if not with positive pleasure, at least with resignation and equanimity. Death and sleep, aptly styled twin sisters, are closely related in the purpose they serve. The close of a long and active life resembles the approach of sleep, welcome because of an overpowering sense of weariness, and the exhausted body willingly lapses into final repose.

These partly theoretical views have been substantiated by the personal experience of the writer. It has fallen to his lot, as a medical examiner of pension claims, to read reports of those present at the death of many thousand veterans of our civil war, as to the apparent cause or causes of death and manner of its occurrence. The fatal result is generally found to have been hastened, if not directly caused, by wounds or disease incurred in service, with old age as a complicating factor, the latter appearing more frequently in recent years. The cases in which it is stated that such deaths have been peaceful and apparently painless have been found to outnumber all the others fully ten to one. It should be noted, too, in the exceptional instances, that convulsive struggles, labored respiration, and similar symptoms, which would ordinarily indicate distress, are without such significance, and usually of a reflex character when noticable at the close of life. The almost invariable testimony is to the effect that the end came peacefully, and

that it appeared to the surrounding family and friends of the dying soldier that he was passing into a quiet slumber.

There appear to be cases where physical suffering has continued to nearly the very close of life. Even in such cases, and it may be said especially in such cases, the end is welcomed as a relief.

From any point of view we can not imagine a greater misfortune than would be an indefinite continuance of existence in a worn-out body, its capacity for usefulness and enjoyment gone, and increasing feebleness, decrepitude and dependence its sole remaining assets.

A morbid repugnance, or dread, in relation to the disposal which may be made of one's dead body, is too obviously unreasonable to admit of serious consideration.

When the vital spark has fled, the body is no longer a part of ourselves any more than is a dwelling we formerly occupied. A sentiment of attachment, based upon past associations, may cling to both, but should not be allowed to so distort our mental vision as to displace reason. We know that with the departure of that intangible something called life, all that remains is but a combination of inert matter, which, in course of time separates into its ultimate constituents. Once again, in the endless cycle of material changes, we have become mere "clods of the valley," shortly to assume other forms, first of vegetable, and, later on, of animated being. Why shrink from the prospect of a future natural disintegration and evolution, which bear no relation to our present sentient being?

An impressive object lesson on this point is an exhibit in the chemical department of the National Museum, at Washington. A glass case contains, in appropriate receptacles, the exact equivalent components of a human body of the average weight of one hundred and fifty-four pounds. These appear divided into three groups, consisting of water, organic compounds (proteids, fats, and carbohydrates) and mineral or earthy substances. The greater part (about seventy per cent) consists of water, and the remainder of a variety of inert substances, with which all are almost equally familiar. Only this and nothing more.

Right here we are naturally confronted by the problem of man's spiritual nature, involving the momentous question whether his personality survives the dissolution of the body. But all this is foreign to the scope of the present article, and outside the domain of physiological investigation.

[Written for the MEDICAL BRIEF.]

Mechanical Vibration in Therapeutics.

BY SAMUEL S. WALLIAN, A. M., M. D.,
New York.

[Third Paper.]

From the combined experience of many observers, the therapeutic possibilities of mechanical vibration may now be more confidently stated.

On the circulation it can be made to produce definite and apparently contradictory results. In other words, arterial tension can be either increased or diminished, according to the methods and intensity of application, and any given viscus or tissue can be made hyperemic or relieved of hyperemia, at will.

Again, the tension or activity of any special nerve center can be either increased or diminished, and dormant nerves, whether afferent or efferent, can be aroused and restored to normal function. Local congestion can be induced, and the same condition can be dispersed. Hyperesthetic nerves and areas of hyperesthesia can be quickly relieved, and all the vital processes, metabolism, nutrition, assimilation and elimination markedly accelerated.

Relying on these effects, clinical results abundantly corroborate the logical inference that vibration, intelligently applied, can be made to materially assist in reducing hypertrophies and discussing nearly all forms of neoplasms and morbid growths.

Since the Roentgen and ultra-violet rays are simply immeasurably rapid forms of vibratory motion, it follows that their action is a result of this motion. According to Sajous, the philosophy of the action of rapid vibratory impulses in destroying morbid tissues is thus explained:

They cause a local heat accumulation and congestion, which induces a rapid

and extensive immigration of nutrophile leucocytes, and these, through their phagocytic and fibrogenetic properties, convert the degenerated cellular elements into benign products.

Mechanical vibration, in a lesser degree, reaches the same results. It induces local hyperemia, a local increase of temperature, and a prompt influx of leucocytes and phagocytes, whence follows that process of phagocytic digestion which is Nature's method for the removal of abnormal or malignant growths and infiltrations.

It has long been known that manual manipulation or massage, is in many cases a valuable auxiliary in the treatment of these maladies, and it is easy to understand that by increasing the depth, force and frequency of the applied impulses, by mechanical means, the salutary effects are decidedly increased.

Control of the circulation, and concurrently of local heat production, explains the process and accounts for the results.

To go more into detail, superficial applications of mechanical vibration stimulate the cutaneous circulation, and promote the nutrition of the skin. Its secretions are stimulated, so that a previously harsh and dry skin becomes softer and more supple.

The induced increase in the force of the circulation, and the promotion of nutritive and eliminatory processes results in a perceptible increase in the number of red corpuscles and of hemoglobin.

Superficial applications also stimulate the lymphatics and absorbents, the value of which, in all morbid conditions, is self-suggestive.

I consider vibratory stimulation of the lymphatics and absorbents of the utmost value in connection with the use of the X-ray, ultra-violet ray, and high frequency currents, when treating malignant growths. With this combination I am convinced that some of the reported failures in the use of the X-ray could have been made successful.

By deep applications, the deep-seated nerve ganglia can be reached, and profoundly affected, and, as in case of superficial applications, the action of these ganglia may be either stimulated or inhibited, according to the length and intensity of the applications. In fact, the great field of mechanical vibration is in connection with these ganglia, and with the recognized trophic centers of the nervous system. Each of the spinal ganglia is a storage battery of vital electricity, and each is credited with presiding over some one function or process. When the ganglia radiating to, and in the main controlling any area or organ is stimulated, that particular organ or area responds. Of course, it is understood that many ganglia are closely interrelated, and thus provide auxiliary power, one for the other, in case of accident.

Omitting much that might be said concerning trophic centers, heat centers, nutritive centers, etc., a dormant or debilitated ganglia may be stimulated, and often fully restored to normal activity by an intelligent application of mechanical vibration.

Coming at once to the illustration and practical application of the treatment, the patellar reflex is an apt instance. It receives its impulse and is controlled by the second and third lumbar ganglia. This is merely an illustrative example.

To take up this line of study systematically, the brain may be reached and influenced by applications made over several pairs of ganglia, ranging from the second to the seventh dorsal. The eyes through the third cervical, and, to some extent, through the various centers as low as the fourth dorsal. Recent cases of ptosis of the eyelid have been promptly relieved by deep applications over the seat of the third cervical. The external ear is reached through the sixth cervical. The middle ear may be influenced by applications made from the second dorsal upward, as well as by applications to the front and sides of the neck.

In treating the throat, the applications are to be made by suitable "vibratodes" behind the rami of the inferior maxillary. In anemic conditions of the throat, these applications should be very light, so as to stimulate, while in congestive conditions deeper pressure will be more effective in disgorging the blood vessels, and dispersing the congestion. In acute and subacute pharyngitis and laryngitis, as encountered in professional singers, some very striking results can be obtained. In these

cases, vigorous stimulation of the lymphatics of the neck and axillary region, and also brisk stimulation of both the liver and spleen will add to the effectiveness and permanency of the treatment.

The heart is reached through various centers, all the way from the third cervical to the fourth dorsal. To affect the lungs, deep vibration is to be applied to the third, fourth, fifth and sixth dorsal centers. Alternate applications to the right and left fourth dorsal. To relax an obstructed pylorus, deep applications are to be made over the fourth dorsal on each side alternately, and to the solar plexus and pneumogastrics.

From the sixth to the ninth dorsal of the right side influence the liver, while the same pairs of the left side control the spleen.

The eighth dorsal is associated with the pancreas, to reach which the solar plexus should also be invoked. The latter more or less influences all the pelvic viscera.

Nausea, from the usual causes, can generally be relieved by vigorous but very transient vibration applied to the fourth dorsal of the left side.

When the pelvic organs are diseased or congested there will ordinarily be found one or more hyperesthetic points along the spine—the fifth lumbar and the eighth dorsal, more frequently than other points. In ovarian trouble, it will generally be found that the fifth lumbar and twelfth dorsal are directly involved.

As this paper does not aim at more than a mere outline of the subject, these brief sketches of the technic of treatment must suffice.

One general caution may be urged, namely, that the amateur operator is almost certain to overdo the treatment. As a rule, the applications must be very brief —not more than ten seconds at a time at one point. This is especially true when deep pressure is being applied.

As to machines, the market is now pretty well supplied, at prices ranging from $25 to $200.

As I have no personal axe to grind, I feel at liberty to speak with entire frankness. I have now used all the leading machines before the profession. Among the number many were evidently designed for the use of masseurs and barbers, and while they accomplish mechanical massage, they are of but little value for therapeutic purposes. Most machines are limited to one of two motions—oscillation or percussion. They either give a simple percussion blow, or they give a rubbing motion with slow strokes. This answers the purposes of the masseurs and barbers. The best machines combine oscillation with percussion, and have a rapid stroke —seven thousand to nine thousand per minute. The highest priced machine claims much for its "rigid arm." This loudly vaunted feature is not without its disadvantage. It secures arm-rigidity at the cost of universal adaptability. It delivers its stroke exclusively in a downward direction, which compels the patient to recline on a table or couch, whereas with the flexible-arm machines, applications may be made in any direction, the patient sitting, standing or reclining, as seems best. Although a preponderance of treatment will be given with the patient in the prone position, with muscles thoroughly relaxed, it is sometimes both convenient and important to be able to make applications to a sitting or standing subject.

Furthermore, this rigid-arm machine is cumbersome, ungraceful as an office fixture, and its price is entirely out of proportion to either its cost or its practical advantages. Equally effective apparatus can be had at less than half the price asked for this one. Some of the flexible-arm machines, on the other hand, are quite undesirable, imparting too much motion to the hand of the operator, spitting oil on the clothing of the patient, and easily getting out of order.

Surgical Operations vs. Medication.

BY PITTS EDWIN HOWES, M. D.,
Assistant Editor of "The Eclectic Review."
Boston, Mass.

The tendency of the day is toward specialties. The cry is that the specialist has more time to devote to his particular branch, and so can become more expert in that line. To a certain extent the statement is true. In the realm of med-

icine, however, such a statement has many elements of fallacy.

I once heard a celebrated surgeon make two assertions which have an important bearing upon our subject. They were these: "A man should practice general medicine ten years before adopting any specialty," and "It shows greater ability in a surgeon to know when not to cut than to operate."

These are important facts, and they are lost sight of to-day in too many cases. The prospective specialist, many times, selects his career before he even commences to study medicine, and all his energies are bent toward gaining knowledge along his particular line.

He forgets that man is a complex organism. That very many factors enter into the pleasurable performance of the functions of the various parts of the body. That the cause of failure in such a performance is just as complex. That in many cases the failure is produced by reflex conditions which are situated remotely from the place where the trouble is manifest. His education has taught him to look at every phase of impaired life through his own particular branch. He is constantly trying to solve all problems, which confront him, along his own lines.

The lack of practical knowledge—which is a result of not doing a general practice of medicine—has a tendency to make many of his deductions erroneous. Hence, instead of becoming a guide and a substantial aid to his professional brethren, he is apt to be a stumbling block, and lead them along wrong paths to their detriment and that of their patients.

Among the many specialties in medicine possibly there is none which is so attractive as that of surgery. The *éclat* which attends a brilliant surgical operation captivates the mind of the medical man in embryo, and leads to enthusiastic acceptance of this branch of the profession as his life work.

The would-be surgeon constantly attends the surgical clinics. He loses no opportunity to perfect himself along surgical lines. His close application makes him an adept in the handling of surgical implements. He longs for a chance to show his skill, and everything is fish which comes to his net.

Possibly there is no branch of surgery which presents so many chances for the ambitious surgeon as that which pertains to gynecology. Women, from their organization, are especially prone to mishaps which bring them as subjects to the surgical knife. The increase of surgical work in this department has been simply enormous in the past quarter of a century. We are constantly told of the wonderful operations which are being performed for the benefit of women, and their great success. Many times such success is only temporary, and the latter condition of the unfortunate victim is decidedly worse than that from which she was formerly subject.

The principal element of the truly great surgeon—to know when human health can be restored without the use of the knife—is lost sight of in far too many instances of latter-day surgery. This is especially true in gynecological practice.

Were our surgeons as thoroughly drilled in the correct application of the various agents of our grand *materia medica* as they are in the use of their cutting instruments, there would be many more reports of a radical cure without the knife than there is at the present time. Not only is this a fact, but much human misery would be blotted out which now is the result of reckless cutting.

How many laparotomies are performed which might have been avoided had the right medication been adopted? Were this question correctly answered, the reply would be simply astounding.

When will this state of affairs be remedied, and this useless mutilation cease? Not until more attention is given to the careful study of remedial agents of the vegetable kingdom, and the reputation of the surgeon depends upon the lasting results of his work rather than the brilliancy and success of the operation.

Our *materia medica* is wonderfully rich in agents well adapted to the curation of many of the difficulties which affect women. Among them may be mentioned caulophyllum, macrotys, helonias, pulsatilla, hydrastis, viburnum pruni,, viburnum op, michellæ repens, scutellaria, hyoscyamus, etc. There is not space in

this article to enter into the correct use of the various drugs named, but when they—and the class of remedies which they represent—are correctly understood and applied, the need for surgical interference, in the field of gynecology, will be lessened to a very great extent, and much practical good be done to suffering humanity.

I do not wish it to be understood that I deplore the department of surgery in the practice of medicine. I believe that it has, and should have, an important place to fulfill. All honor should be bestowed upon its legitimate field of action, and the beneficent results thereby attained.

Notwithstanding this, I firmly believe that surgical operations are many times performed which are not only needless but absolutely harmful in their results. The time is coming when surgeons will be held more closely to account for the result of their work than they are at the present time. When that day arrives they will be more careful to investigate all methods of cure before resorting to the knife.

[Written for the MEDICAL BRIEF.]

The Secret of Health and Its Possession.

BY AXEL EMIL GIBSON, M. D.,
Los Angeles, Cal.

Back to Nature.—It is by sheer force of instinct that man again and again strikes out to regain the old trade winds of health and happiness in his evolutionary cruise. Back to simplicity and common sense; back to the sane and concrete, to decency and manhood in the art and science of living.

Yet the word back, in this relation is not to be taken in the sense of moving backward. No entity can retrace his steps in evolution and live—not more so than a thing of life and growth can reoccupy a mold which it has once outgrown. Back to Nature means rather to pause, to wait for Nature's summons, and to yield to her efforts to re-establish her seat in the council chambers of the mind. Gradually, and under the stress of recurring penalties, the individual will learn that there is no royal road to health. He will learn that action and reaction, cause and effect, are the governing forces of existence, and lie back of all true growth. To over-ride this law means to step out of the highway of life, and stumble along illegitimate paths of existence. Action and reaction are equal and inseparable, and the expenditure of vital energy involved in the former must reappear and reassert itself in the latter as an inevitable rebound.

Hence the futility in attempting to restore broken-down health by any other method than in undoing what has been done wrongly, and in doing what ought to have been done, but neglected, in our relation to Nature. Only one course is left open, a course which, by aiming at the re-establishment of a disturbed vital equilibrium, involves self-denials, proportionate to the gravity of the offense, and as offenses leading up to functional collapse generally consists in errors of diet —over-eating or wrong-eating—or in neglect to enter into vital touch with Nature through outdoor life, and in the proper exercise of lungs and muscles, etc., it follows that the restoration of health is possible only in adapting methods of living, involving a corrective of the blunders committed.

Offenses Against Nature.—One of the most serious offenses against Nature lies in over-eating. The human body, in one of its aspects, resembles a furnace, and like the latter must be supplied with fuel in order to generate heat. And as in the case of a furnace, the supply of fuel required for generating a proper amount of heat must be gauged by the degree of draught back of the combustion—so the human body depends for its healthy assimilation on the capacity and opportunity of the lungs to supply the physiological "draught" with its concomitant of oxygen. For the assimilation of food does not wholly depend on a good appetite, nor yet on a good digestion, but rather on the power of the lungs to supply an amount of oxygen sufficient to oxygenate the digested food-stuffs (chyle) transmitted by the agencies of assimilation into the bloodstream. Emptied by the thoracic duct into the vascular circulation, the chyle floats with the bloodstream into the heart, whence it is pumped into the lungs,

where it is brought into contact with the oxygen of the air-current, by the vitalizing touch of which its pale fluid is changed into the red color of the blood.

Gluttony, Suicide.—Now, if the chyle requires more oxygen than respiration makes available, *i. e.*, if the individual has taken more food into his body than he can assimilate, the oxygenation remains incomplete, while the mass, now rendered poisonous, is carried by the bloodstream to the different organs and tissues, finally to be eliminated through the several emunctories, principally the kidneys, as waste products—physiological ash. Thus after having brought the ingested food-stuffs through a series of complex and vitally exhaustive changes up to the final point of assimilation, and subsequent recompensation for the expenditure—Nature finds herself compelled to continue the ruinous economy by reversing the processes, and reduce the miscarried compounds into stages of elemental decomposition involving a constantly increased loss of vital power. Thus, like the crammed furnace, which in place of heat can only turn out smoke and half-burned ashes, the over-fed body in place of generating the vital fires of health and growth evolves nothing but the smoke and waste products of decomposition.

The breakdown of a glutton is only a matter of time, though an originally powerful constitution may successfully endure the imposed strain for a longer or shorter time. Yet signs of brooding disaster will soon make their appearance in his body. On the other hand, to associate a rounded-out, well-fed and well-poised physique with gluttony is a mistake, as the habitual glutton will soon lose his healthy appearance, and not infrequently in the course of his over-indulgence become reduced to a sickly-looking, hollow-cheeked, dull-eyed, drowsy and unprogressive individual. For, as in the course of his over-indulgence the expenses involved in his physiological industry exceed his income, he is likely to experience an embarrassment similar to that of the owner of an industry, the income of which is unequal to the expenditure involved in its operation.

In either case, the only sane and logical measure is to shut down the expense, which in the case of the body would mean to reduce the diet so as to bring it within the power of the system to assimilate it. A restricted diet, or, better still, a moderate length of fast, gives to the system a well-needed temporary rest, during which Nature may adjust deranged functions, build up broken-down structures, clean out congested organs, and remove old waste deposits from the muscles.

The Healing Power of Fasting.—The depth and permanence of the general tonic effect imparted to the system through a fast of some six or seven days' duration, surpasses any effect due to the action of drugs or electricity. Relieved by the fasting from the labors entailed by her daily routine of digestion, Nature can turn her attention to the condition of the structures themselves and proceed to weed out sediments and various waste-products deposited in the muscle-fibers and drainage tubes of the great vascular systems of the body. Extended long enough, and scientifically guided, fasting has even been found to remove malignant tumors. The armed police force, employed by Nature in the defence of the body—the phagocytes—are equipped with powers normally adequate to meet any invasion of alien microbes. And as any abnormal growth in the body arises from a failure of the phagocytes to properly defend their territory, it follows that any condition which relieves the strain of their routine labors, adds to their efficacy and success in fighting the common foe. Hence, fasting, by temporarily relieving the phagocytes from the guerilla war, continually waged against the minor foes of micro-organisms daily entering the system by way of impure air and food, provides a well-needed opportunity for this bodyguard to break down and expel the intrenchments which a more formidable and deep-seated foe in the form of ulcers, tumors, and promiscuous growths are constructing and maintaining in the vital tissues of the organism.

A case in point is at present in progress at the Deaconness Hospital, Los Angeles, Cal., where a patient, aged forty-eight, is suffering from the combined ailments of psoriasis and arthritis deformans, which,

in the course of time, have covered him with loathsome sores, while simultaneously a process of ankylosis has attacked and locked up every joint in his anatomy. His treatment in the hospital is limited to a course of fasting, which at present has extended over a period of twenty-eight days. The result up to date is in the highest degree gratifying. Already at the end of the tenth day the skeleton rapidly began to evince signs of movement, and at present every joint yields more or less to his will, while some of them—the toes and elbows—exceed in their power of movement half of the normal range. As the fasting is still in progress, though alleviated at present by some light form of liquid nourishment, such as koumiss, albumin and unfermented grapejuice, the final result is not yet in sight. From the present outlook, there are probabilities for a complete cure.

The Philosophy of Fasting.—The forces at work in this case are readily discerned. Unhampered by the routine work of digestion and assimilation, the bodyguard of defense—the leucocytes, phagocytes and lymphocytes—can devote themselves entirely to processes of elimination, and to dissolve and drain the congested and hardened tissues.

To the certain knowledge of the author, tumors of various kinds—even malignous—have been absorbed under conditions brought about by fasting. The rationale of this curative power in fasting lies in the fact that all tumors, being foreign growths, are the work of microbic invasions. But inasmuch as Nature under normal conditions is ever adequate to hold her own in defending the body against attacks of alien microbes, it follows that back of the possibility of such attacks must be found a derangement of functional activity, giving rise to malnutrition and general weakness. The bodyguard defeated, the victorious foe, after having intrenched himself in the conquered territory, proceeds to form centers or colonies of activity, with an organization all their own, while leveling a devitalizing tribute on the body commonwealth for support.

Tumors: Physiological Anarchy—How to Restore Order.—Such a humiliating state of vassalage can exist only as long as the bodily system remains under the strain and stress of some influence or condition preventing the protective cells from offering adequate resistance to the attacking microbes, conditions which in the generality of cases spring from too arduous labors in the fields of digestion and assimilation. For, in a system overloaded with food, the cells engaged in offices of secretions and excretions are too busy in eliminating specific waste-products from the output of an overcharged and unceasingly protracted digestion, to find time and opportunity for the federal work involved in the general defence of the body against microbic invasions. The peril arising from an accumulation of waste-products with the inevitable output of poisonous substances, is more immediately threatening to existence than the more distant peril involved in the slow pathological changes brought about through the work of an already established and tolerated foe.

In the light of these observations it follows that any respite from the pressure of daily routine work as represented in digestion and assimilation, tends to provide time and opportunity for the defensive micro-organisms of the body to concentrate their forces on any specific point of suffering from a parasitic attack—a procedure which forms the therapeutic reason for all systematic fasting, and for the almost miraculous results accompanying this sovereign of all methods of elimination. But a fast, in order to effect the removal of all tumors or any other deep-seated specific evil, must extend at least over a period of twenty days, and proceed under the direction of some person capable of administering intelligently to any emergency that may arise.

Appetite Versus Digestion.—But even outside the power of removing specific maladies, fasting has a great general therapeutic value. As a purgative for a systematic and thorough cleaning out of the alimentary canal, a few days of fasting has no equal. In view of our present artificial mode of living, when normal appetite has given way to craving, and real hunger—the only reliable counsellor in matters of eating—has become an almost unknown and unfelt quality, it is

inevitable that there should arise grave complications in the process of digestion and assimilation. Under the strain of a bill of fare aiming more at gustatory development than the strengthening of digestive and assimilative functions, the latter are utterly inadequate to meet the insane demands of a disproportionately developed appetite. Yielding to the dictates of this monster appetite, the individual loses his sense of physiological balance, and crowds more nourishment into his system than the latter can utilize. The organs of elimination—liver, kidneys, lungs, skin—failing to dispose of the continually multiplying waste-material, must suffer it to remain in the blood, whence it is deposited in the muscle bundles, and various tissues of viscera and organs. The result may either manifest in a specific character, or in a general lessening of tonic and functional vigor, leading to a final structural breakdown in the form of diabetes, Bright's disease (interstitial nephritis), apoplexy, etc., or in a sudden attack of alien micro-organisms with the corresponding development of some acute disease, viz., pneumonia, typhoid, la grippe, acute yellow atrophy, etc.

Scavengers in the Human Body.—Aside from these more serious issues, the continued accumulations of waste products from an overtaxed assimilation will call into operation a law governing the general assets and liabilities involved in natural evolution. A carcass thrown on the field will presently become the breeding place for myriads of maggots, which in the scheme of an ever-present, evolutionary provision seem to be commissioned to transform decaying substances into compounds more available to Nature's economy.

The mass thus accumulated from a miscarried assimilation meets the same fate as the putrefying carcass on the field. The tissues in the over-fed body, under the strain of the same law, proceed to breed countless hosts of maggots, which may henceforth take up headquarters in the body as permanent parasites, with a subsequent weakening and final breaking down of every function, if the disorder remains unchecked.

In this big appetite and craving governed era, the number of maggot-breeding people must, indeed, be appalling. Kidney, liver and intestines are the haunts, *par preference*, for these representatives of bodily decay. The remedy is invariably and infallibly the same: a grand cleaning process through the eliminating action of a few days' fasting, followed up by a mode of living more aiming at a strengthening of digestion than of appetite, hunger in place of craving, and positive need and necessity, in place of gustatory fits and notions.

In infinite degrees of expression and power, this scavenger work extends throughout the entire system, involving every tissue showing tendency to breakdown. And while the workers in this great and ingenious system of Nature's house cleaning may descend in the sliding scale of life from the visible to the invisible, from gross maggots and vermins to micro-organisms, bacilli and bacteria, the principle of the back work remains unchanged. The formidable undermining of the human organism, as represented in the ghostly spectacle of pulmonary consumption, is an impressive illustration of the principle at work in this at once horrifying and salutary nature—process through which the economic balance of the universe is maintained. For the onslaught of the tireless microbe, however terrifying the result wrought in the involved tissues, is itself harmless and beneficial—in fact, constitutes a guaranty for a continuation of ascending life. The principle at work in this at once horrifying and admirable process is revealed in the fact that the decay of the tissue is not due to the presence of the microbes, but, on the contrary, the presence of microbes is due to the decay of the tissue. And as the destructive work of the microbe depends for its progress on a native weakening of the constructive power of the system, it follows that a strengthening of the latter means a corresponding weakening of the former. Hence, in relation to health, the microbe represents a passive force, which must be invited by suitable, *i. e.*, pathologic conditions, in order to find a field to enter. Any attitude of healing, aiming at the mere destruction of the microbes is entirely misplaced, and possesses no more truly scientific value for the establishment of health than the

chasing away of carrion birds from the carcass prevents the latter from decay and corruption.

Microbes are evolutionary agents, and their work is as much in conformity with the laws of life and existence as the action of the phagocytes and lymphocytes in their work of defending the integrity of the physical body. The offence is to be sought for in the diseased entity, who by violating a natural law invokes forces which for the restoration of a disturbed cosmic balance have become inevitable. For inasmuch as man is a part of the whole, enjoying the protection which arises from cosmic order, it likewise follows that through his personal, lawless indulgences the balance of the universe may be disturbed, a disturbance which can find its restoration only in following up and equalizing the disintegrating influence until it finds its functional level—the individual body. If the balance of the universe should be affected to a degree that its return to equilibrium could proceed only through a sweep of force-currents involving the destruction of the organism in which the disturbance had its seat, the issue would be death to that organism.

(To be continued.)

[Written for the MEDICAL BRIEF.]

Asthma.

BY J. H. JERGESEN, M. D.,
Milwaukee, Wis.

[Paper No. 1.]

A physician can never be placed in a more distressing position than when he is called to relieve an asthmatic in one of his paroxysms. At first, everything and anything he does to relieve seems to aggravate his condition, His suffering is so great that one hesitates to suggest remedies. Seemingly, a patient in an asthmatic paroxysm suffers more agony by his efforts to escape suffocation than well could be equalled by any bodily pain. A physician looking on, while an asthmatic suffers the horrors of suffocation, his face bathed in cold sweat, his eyes bulging, his mouth open, and the muscles of his face distorted, can not feel indifferent in his presence, but seems to be seized with an impulse of acting or assisting in acting his part. In bodily pains a patient can groan, shift, try to ease himself by moving, rubbing and pressure, and in all the other ways a sufferer has whereby momentary ease might be obtained.

A patient in a paroxysm of asthma sets as if he was placed in a vice, unable to move, or speak or even make a sign; the least exertions aggravate the condition the minute they are thought of. The muscles of the face are set in intense anxiety and rigid. Cold perspiration bathes his forehead.

It has been my lot to see quite a number of patients in a paroxysm of asthma, and I have come to fear the night calls to asthmatics. To see them struggle for breath affects me sympathetically as nothing else does. Often I have felt as if I was taking part in their suffering.

The condition one observes in a typical asthmatic paroxysm are nearly as follows:

On entering the sick chamber I observed an elderly man (aged forty-five) sitting in an arm-chair, undressed; a woman's shawl thrown over his shoulders. In the room with him was a woman (his wife), crying and lamenting profusely. Said she: "My husband has had asthma for twenty years, but never has he been as bad as this morning, and I am afraid he will not live through it." Now this is the tale that will always be poured into your ears; the last spell is always, they think, the worst on record.

Observing him from a distance, because he could not endure to have any one come near him, I noted that he, indeed, struggled terribly for breath, and was by far the worst case I had ever seen.

He sat there rigid, unable to move; barely moved his eyes in my direction, clutching at the arms of his chair, his eyes wide open and bulging, his nostrils dilated, his mouth partly open, his head thrown back, his shoulders raised to nearly the level of his ears. With every inspiration he would move his head back, and with every expiration his head would sink forwards, as if he was so deadly tired and his exhaustion so great that, life or death, come what may, he was not able to draw another breath.

His hands, arms, feet and legs were icy cold and wet from perspiration; they looked bluish, shrunken and dead-like. His pulse was very rapid and so small that I was unable to count it. At the end of the paroxysm, when the pulse had become strong enough to be counted, it was one hundred and forty per minute.

The muscular effort and the terrible strain he was put to was displayed to great advantage by observing his body. I dare say there was not a muscle in his whole trunk that was not rigid and set, and had become accessories to inspiration. The muscles and especially the trapezins and sterno-clerdo-mastoid, stood out like cords forming the occipital triangle into a deep cavity.

All the muscles passing from the head to the shoulders, clavicles and ribs, were rigid and set. The head was made a fixed point from which they could act on their respiratory attachments. Ordinarily, such muscles as the splenii and scalenii have their origin or fixed point at their inferior attachment, and their action, as we know, are to move the head and neck; but in this case their superior attachments were fixed and from them they acted as mediate and immediate elevators of the ribs, and thereby assisting in distending the thoracic cavity. Even the omohyoid and thyrohyoid, whose superior attachments are at the hyoid bone, and because of its floating character can not be used as accessory respiratory muscles; but, anyhow, they are seen at each respiratory effort to contract, but instead of helping to raise the thoracic frame they only succeed in pulling down the hyoid bone and consequently through the geniohyoid and geniohyoglossus depresses the lower jaw, which gives the patient the attitude as if he was gasping for breath. The action of the omohyoids are to assist the platysma myoides in preventing the integuments in the neck from being drawn into the chest cavity under prolonged suction or in a condition, as in asthma.

On the other hand we must be thankful to Nature that this is so. Without this compensative effort of Nature it would, indeed, be a discouraging profession to practice medicine.

But with all this strain and force that was put on all these accessory muscles all seemed to be of no avail. The chest was expanded more than three inches over his normal chest measure. The lungs were enormously expanded, but unable to collapse and it seemed impossible that air enough could be squeezed out that an expansion could be noticed in the next inspiration. The chest was in a continuous expansion, without the corresponding collapse or depression; the chest remained nearly still and motionless; its walls were fixed and hard and remained as in a vice, full of air, but because of its rigidity, unable to exhale it. The muscles, as we have seen, all contracted and cord-like, held the chest rigid and expanded, as in extreme inspiration. The clothes that ordinarily fitted him could not be brought together by more than three inches.

Ordinarily, in health, inspiration is longer than expiration, but in this case expiration is much the longest, and expiration, instead of being a short, gentle collapse, is an abnormal, long, wheezing and straining productless effort, by which the air is slowly and painfully driven out of the lungs. The terrible strain under which this is carried on is seen to advantage in his eyes, which, under each expiratory effort bulged forward in their sockets.

Inspiration is, seemingly, comparatively easy, but whereas expiration was productless, no pulmonary collapse occurred; therefore, inspiration, if it shall not end in asphyxia, must be acomplished somehow, and so a seemingly final and last effort at expansion of the chest wall by respiratory muscles and their accessories are produced, with the result as before stated, that each succeeding inspiration the chest and lungs are a little more expanded to give room for just a little more air than was driven from the lungs, until at last the air cells in the lungs give way and the condition known as emphysema is the result.

Under auscultation the ordinary respiratory murmurs are absent; but instead we find what one aptly has called, "the full orchestra of tube sounds," of every pitch and note, sonorous and sibulant rhonchis, could be heard in great profusion over the whole thoracic walls. The sibilant being far in excess of all other sounds, sometimes resembling the chirping of a bird

and then again the sounds would be like the squeaking of a nest of little mice; when all at once they would become subdued and resemble the mewing and purring of a kitten; then again become whistle-like and so shrill and intense that one could hardly endure to listen. That was the case when I first applied the stethoscope over the apex lung, but they soon changed locality and were heard about two inches further down and at the apex nothing was heard. These sounds would move from place to place and change in pitch as they moved, from the highest to the lowest key. In this way one might station the stethoscope and in the course of one minute hear all the sounds struck on the key-board, so would the sounds and site change in the most remarkable manner.

The next observed, of any note, was the great quantity of clear, limpid urine of a very low specific gravity that was passed in the three hours the paroxysm lasted.

The first sign that paroxysm was abating was the gaining in strength of the pulse; it became more prominent at the wrist, the cold, clamminess of the skin disappeared, and gave place to a dry and warm feeling. The duskiness or bluish pallor changed to a clear and natural pallor, very soon the rigidity of the most prominent muscles of the neck, such as the sterno-cleido-mastoid and trapezins, relaxed, and his head moved somewhat forward; the shoulders were released and lowered. Soon he raised his hand and leaning his head against it, drew a deep sigh, which provoked an effort at coughing. In a few minutes he coughed and raised a pellet of mucus.

About fifteen minutes from the time I first noticed the increase in strength of his pulse it had become full and vigorous. His forehead was dry, his skin warm, his eyes and mouth closed, he was breathing through his nose. Soon his weariness and exhaustion gave way to a fitful and restless sleep, which, however, within half an hour changed to a sound and refreshing sleep.

The urine he passed during the night amounted to fifty-five ounces, clear and limpid, of a specific gravity of 1008.

In this case, as in several other cases, I have been able to verify Dr. Salter's (London) original discovery of a phenomena seen in asthmatics, namely, the itching of the chin. Dr. Salter does not attempt an explanation of this symptom, but merely states it as a fact. This case was very pronounced in itching of the chin. He would seemingly become more uneasy, and swing his head from side to side, as one might do if he wished to rub his chin when his hands were engaged. He would not think of taking his hands from the arms of the chair which he was clutching with all his power, but suddenly he would let go the chair and reach up and rub his chin. On several occasions while his paroxysm was the worst, he had to abandon the attempts, his hand would be raised midway and drop back and clutch the chair tighter than before. If, however, he was successful in reaching his chin and giving it a good rub it seemed as if he was greatly relieved. Questioning him afterwards about it, he did not know that he had done so. One patient in whom I also observed the rubbing of chin, claimed that it gave him immense relief to rub his chin, but I observed that the relief consisted more therein that he afterwards was able to give his undivided attention to his respiratory difficulty and not from any direct relief obtained in that way.

735 Third Street.

Stillingia Sylvatica—Stillingin.

BY V. A. BAKER, M. D.,
Adrian, Mich.

In the practice of physic covering an experience of many years, I have found no more reliable alterative than stillingia sylvatica, provided, and this proviso must be respected, viz., it must be gathered at the right time, and prepared in the right way, or it will disappoint when tested for its alterant effect. The dried root is feeble in action, no matter how nicely prepared, and the fresh root is but little better, if subject to heat, as boiling renders it nearly inert.

Formerly I prepared my own remedies largely by tincture made from the fresh

plant, after having an experience with the dried root, and failing to get satisfaction. I prepared the fresh root, using eight ounces of same to one pint of alcohol, using from five to twenty-five drops, as age and condition of patient required.

I have used the active principle, so called, as may be purchased in the market labeled stillingin; have tried that made by different houses; patient investigation compelling me to say it is worthless as an alterative. For a number of years past I have used it *specifically* prepared, and as it does not disappoint me in effect, can recommend it to my brother practitioners with confidence in all cachetic conditions, in syphilis, and depraved physical conditions.

I have just dismissed a patient, sixty-five years of age, who had been subject for a number of years to pereostitis, at times severe; nodes had formed on different parts of the body, and furunculous developments had caused him no end of trouble; irritable ulcer of tibial region, headache and concomitant symptoms. This man had no history of syphilis, but stated that it followed ivy poisoning, which was severe at times. He had been doctored and doctored, as he expressed it, and failing to get relief had tried the most extensively advertised patent medicines, with no permanent benefit.

I prescribed the following:

℞ Stillingia, Specific Tincture.....4 ounces.
Rumex Crispus, Spec. Tr. .....4 ounces.
Arctium Lappa, Spec. Tr. .....4 ounces.
Gentian Elixir and Glycerine—
equal parts .....4 ounces.

Making in all a sixteen ounce mixture, he residing some distance from the city being the reason of so large a quantity at a time. I ordered of this a dessertspoonful before meals and at bedtime.

The ulcer was treated with oxide of zinc, one part, and powdered starch three parts, well mixed, and applied directly to sore, and suitably bandaged; dressing reapplied as indicated, two to three times daily, no water being used.

The patient, after four months' treatment, is well.

In the treatment of all depraved conditions of the system, I restrict patient as to diet, interdicting coffee, beer and tobacco, while under treatment, and the advice, when heeded, yields gratifying results in connection with suitable treatment in all chronic diseases.

A word in conclusion regarding the stillingin, a thorough testing of which assures me of its worthlessness, but of specifically prepared stillingia sylvatica, I have looked in vain for its equal in all systemic conditions requiring promptness and certainty of effect it is without a peer.

[Written for the MEDICAL BRIEF.]

Suprapubic Prostatectomy.

BY M. R. BARKER, M. S., M. D.,
Chicago, Ill.

In previous articles we have discussed, at some length, the subject of perineal prostatectomy. In these articles we have not alluded to the subject of suprapubic prostatectomy, preferring to make that the subject of a paper, and thus, by keeping the discussion of these subjects separate, enhance the effort to elucidate both, rather than risk obscuring both by discussing them together.

That suprapubic prostatectomy has a legitimate place in the surgery of the prostate, and is sometimes the operation of choice, there is no question. Its distinctive claim to this place is the time saved in doing it. Further than this, its advocates have established no claim for its preferment, in any case, over the perineal route. We have used the term established here advisedly. We know that other claims have been made in support of this operation. For instance: It is claimed by some that a smaller per cent of impotency follows this operation than follows the perineal operation. (I wish to call attention to the difference between impotency and sterility.) This claim, however, has not been established, and in my judgment, can not be. But, if future work does establish this claim, the scope of this operation will be greatly extended, for this operation will then take precedence where the question of impotency is the controlling one, as well as in that class of cases where time is the important feature in choosing the method of operating. But, as before stated, time is the only established element in this operation which ever gives it preferment, at the

present time, over the perineal route. Hence, in discussing this operation, we must limit ourselves to that class of cases in which time is one of the important elements in selecting the method of operating. The class of cases in which this operation seems to be indicated, is that in which the patients are feeble and unable to stand the more protracted perineal route, and in which the patients can not stand the usual, general anesthesias, nor sufficient local anesthesia to do the perineal work. It will not do, however, to put all who are feeble in this category, but a differentiation must be made, based upon the cause and degree of feebleness. Feebleness, due to senility, might or might not place the patient in this class, depending upon the degree of feebleness. If the patient is so feeble that the time to do the perineal work would hazard his life at all, the suprapubic operation must be the one of choice; but, if the degree of feebleness is such as to justify the perineal operation and escape the disagreeable conditions that are imposed by the suprapubic operation, the perineal work should be chosen. The judgment of the surgeon must here decide. We wish, however, to make a very broad distinction between senility and old age. By senility we mean old age manifested by physical and mental weakness and decay. The man of sixty may be senile, while the man of eighty does not possess a symptom of it.

If the patient is feeble because of a septic condition of the bladder, and from the absorption of pus-ladened residual urine alone, and the bladder is accessible for treatment by means of a catheter through the urethra, this operation would not be indicated, nor would any other, until the cause of the feebleness had been removed by properly treating the patient and his bladder until well. Then the perineal operation would be the one of choice, in all probability, as the feebleness would disappear when the infected bladder was relieved. If, however, the bladder was not accessible for treatment by means of a catheter through the urethra, which is the case in a certain per cent of these infected cases, and we were compelled to do a suprapubic cystotomy, in order to treat the bladder, we would remove the prostate through this incision, at a later time, provided some condition did not arise to contra-indicate it.

We do not wish to convey the idea that in all cases where the catheter can not be passed into the bladder, through the whole length of the urethra, in these infected cases, and the bladder treated through this catheter, we would do a suprapubic cystotomy from choice, and treat the bladder through that incision. We have stated: If we were compelled to do a suprapubic cystotomy, etc. There are cases so feeble, by the constant absorption of septic matter, for a long period of time, that a general anesthesia could not be thought of at all, and enough local anesthesia, to render a perineal operation for drainage and treatment of the bladder possible, would probably be fatal, when the patient could stand sufficient local anesthesia to do a suprapubic cystotomy.

Hence, in this class of cases, we are literally compelled to abandon the perineal route, which is the best method of draining and treating the bladder in these cases, previous to operation, when the catheter can not be used. In such cases we would remove the prostate through the suprapubic incision, if conditions did not arise contra-indicating it.

While it might be justifiable in some cases to remove the prostate by the perineal operation, during an infection of the bladder, for reasons of the superior advantages this route affords for drainage and treatment, such a procedure would be open to righteous criticism, through the suprapubic route, by reason of the inadequate means afforded by it for proper drainage and treatment, not only of the infected bladder, but also the wounded tissues from which the gland has been removed, and to which the infection is sure to spread. Hence, for these reasons, a case could hardly arise wherein one would be justified in removing the prostate, suprapubically, in the presence of an infected bladder. There is also danger of infecting the abdominal wound by draining the infected bladder through it. This is obvious. It is not hard to understand the disagreeable position of the surgeon, and the danger to the patient, by reason of an infected abdominal wound, the source of which can not be stopped until

the bladder is well, and the bladder will not get well, for it, in turn, is infected from the abdominal wound. Thus a vicious circle of infection is set up that taxes both surgeon and patient to the extreme, if it does not destroy the life of the patient. It is true that this condition does not always follow drainage and treatment of an infected bladder through a suprapubic incision, but it does follow in quite a large per cent of cases. Hence the statement that we would remove the prostate, through the suprapubic incision, later, if conditions did not arise to contra-indicate it. In septic cases, then, the suprapubic route, for prostatectomy, is a very poor dernier resort.

Feebleness due to other disease conditions: For instance, diabetes, nephritis, organic heart disease, arteriosclerosis, etc. When such conditions complicate, suprapubic prostatectomy is frequently the operation of choice. It can be done in so short a time that nitrous oxide gas may be given as the anesthetic, provided it is not wise to use the usual anesthetics. We believe this is eminently the legitimate field for this operation. In patients so feeble that it would be risking too much to attempt the usual anesthetics, we can adopt this operation and use the nitrous oxide gas, and thus bring the benefits of this operation to many who otherwise must be deprived of them.

It may be urged that if these old patients are so feeble, from complicating conditions, that it is dangerous to administer the usual anesthetics, why attempt to do anything? Make them as comfortable as possible, and let them die. Our mission is to ameliorate suffering and to save life. It is not for us to discriminate. Whether the patient is an octogenarian, or a babe in its mother's arms, our duty does not change. Our position towards our patient does not change because of complications that make our work more difficult. If there is a way pointed out, which has been successfully followed in such cases, and we know a very large per cent of the patients who have pursued it have been greatly benefited if not cured, it is our duty to point this way out to them. The complications may be caused by the conditions produced by the diseased prostate, and when these are removed, the complications may disappear, strength and courage return to the patients, and a score of years may be added to many useful lives. There is hardly a prostatic, suffering with almost any combination of diseased conditions, that cannot have the benefits of this operation. Hence, we repeat, suprapubic prostatectomy has a legitimate and an important place in the surgery of the prostate.

This question might arise: If this operation can be successfully used with the feeble, non-infectious cases, why not use it in all clean cases, whether feeble or not? We do not use it in all clean cases because of some disagreeable things which follow it. Among these we may mention, as the most prominent, the fistulous opening that continues so long after the operation. This is not a specially dangerous condition, but is extremely annoying. These fistulæ do not close, in a majority of cases, for from sixty to ninety days, and sometimes even longer. Why are they so long in closing? After removing the prostate, a drainage tube must be kept in the bladder, siphoning the urine out as fast as it runs in, until the wound, caused by the removal of the prostate, has healed.

If this is not done, extravasation of urine will take place, through this wound, and infiltration of the paravesical tissues results. It does not require the same length of time for the wounded tissues at the neck of the bladder to heal, in all cases, but it requires a good deal of time, in every case, from twenty to thirty days on an average. Then the tube is removed, and the fistula is left to heal as quickly as Nature, in each case, will do it. But Nature does not always hurry these matters as rapidly as the patient would wish, and a month or six weeks, or perhaps a little longer time, elapses before the case is through.

A month or so of dribbling urine while the tube is in place, and a month or so of dribbling urine after the tube is removed. Most patients become disgusted with the dribbling urine, and most surgeons tired of the dribbling patient, before the last dribble has dribbled away. Hence, the element of time that is saved to the patient by this operation in doing the work, is more than over-balanced by this dis-

agreeable feature if the patient is able to stand the perineal operation.

As stated in a previous article, I have been able to avoid a perineal fistula by using a catheter, passed through the penis into the bladder, and changed daily for a sterile one, continuing this for two or three weeks. Then, when the catheter is removed, the urine passes away by the natural channel. Hence, this disagreeable after-feature is shortened very much by doing the perineal operation.

Technic of suprapubic prostatectomy. The patient is prepared as for a laparotomy. A catheter is passed through the penis into the bladder, and the bladder thoroughly cleansed by some antiseptic solution which is allowed to escape. The bladder is then filled with warm sterile water until the patient complains some of the pressure. The catheter is now either tied in a knot or plugged tightly so that the water can not escape through it, and a rubber band is placed around the penis so that the water can not escape through the urethra outside of the catheter.

The patient is placed on the operating table, and every detail is ready for doing the operation before the administration of gas is commenced. The surgeon and assistants are in their places. The instruments are ready, and every detail carefully attended to. The patient is put into the Trendelenburg position, while the surgeon is opening the abdomen through the prevesical space. One minute is sufficient to expose the bladder. Two stitches, to be used as tractors, are now placed through the wall of the bladder, parallel to each other, their ends left long and clamped with forceps. These are used to help manipulate the bladder during the work. The bladder wall is opened between these stitches for about two inches. The water is now pressed out of the bladder by depressing the abdominal wall. One minute of time is sufficient for all this. The catheter in the urethra is a guide to the neck of the bladder.

The surgeon now, with the point of the scissors or a knife, makes an incision either at the right or the left of the mouth of the urethra, extending through the wall of the bladder to the prostate, and long enough to admit one or two fingers. The fingers are now swept around the gland, as rapidly as possible, breaking up adhesions, and completing the enucleation. The whole hand will have to be introduced into the bladder. The bladder wall will stretch sufficiently to allow this with a two inch incision. This will require two or three minutes of time. From five to seven minutes, from the time the first incision in the abdominal wall is made until the prostate is enucleated, are necessary.

The pocket from which the prostate was removed, is now packed with gauze, one end of which protrudes through the abdominal incision. A drainage tube is placed in the bladder in the most dependent portion, one end extending out through the abdominal incision. The bladder wall is closed, as far as the drainage tube, with fine interrupted silk sutures, care being taken not to pass these sutures through the mucous membrane of the bladder. The abdominal wound is closed, as in a laparotomy, with drainage. The abdomen is dressed and the patient put to bed. The drainage tube is connected with a receptacle beside the bed by means of a long rubber tube. The packing in the bladder is removed in twenty-four hours. Large quantities of water should be given the patient. The patient should have a back rest the second day, and be out of bed on the fourth or fifth day.

4625 Greenwood Avenue.

The First Baby.

There ain't no use in talkin',
The crops are lookin' fine;
An' nary farm around us looks
As nice as that o' mine.

The wheat is holdin' up its head,
The hay is in the mow;
The pastur' lot is full o' grass
To feed the brindle cow—

That had twin calves las' April—
They're doin' mighty fine;
An' everything is boomin' on
That little farm o' mine.

An' as fer me, I'm happy—
You bet my heart is light,
Fer the doctor brought a baby
'Bout ten o'clock las' night.

—L. A. LONG, Editor The Argus Publishing Co., Hillsboro, Ore.

[Written for the MEDICAL BRIEF.]

Intestinal Surgery.

BY DRS. PENNEBAKER AND TRIPP,
Pleasant Hill, Ky.

At the present day of better diagnosis and competent surgery, under the heading emergencies, certainly are to be included operations upon the enteron.

Intestinal ulceration is a pathological condition that frequently can be recognized, and is at times as amenable to surgical treatment, when perforation or hemorrhage occurs, as is extra-uterine pregnancy.

A patient suffered for six months with agonizing pain and sickness, which was diagnosticated duodenal ulcer; the last attack proved fatal. At the *post-mortem* examination, the abdomen was found filled with fetid gas, and about two quarts of brown, turbid fluid, with yellow shreds abounding. Upon raising the transverse colon, a round perforation one-half inch in diameter was discovered in the duodenum.

In seven cases, ulcer of the duodenum was diagnosticated during life; four died as the result of perforation, and one from hemorrhage. Perforation is more common in ulcers of the duodenum than in ulcers of the stomach. Wm. H. Thompson says that an ulcer in the male would point to the duodenum, and in the female to the stomach.

The accumulation of free gas in the peritoneal cavity is given as an evidence of perforative peritonitis, but this symptom is occasionally absent.

Perforation of the typhoid ulcer can be recognized generally at the time of its occurrence.

A man who had been sick eight days, suddenly experienced agonizing abdominal pain, followed by a drop of temperature, which later rose; the abdomen became greatly distended. He was operated upon two and one-half hours from the onset of the pain. A small opening was found, eighteen inches from the cecum, which was closed, and the cavity irrigated with sterilized water, and the wound brought into apposition without drainage. The patient died in thirty-six hours from septic pneumonia, due to the inspiration of vomited matter.

Perforative peritonitis has been reported in an infant three days old, the opening in the gut being the size of a pea, and situated at the junction of the jejunum and ileum. The author described the cause of the ulceration as a strangulation of Meckel's diverticulum.

The duedonum has been perforated by a round worm, peritonitis and death following. The patient was a girl thirteen years old.

The clinical picture of traumatic rupture of the nutrient tube is graphically rendered by Dr. McMurtry, in his report of traumatic rupture of the duodenum, caused by a kick by a horse. The accident occurred directly after the man had eaten a full meal, he being seen fifteen minutes later. He was rolling in most intense agony, pain being referred to the umbilical region, and he presented a full array of the symptoms of shock. He was never free from pain, dying in nineteen hours. There was no abdominal swelling before death, and the bladder had expelled urine twice.

At the *post-mortem* section, a rent in the duodenum was found two inches from the pylorus, through which the fingers could be introduced. The meal he had eaten was in the abdominal cavity.

If evidence of rupture exists, immediate operation is indicated; if soon after the injury, twenty-four to thirty hours, there are signs of sepsis, operation is contra-indicated, and a low temperature with constitutional symptoms is unfavorable. Rupture of the enteron is indicated by absence of the line of dullness, frequent and uncontrollable vomiting, and the appearance of peritonitis if lesions of the kidneys, bladder and spleen are excluded.

In wounds of the stomach and intestines, the use of gas alone reduces the time required in seeking for a perforation at least seventy-five per cent, and with the addition of an antiseptic solution the time can be reduced ninety per cent.

Abdominal wounds in time of war, excluding those who die during the first twenty-four hours, tabulated under the form of penetrating wounds, are amenable to surgical treatment; about sixty per

cent recover. These cases are generally so injured that the area of the small intestine is not crossed; when this region is traversed, the mortality is very great.

Without an exploratory operation, we too often can not diagnose perforative wounds, and while laparotomy is not justifiable in every case of penetrating wound, it should be made upon the first evidence of this accident having occurred.

In the Spanish-American war, Senn reported that all patients who were operated upon died; during the Boer war in Africa, only two successful operations for wounds of the intestine have been reported. In the Philippines, Dr. Robinson reported five operated upon, and four died.

In traumatic cases of perforative peritonitis, it is proper to make a resection of the intestine, if necessary; in pathological cases the operation of resection will depend upon individual conditions, the treatment being analogous to gangrenous hernia in deciding if immediate closure of the bowel be done. The gangrenous intestine necessitates resection, and direct closure or an artificial anus. Bowel fistulæ generally heal, but it is dangerous to free old adhesions and unite old wounds.

There are cases that may have half of the bowel slough away and yet recover. Three feet of the intestine came away from a child per rectum, and the child lived. While such cases occur, surgical practice is not to be guided by them.

The surgeon should never leave the room until the hernia is reduced by natural means or by the assistance of the knife. No surgeon in the land should delay the relief of strangulated hernia after fecal vomiting has supervened. There has not been reported a case in which recovery occurred when fecal vomiting had lasted over twenty-four hours. Such cases call for a prompt diagnosis, the withholding of opium, and an exploratory operation.

The experiments of Curtis show that the distension of the strangulated loop is not due to gas, and the intestinal contents forced into the knuckle from the proximal side, but principally to disturbances of the circulation in the intestinal wall.

In hernia with gangrene, it is safer to first make an artificial anus, afterwards resecting and restoring the continuity of the gut.

Diaphragmatic hernia is of interest, owing to the mechanism of possible strangulation, and complications arising therefrom affecting the thoracic viscera. The elasticity of the orifices in the diaphragm permit the passage of organs of enormous disproportionate volume and size. Once a hernia is established, adhesions may unite the circumference of the ring to the organ, predisposing to incarceration. The strangulation of these hernia not only endangers intestinal obstruction, but exposes the patient to serious disorders of the thoracic organs, as compression of the lungs or heart, infection of the pericardium, pleura, etc. In Poucet's case, perforation of the colon determined the formation of a true fecal empyema.

The tissue surrounding the margin of a ventral hernia is never so firm or strong as normal tissue, and to secure firm union, it must be excised. Ventral hernia may occur in any case after laparotomy when the deep fascia is not held together until it unites firmly.

Atropia has been extolled in the treatment of incarcerated hernia, spontaneous reduction occurring; relief from pain follows almost immediately, and as well, improvement in the general condition.

Its mode of action probably varies, intestinal peristalsis being increased. The blood vessels involved in the incarceration are contracted, and the muscular structures surrounding the opening in the abdominal wall are made more lax. The use of this remedy should be substituted for taxus, but not where herniotomy is required.

In a girl of seventeen years, who was tuberculous, symptoms of intestinal obstruction appeared. For the relief of this, three and one-half feet of the ileum were resected. On examination of the excised bowel four distinct strictures were found. Indications of intestinal obstruction had existed from early childhood. All four strictures were the result of cicatrices formed in old tuberculous ulcers. Six days after the operation the patient's condition was satisfactory.

In fifteen resections of the cecum, only three were for tuberculosis. The differ-

ential diagnosis between tuberculosis and cancer in this region is difficult. In cancer, the tumor alone is felt, and the constriction of the intestine occurs quite rapidly. In tuberculosis, the whole cecum is thickened and infiltrated, and the condition is painless. The immediate results of resection are far better for tuberculosis than for cancer, but the ultimate results are extremely unfavorable.

A tumor is characteristic of malignant stenosis of the bowel, which is the exception in inflammatory stricture. Malignant new growths may be engrafted upon an inflammatory cicatrix. A cancerous tumor of the intestines quickly affects the liver by metastasis, and blocks the portal circulation as well as the vena cava, passing behind it. This causes ascites through exudation, and back pressure from the veins of the stomach and intestines, as well as from the vena cava inferior.

Primary sarcoma of the intestines is rare. Fourteen cases are reported by J. C. Warren, of Boston, Mass., and fifteen cases by C. Van Zwalenborg, of Riverside, Cal.

Dr. Arthur W. Booth, of Elmira, N. Y., gives the following review of a case: The duration of his patient's trouble was one year, dating from the first appearance of pain in the region of the tumor. The fever preceding death bore strong resemblance to typhoid, although there was no *post-mortem* evidence of infection of Peyer's patches, or a friable condition of the spleen. At the examination, held sixteen hours after death, the mass previously recognized proved to be a tumor of the small intestine, about four inches from the pylorus, located mostly in the left hypochondriac region. It was irregular in outline, and a single portion of the intestine could be seen entering and leaving the mass. On removal and section it appeared to be an overgrowth of the mucous and sub-mucous coats, with some involvement of the muscular layer, the peritoneum being intact. The lumen of the bowel was somewhat larger than normal on account of erosion, evidently retrograde, *i. e.*, due to necrosis and hemorrhage.

Upon microscopical examination, the growth was found to be a round celled sarcoma. A few enlarged mesenteric glands were discovered, the remaining abdominal viscera being normal. The man was a cemetery worker, where he was in the habit of drinking water from a shallow well, undoubtedly contaminated by surface drainage.

The duodenum had been opened by misadventure. One fatal case is reported from the continuous roll of fluid feces which could not be arrested. The patient had taken freely of purgatives before the operation.

After resection of the continuity of the enteron, approximation must secure means for producing accurate contact of surfaces; speedy and permanent adhesion of the opposed surfaces; the maintenance of a sufficiently large opening in the bowel for immediate requirements, and cicatrices that will not contract to an impervious degree.

In making the end to end union after resecting the bowel, we face a law of stenosis that is irrevocable, and beyond the control of the surgeon; hence, preference has been given to lateral anastomosis; end to end union gives better results than lateral approximation.

In closing the enteron, the Czerny-Lembert suture protects by its intimate apposition the underlying tissues from exposure and infection. Rindfleisch shows that with this suture there necessarily occurs a narrowing of the lumen of the enteron.

Halstead prefers the plain quilt suture to the Lembert. The vessels of the incised intestine are ligated by circumvection.

A solution of corrosive sublimate, one twenty-thousandth, or normal salt solution, used by means of irrigation, is most important when tying the stitches.

(To be continued.)

[Written for the MEDICAL BRIEF.]

Acetanilide.

BY J. A. BURNETT, M. D.,
Cecil, Ark.

In most acute diseases there is usually fever present, which must, in most instances, be controlled for the comfort of the patient, and the satisfaction of their friends. For this purpose there is no drug that equals acetanilide in being quick in action, and cheap in price.

It can be given alone, or in combination with other remedies.

When in need of a diaphoretic, in fevers, a combination of acetanilide, capsicum and quinine fills the bill. When prescribing acetanilide for patients who are very weak, it should always be combined with capsicum and quinine, and if the diaphoretic effect of this combination is not desired, an addition of belladonna should be added to it.

In malarial fevers it is a good plan to prescribe quinine as usual, and, thirty minutes before the chill is due, give five grains of acetanilide and two grains of capsicum. This will usually abort the chill.

During a malarial fever it is not necessary to wait until the fever is down before giving quinine. It can be given during the fever, if combined with twice the amount of acetanilide, or even equal parts can be used.

It is not generally known by physicians that acetanilide will prevent abortion. For this purpose it is given in ten-grain doses. Usually one dose is sufficient, but if not repeat in one hour. It is much better to use viburnum prunifolium for this condition, if at hand.

A small amount of acetanilide put in the hollow of an aching tooth will quickly relieve it. Guaiacol is superior to acetanilide for toothache, and should always be used in place of acetanilide, when on hand. A combination of acetanilide and salicylate of sodium applied to the tonsils will cure tonsillitis. The sodium salicylate alone is of great value in this condition.

Dr. M. E. Johnson says of a combination of acetanilide and salicylic acid, four of the former and one of the latter.

"When this combination is given, a typhoid case, there will be little or no bloating, no offensive stools, and the fever can be kept within a safe range.

"La grippe and this powder can not remain long in the same hide at the same time. All that is necessary is to give enough early in the disease. Reduce the fever, aching and discomfort of malaria with this before giving quinine.

"Sciatica can not stay where the system is saturated with this remedy, and will speedily get well; rheumatism likewise.

"These are only a very few of the places where you can use it to great advantage. Now, remember this is only a part of the treatment. In all cases such other treatment should be used as may be required. Always remember to keep the bowels going well and thoroughly, and the intestinal antiseptics are all right, and should most always be given. This combination does little or no good in passive congestion, or where the temperature is normal, and should not be thought of when a stimulant is demanded.

"In pneumonia I always reduce the fever and hold it down with my acetanilide and salicylic acid powder, and have never lost a case under this treatment in fourteen years. I have found out that it is hard for an inflammation to make much headway when I control the fever and keep it down."

A bottle of the combination of acetanlide, four parts, and salicylic acid, one part, should be in every physician's medicine case.

Acetanilide and salol works well together. Equal parts should be given in five to ten-grain doses as an antipyretic.

Coffee is a good antidote for acetanilide. This should be mentioned to patients when prescribing it, as it may prevent much harm, and save life.

[Written for the MEDICAL BRIEF.]

Castor Oil in Dysentery of Childhood.

BY J. H. KENNEDY, M. D.,
Aberdeen, Md.

It is usually administered in full dose, alone, or with calomel, in first stage of the disease. Later, and at intervals, it is a valuable remedy, alternated with the array of other remedies in use when pain, fever and bloody stools do not yield to the latter, given in ten to fifteen-drop doses, combined with a little liquid opium, and suspended in aromatic mucilage, every two or three hours, until the upper bowel is again cleared, and a fair field for the action of antiseptics and astringents, from bismuth to resorcin, provided. Keep the mixture at hand for alternate use.

[Written for the MEDICAL BRIEF.]

State Board of Medical Examiners.

BY D. S. MADDOX, M. D.,
Columbus, Ohio.

The institution known in this country as the "State Board of Medical Examiners" is a phase of paternalism transplanted from the old world, and has no proper place in a land where freedom and independence are presumed to be concrete facts, and not mere abstractions.

No good and sufficient reason has ever been given, for establishing a tribunal of this character in any State of the Union, yet we find them everywhere. It is an absolutely unnecessary piece of legislation, for it benefits neither the public nor the medical profession. A board of this kind is a medico-political fungus, an irritating excrescence on the body politic, arising from misrepresentation, chicanery, and lust of power on the part of irresponsible medical politicians.

These boards humiliate and insult the medical profession by arrogating to themselves the absolute guardianship of the moral and professional integrity of its members. They are narrow, arrogant, dictatorial, and are constantly importuning legislatures to grant them more authority, so that they can with impunity persecute and put on the rack anyone who dares contradict them, or in any way assert his independence of thought and action. They demand that the profession be placed under their complete subjection in order that punishment may be meted out to all who do not render instant and slavish obedience to their behests.

In this respect they resemble the Spanish Inquisition of the thirteenth century.

In many instances these boards presume to interpret the laws (a function belonging solely to the courts), thus exalting themselves into judges and lawgivers. In this way they usurp powers the legislature did not intend they should have, and so manufacture excuse for arbitrary rulings of every description. A board of this sort is tyrannous, because the entire profession of the State is placed at the mercy of a select few of their number, from whose mandate there is no adequate appeal.

In some States, at the mere whim or caprice of a board, a qualified physician may have his business broken up, and himself denied the right to earn his bread, and all this without an opportunity to have his case heard in a regularly established court of justice.

A few years ago, had anyone predicted that any class of citizens would be singled out in this democratic country of ours as proper subjects for oppression and vassalage, and their constitutional rights abridged in this summary manner, he would have been laughed at. Yet this extraordinary and humiliating spectacle now confronts the physicians of the United States. We have been told that these examining boards are for the purpose of protecting the people from incompetent doctors. But is there any record of the people ever having demanded that guardians be appointed for them in this matter? On the contrary, the people have always claimed the right to select their own medical attendants without regard to school, pathy, diploma, or anything else.

It is a moral right they possess, and they will continue to exercise it just as long as suffering and disease hold sway in this imperfect world of ours. If we do not soon get rid of our existing medical laws, the people will have to demand special laws to protect them against their self-constituted medico-political guardians.

How can a State board examination determine the fitness of a medical graduate to practice? A little reflection will show that it can do no such thing, that the whole performance is a howling farce. Is it not a fact that a doctor's skill can be measured and estimated only in actual practice, and in the presence of actual disease? How many of us have seen doctors that were veritable walking encyclopedias of medical lore, that when confronted by a medical or surgical emergency were absolutely bewildered and helpless? Who, in fact, seemed to have no sense at all?

I fancy we have all seen them. Yet these men are shining lights of science at a medical board examination, and go forth labeled as the only Simon pure.

What, then, is the inference? The inference is that the people alone must be the real judges of the doctor's worth and

ability. The ultimate judgment of the people in this, as in other matters, is unerring. They can always be trusted to distinguish the true from the false, the honest physician from the charlatan. It appears that the various State boards have, in order to more completely oppress the rank and file of the profession, formed a national association. About the first thing this association did was to declare by resolution that a diploma is not worth the parchment it is written on, except as a means of identification. Think of a man putting in three or four years' hard work, passing numerous examinations before the faculty, and expending large sums of money, only to be told in the end that the coveted diploma is merely a card of identification by which he may be recognized as Smith or Jones, when he wanders forth from his *alma mater*, or crosses a State line in search of a new location.

Webster says that a diploma is "A letter or writing, usually under seal, conferring some privilege, honor, or power." But your State board, sublimely indifferent to Webster, or any other authority, says it is no such thing, although it may bear the names of medical authorities and teachers of the highest eminence, and world-wide fame. When the applicant for license appears before the board, and presents his diploma, he is given the laugh and told that the document is no good. that before he can practice he must submit to an examination, paying the board a fee from $25 to $50 for their trouble. If he refuses to be "held up," and attempts to earn his living without the board's permission, he is arrested, like a common criminal, fined, and perhaps thrown into jail.

The attitude of these boards toward the diplomas of reputable medical colleges is so arbitrary, unjust and despotic that it ought to be vigorously resented by every graduate and every medical faculty in the land. A ruling of this kind would be an insult to even the feeble intelligence of a Hottentot. But when thousands of educated American citizens are asked to swallow it without question or protest, the dose becomes absolutely nauseous. The question naturally arises, what are we going to do about it? The problem is really not as difficult as it appears at first glance, for right will invariably prevail when its advocates become active in the cause. The majority of physicians in this country believe in medical freedom, *i. e.*, the right to think and act, and carry on their business as they see fit, without being dictated to, regulated or coerced by any board or tribunal established *pro hoc vice* by legislative enactment. Now, in order to correct the present evil, all that is necessary is that the liberal element get together and demand reasonable, impartial and just laws, in place of the bad ones now in force. Such a movement has already been started by "The American Medical Union," a national association embracing all schools of medicine. That the movement meets with general approval is shown by the rapidly increasing membership of this association, and the organizing of auxiliary State unions. Every liberal-minded physician who wants to see right and justice prevail ought to interest himself in this movement, and help along the good work by word and deed.

[Written for the MEDICAL BRIEF.]

Diphtheria.

BY JOHN MAYFIELD, M. D.,
Denison, Texas.

I see so much written about this disease (diphtheria), and physicians differ so much in regard to the nature and treatment of the disease—some still treating it as a local disease, confined to the throat. First cases I had treated as local, cauterizing, poulticing, etc., which treatment evidently seemed to aggravate the disease, consequently nearly all died. Those cases I met with in 1864, in Kentucky. The same year there was an epidemic of the disease in the vicinity of Lexington, Ky. Through the influence of Dr. Bush, of the same place, a number of physicians assembled there in convention for the purpose of coming to some understanding in regard to the nature and treatment of the disease, and to form a proper diagnosis of the same; and this was the conclusion, after due delibera-

tion: That diphtheria was a constitutional disease, affecting the entire system, and should be treated accordingly. Before giving treatment, I will give diagnosis. On examination of the throat, we find the tongue, uvula, tonsils and upper part of larynx covered with what is termed "little creamy excrescences," over tongue, uvula, tonsils, etc. Without treatment, as the disease progresses, these excrescences become still darker in color. In *post-mortem* cases, we find this same formation extending down the bronchial tubes. When these reach the lungs, death ensues. Temperature is rarely over 100° F., pulse ranges from one hundred and ten to one hundred and twenty, generally attended with difficult respiration, caused by enlarged uvula and tonsils; circulation not equalized, capillary circulation cut off to a great extent, rarely affects the glands. No other disease I ever met with presents the same conditions, consequently it is no trouble to form a proper diagnosis.

Treatment: Muriate iron and chlorate potash, given together, forms what is known as chlorine mixture. For a child five years old, a teaspoonful of solution, five drops ferri, every three hours. As no disease is so depressing on the system, it is recommended to use quinia and whisky from the beginning. In extreme cases, I have them stripped of clothing and given a good alkali bath and rubbing.

During the spring and fall of the year 1865, I treated ninety-five cases with this treatment and all recovered but two. In some of these cases the treatment was commenced in its earliest stage.

About this time, Dr. William A. Hammond, a surgeon in the U. S. army, located in New Mexico (soldiers in that wild country were often bitten by rattlesnakes), came to the conclusion that if it was a specific in diphtheria it would be good for the bite of the snake. After that no more soldiers died from the bite.

Readers of the MEDICAL BRIEF, I would like to hear from some one who has had some experience with placenta-previa, and in reporting your cases of pneumonia, say whether your case is single or double, what you find on auscultation and percussion, and if the expectoration is of the brick-dust variety.

[Written for the MEDICAL BRIEF.]

A Case of Extra-Uterine Pregnancy.

BY L. E. BARTON, M. D.,

Malta, Ill.

Was called to see Mrs. O., whom I found in a state of collapse, following an excruciating pain in the lower part of the abdomen. There appeared to be no reaction for twelve hours, and her temperature was slightly sub-normal several hours longer, after which temperature ranged from 103° to 104° F., for a period of three weeks. Abdomen very tympanitic. A vomiting of a grass-green material so continuous that it seemed all efforts to sustain vital power would fail. During this period patient's condition was so grave that several consultations were held concerning the nature of the illness. One consultant who was at that time budding into great notoriety, ascribed the green vomited material to a deranged condition of the digestive organs, and as a small creek was within sight of the house, that such digestive disturbance was caused from malaria.

Another consultation with an elderly practician, who had received much flattery from the laity as to his medical ability, very quickly, and with an air of one who knows what he is talking about, said, "You have a case of pelvic cellulitis."

Up to this time, fourteen days after the beginning of the illness, I felt that whatever the cause for such serious distress, it was obscure. In addition to a condition of the abdomen resembling peritonitis, we had an exudation of pus through the cervix which was continuous. The uterus was enlarged and tender. I was inclined to the opinion that we had a pus tube, and a general metritis.

After twenty-one days, temperature subsided, followed by a general condition of improvement. In eight weeks from first attack, she was again able to leave her bed. In eight weeks more, was recalled to find the same condition of pain and shock, and she ran the gauntlet of four weeks more of the same condition she had previously been subjected to, but now it was evident that she was pregnant. She again recovered sufficiently to leave her bed. At the eighth month the same

symptoms were renewed. I secured my choice of consultation. A careful examination into all conditions was made. The cervix, to an experienced finger, revealed nothing peculiar. The final decision was to terminate labor in the hope of saving mother and child. We found, upon exploration, an empty uterus, whose cavity extended nearly to the most superior portion of the mass, which contained a living, moving child.

No surgical interference would be permitted by the husband, and the writer was forced to remain at the bedside of a suffering mortal three long days, and witness the most awful death which has fallen to his lot in twenty years' practice.

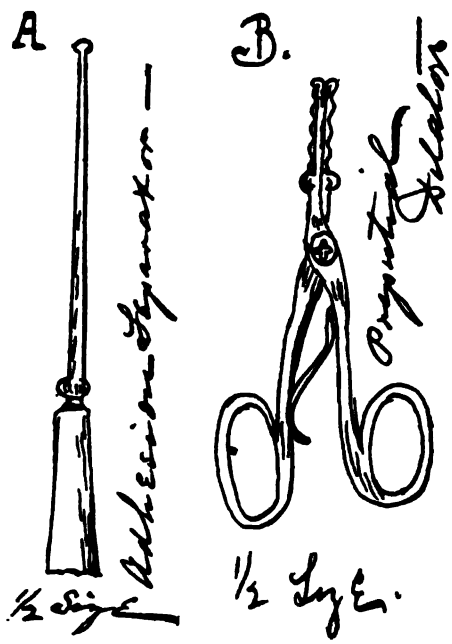
At least half a dozen doctors, some possessing more than ordinary ability, failed to make the right diagnosis. Would another case be so obscure?

[Written for the MEDICAL BRIEF.]

A Simple Method by Which Operation of Circumcision is reduced to a Minimum.

BY E. C. SCHOLER, PH. G., M. D.,
Chicago, Ill.

Within the past fifteen years I have had to resort to only two operations for circumcision. Over ninety per cent of cases where we have a constriction of the preputial orifice and membrane, or where adhesions exist, same can be remedied and corrected with very little difficulty, if promptly attended to directly after birth. The following method I have resorted to in every male birth requiring treatment with perfect success. The following day after delivery, after having attended to the mother, I ask the nurse to place the baby on a pillow on the table, and instruct her to hold the baby's limbs firm and apart while I examine the child's organ. If there are any adhesions, I take the small instrument (A) and pass same under the preputial membrane as far back as the corona glandis, then, with a rotary motion, I pass the instrument from side to side, loosening whatever adhesions there may be. Next, I insert instrument (B) and dilate the preputial membrane gently. Next day, upon my visit, I repeat the same treatment, and usually by the fifth day the dilatation is complete, so that any constriction or adhesions of the prepuce are entirely corrected and the membrane can be easily drawn backward, uncovering the glans. My next procedure is to remove all the smegma perputic, if any has accumulated, under the membrane back of the corona glandis, and after cleansing same I anoint thickly with a suitable ointment and draw the membrane forward again. By the time I make my last visit, the organ is in a normal and healthy con-



dition, with no probability of having to perform circumcision later. I also instruct the mother to draw the membrane back occasionally when bathing baby and keep parts thoroughly cleansed, anointing same and not forgetting to draw the membrane forward again after cleansing. Phimosis in children has produced conditions well worthy of serious consideration. Convulsions, epileptic seizures, chorea, paraplegia and serious reflex nervous disturbances have been known to come from a reflex irritation of a contracted and constricted prepuce.

How frequently do we find a child pulling and meddling with its organ, and, in fact, even becoming masturbators from no other cause than the itching and irri-

tation produced from the accumulation and impaction of smegma behind the corona glandis. Of late years I have kept account of all the abnormal cases I have been called on to attend and correct, and in one-fourth of the cases the mother had been attended by a physician. It seems to me inexcusable, where so slight an abnormal condition exists, that can be corrected so easily, the attending physician should fail to attend to same and relieve the little one of much needless suffering and inconvenience, for later the condition will have to be corrected, and then only by an operation. Then, again, if the doctor fails to mention the fact that the child's organ is not right, and in after years the child has to undergo an operation, the parents will be sure to censure the attending physician for his carelessness.

In quite a number of families, where I attended the mother in the last confinement and corrected those abnormal conditions, my attention was called by the mother to the other boy members of the family, and in various cases I found adhesions and constrictions. Some of the cases were even then corrected without operation, while in others there was no other remedy. Of late years I have found these abnormal conditions occurring much more frequently than when I first began the practice of medicine, and have often felt I would like to ask through a medical journal whether my colleagues have had like experiences in their family practice.

[Written for the MEDICAL BRIEF.]

Sex and Tide Cycle.

BY T. E. REED, M. D.,
Middletown, Ohio.

A knowledge of the principle of tide cycles can be so valuable in so many ways to the practitioners of medicine that I would like it agitated until, at least, some physicians become interested.

I am prompted at this time to stir up the subject by Silas Hubbard, M. D., again coming to the front with his sex theories, and *theories* they truly are. I will leave others to judge of them pro or con.

If some married couples should be desirous of procuring one or the other sex, let them adopt his methods and note results.

If a plan will not succeed, then of what account is it? How many test cases can he point to after over fifty years of observation?

The Doctor would like to bring in his theories to help explain the *law* I advocate for production of sex at will.

He says, "the perfection of the flow of the tide is in the day-time under the attraction of the sun." I must say that this is new to me, although I have made a study of tide cycles for years.

Now, it is a question as to what causes the tides. The theories advanced in our works on astronomy are *presumptious* and about as tangible as Dr. Hubbard's theories on the sex question. We do know, however, the effect of these cycles and that the moon is the time-keeper for the tides.

I have been surprisingly impressed with how little so many, otherwise intelligent, doctors know about the habits of the tides, to say nothing of their influence upon all life. Many seem to think that the tide *flows* in the day-time and *ebbs* in the night-time, or vice versa. I am afraid that Dr. Hubbard belongs to this class; his remarks, just quoted, would lead one to think so.

Any one acquainted with the tide cycles know that not one hour in the twenty-four has precedent over another when we consider the month through, or I may say two weeks, for the tides make two complete revolutions in one month's time.

For those desiring to investigate, I would advise to address O. H. Tittmann, Superintendent Department of Commerce and Labor, Washington, D. C., for *Tide Tables* for 1905. This is a large pamphlet (price fifteen cents) giving the time and height of high and low water at numerous points along the whole Atlantic coast, including Canada and the West Indies.

A little study of this pamphlet will enable any one to locate his latitude on the continent compared with some given station on the coast, and judge of incoming and outgoing tidal influence every day, whether on land or sea, which are not two days the same. until perhaps, like the

solar cycle, seven years are covered when they again traverse the same exact path as regards time.

When acquainted with these cycles you have but to observe that from a copulation, producing a result, occurring during the *flow* cycle a *male* child will result, but during the *ebb* cycle a *female* will appear in evidence.

I care not whether the time happens to be day or night, under the rays of a blazing sun or in the shade of a mellow moon, before or after sleep, preceding or succeeding the monthly flow, with ova new or ova old, ova high or ova low, if the woman initiate or acquiesce in proceedings, if she be mad or meek, cross or caressing, happy or hateful, spoony or spunky, voluptuous or virtuous, saint or sinner, active or passive, *the law of time cycles alone will decide the nature of the sex*, vague speculations and wild theories of some M. D.'s to the contrary notwithstanding.

Mistaken Ideas in August Medical Brief.

BY PATRICK T. MELDON.
An Experimental Medical Scientist.
San Bernardino, Cal.

Why do medical writers—in BRIEF articles—write so ardently on the pathology of a disease and cool down before prescribing for it? At least tell us what you think is best to do in the case. One might even suggest a treatment that might be good, if he has one to suggest; suggestions are often very helpful.

Silas Hubbard on the sex question: Is he of opinion that the sun controls the tides? Marine scientists note the tides according to the moon, and this science is founded on the science of astronomy.

A man of my acquaintance began with those fads in 1889; he knew everything about the sex question, got married and was going to raise all boys. He is today supporting five daughters.

Wm. H. Tate, M. D., on hydrophobia: The celebrated madstone of Virginia is seemingly not the only madstone in the world; a man from Missouri tells me that every other man in that State has a madstone. I swallowed that as one on Missouri, and concluded that any old stone is good enough when applied to wounds that have not absorbed the virus.

If you meet with a rabid dog—not a mad dog— in your experience, try this treatment on him; and follow it as judgment shall dictate in the case of a human being:

℞ Acetum ..... 20 drops.
Cupri Sulphas ..... 1-60 grain.
Aquæ ..... 1 drachm.
M. Sig.: Inject in the back of the neck.

Give the dog acidulated drinks and it will astonish you to see how he will enjoy them.

Henry L. Shively, on tuberculosis: Milk and raw eggs simply bloat a tuberculous patient; do not call that a cure! Six months, at most, is as long as any patient can take this treatment inordinately. Then a high fever, night sweats, headache and a violent, incontrollable diarrhea sets in, while the milk and raw eggs pass from the bowels, but slightly discolored and almost cooked. Such, in brief—on this subject—is what I have learned in six years steadily treating tuberculosis. But I shall still make the subject clearer for you.

(1). Milk will culture the bacillus of tuberculosis; (2) would you care to slowly swallow a glass of milk that had been exposed twenty-four hours in the room of a tubercular patient? (3) Would the milk seem especially inviting to you had the patient been drinking out of the glass? (4) Should you have a tubercular affection in your throat, would it seem possible for you to cauterize that affection with any quantity of milk?

If we are to be scientific, let us scientifically oppose this or any other disease as we understand it. Fat is a protective tenacious property of the bacilli. Milk, raw eggs and sugar gives them a source of fat, and with it they produce an unctuous tubercle mass to the extent of systemic poisoning. On this account tubercular patients have a preference for acidulated drinks and a repugnance for sweet ones. The mind, as it were, instinctively prefers that which is most likely to break up the tubercle mass and destroy the bacilli. Why, then, have we

so long imposed milk and raw eggs upon those patients?

Put your patient on a substantial, nutritious diet, and he will do best. Have him take several small doses of salt during the day; he can swallow the salt with considerable water, and increase on the quantity of both as he gets used to them. Give dilute phosphoric acid as a tonic and you will help him but not cure him. The cure of this disease, however, is almost at your hand, but for the time being, let me say: Milk and raw eggs in the treatment of tuberculosis was but a damnable theory at best. And I am sincerely hopeful that the medical profession shall never again recommend it.

[Written for the MEDICAL BRIEF.]

Expert Medical Witnesses.

BY A. M. STEEN, M. D.,

Palatka, Fla.

Testimony, as given in the courts, are of three kinds: One is a common witness, in the ordinary acceptation of the term, who testifies simply to matters of facts of which he has personal knowledge.

The learned witness imparts to the court information as to facts peculiar to his particular trade or profession.

The expert witness is a witness of opinion only. But concerning matters of facts, of which he has special professional expert knowledge, such as the ordinary witness can not from the nature of the case, be expected to have.

Every citizen may be called upon to testify to matters of fact of which he has personal knowledge.

The medical expert witness, however, is of a kind different from the ordinary witness. He is called upon by the prosecution or defense to give an opinion or testimony as to facts of which he has no personal knowledge, but concerning which he is specially qualified to express his opinion on account of his professional training. No law can compel a physician to make an examination of the contents of the stomach with a view to determining whether they contain a poison, if he refuses to do so.

The medical expert should remember that his answers to questions are taken down, recorded, and often printed, and the evidence you give this day may be re-investigated at a subsequent trial, and your opinion in this case brought before you in some other issue, so you should clearly understand each question put to you, and answer it deliberately and carefully, using plain, simple language, avoiding technical, medical and scientific terms wherever possible.

Of the many cases in which the introduction of expert testimony becomes necessary, cases of insanity are the most frequent, and the most important. A client is brought into court for murder or some other atrocious crime. His attorney enters the plea of insanity, in any of its one hundred and fifty forms. The facts of the crime may be correctly detailed by any one of sound mind; but the culprit's physical and consequent mental condition can not be so easily ascertained.

To the ordinary observer there may be no manifestation of the disease of the central nervous system. To him, preceding attacks of disease, a history of alcoholism, a history of syphilis, or a family history of nervous diseases in various forms, extending back several generations, may have no especial significance. Some one is needed who can put all facts of this man's life together, who can note his gait, test his reflexes and notice all other physical phenomena, and from these facts and phenomena determine if the accused is of sound and disposing mind, and whether he be responsible for his acts or not. Hence, the expert witness becomes a necessity. Upon his dictum depends, perhaps, the life of a human being, the desolation and disgrace of a home, or the administration of unerring justice.

Unfortunately, the average medical expert seen in our courts to-day is an out-and-out partisan and advocate, and is so regarded by the judge, jury, lawyers, spectators, newspapers and public alike. What is far worse, moreover, the general conviction is that the opinion of such an expert, though given under oath, is purchasable. The conviction is becoming daily more deeply seated in the com-

munity that the professional opinion of the medical man who appears as an expert runs with his fee.

Now, all this is entirely wrong. It does not help, but hinders, the administration of justice, and is injuring the reputation and high standing of our noble profession. This unfortunate condition has brought expert testimony to the condition where members of the legal profession have taken advantage and cast ridicule upon the expert.

Men who rank high ought to be able to agree in all essential points of a diagnosis, and they should speak the truth regardless of the circumstances surrounding their introduction into court. There are many and important medico-legal cases aside from those of insanity. They occur at unexpected times and in unexpected places. Therefore no physician should ever give expert testimony without previously and thoroughly investigating from every possible standpoint the question at issue.

To prosecute such investigation is a duty which he owes to himself, to the court and to the accused. When medical men learn to investigate in this manner, then medical expert testimony will regain the high standing and reputation it once enjoyed. While on the stand the expert will be questioned and cross-questioned by shrewd, brainy men, whose business it is to confuse him, to lead him from the truth, to cause him to make contradictory statements, to cause him to lose his temper and say injudicious things. He must remember that this is the business of the lawyer, and he has studied his art well. Physicians as a rule are not calculated to cope with such men.

The lawyer can read standard works on surgery or practice as well as any one, and with a few weeks' preparation, he is often as well or better informed upon the subject in hand than the man he examines. The witness, then, must know his subject well, that he may not subject himself to ridicule, that he may deliver a sound opinion, that the truth may not be made to appear false. The witness should never lose his temper. The moment he does, the examiner gains a point and the witness loses in the estimation of the court and jury. He should not make haste to answer questions, but should think well before he speaks. He should be very careful and not quote authorities, for there are many and contradictory authorities.

It must be remembered that the expert is called to give his opinion, and not to say who agrees or who disagrees with him. If a quotation from the works of a deceased authority is read to you in cross-examination, and if you are asked if you agree or disagree with the opinion expressed, never under any circumstances accept the quotation as expressing the opinion of the authority in question. Neither assent to, nor dissent from the quotation, until you have asked to be permitted to see the book from which the quotation is made.

If from lack of knowledge or other reason he is unable to answer any question he should frankly say so.

Some experts seem to think that to confess they have not read a paper or treatise of this or that author, or are unfamiliar with his views or opinions, is an admission of ignorance which is discrediting. Better far, however, make such admission frankly than to claim familiarity and have it demonstrated in the next few questions that the statement is unwarranted.

An experience that the author well knows happened to one of the brightest medical men of the community and which I have never forgotten—the embarassment of the doctor as he left the stand.

In the trial of a poisoning case, the Doctor was asked this question:

Counsel.—Doctor, are you familiar with the history of poisoning?

Doctor.—Oh, yes, perfectly familiar with the subject.

Counsel.—Doctor, please tell the court and jury when was the first law enacted specifically relating to the crime of poisoning?

Doctor.—Oh, I can't tell it to you now!

Counsel.—Doctor, tell the court at what period in the history of the world, that the idea of antagonizing the action of one poison by another, was first developed?

Doctor.—I can not answer such a question.

Counsel.— Doctor, did you not a few moments ago tell the court and jury that you were perfectly familiar with the history of poisons?

The Doctor left the witness stand very much embarrassed, and lost his reputation as an expert witness, and the public at large seemed to think that he was not as well informed in the medical profession as he was given credit for.

It is settled by law that an expert witness may testify as to his opinion, derived entirely from his reading, yet medical books and excerpts from them are not admissible in evidence, though they be recognized standard authorities. The reason for the exclusion of such medical books is that the opinions of the authors, therein stated, were not written under oath, nor had the defendant an opportunity to cross-examine the learned writers, nor to ascertain whether their views may not have undergone any change since their article was written. But for the purpose of contradicting and discrediting the witness, extracts from medical works which are in conflict with the views expressed by the witness in his examination in chief may be read to him, and the question put whether he subscribes to the same.

The counsel will not be permitted, under the guise of cross-examination, to read excerpts from medical works not in contradiction of the expert's evidence in chief for the purpose of sustaining the cross-examining counsel's theory of the case.

No one has any title to respect an expert, or has any right to give an opinion upon the stand, unless as his own opinion; and if he has not given the subject such careful and discriminating study as has resulted in the formation of a definite opinion, he has no business to give it. Such an opinion can only be safely formed or expressed by persons who have made the scientific questions involved matters of definite and intelligent study, and who have, by such application, made up their own minds. The jury are only concerned to know what the witness thinks, and what capacity and judgment he shows to make his opinion worthy of respect.

[Written for the MEDICAL BRIEF.]

Enteric, or Typhoid Fever.

BY A. J. HALL, M. D.,
McKenzie, Ala.

So much has been said of the fever of which I have made the subject of this paper, that I am free to admit that it looks a little egotistical on my part to say more, yet it has been said by so many, and good authorities, too, that "typhoid fever" can not be aborted or cut short. I am not here to assert the error, but I do say that if two cases are handled by two doctors, and one gets his case up sooner than the other, and it happens this way several times in succession, does it not strike you that the time has come when a little study or reflection as to the cause of this phenomenon is in order? Well, I would say yes.

In all schools so far as I know, the rule is to clean up, clear out as a starter. Some use one agency while another will use some different way to clean the bowels. My plan is to use powdered hyd. chloride mite, rhei and podophyllin with soda, in a sufficient dose, not doses, but a single dose sufficient to clean up from stem to stern, removing all debris that may have accumulated for a lifetime, invariably following, as may seem proper, with a saline purgative, or oil and turpentine.

The foundation of the life struggle is now laid. You are ready now to begin with your intestinal antiseptic. My standby is sulphide of calcium, used to saturation. Then, in more moderate doses during the entire spell, except in the event there is a bowel trouble sets up, in which case I use the sulpho-carbolate of zinc, which is the purifier and cleanser of the entire alimentary canal, and while I use cactus and strychnia for heart stimulation, and aconitine for fever, I am pretty well convinced that the sulpho-carbolates are a whole team themselves, and would cure in nearly every case entirely unaided by other medicine. If the kidneys need to be whipped up, suppose you use the bottle soda water, or the common bicarb. soda, in proper doses. Yet I desire to emphasize, I do not think much else but the calcium sulphate and zinc sulpho-carbolate is needed, for they seem to cure, to

weed every row, and leave no organ begging for help.

Watch your patient carefully and give no more medicine than is actually indicated by the symptoms, and your patients will rise and call you blessed.

It is well to have your nurse keep a record of the temperature, and hand it to you at each visit, but never allow a nurse to meddle with the thermometer except for your own edification, and not by any means for his or her amusement.

Nourish well with any liquid diet; any fruit juice, grapes, are great for typhoid cases. Malted milk and extracts of beef are also up-to-date. Do not fail to keep the bowels in good condition, and my word for it, you will have no complication, if the proper and above treatment is pushed to its needed limit.

Carbolic Acid a Scientific Magic. (Supplement.)

BY ROBERT GRAY, M. D.,
Pichucalco, Chiapas, Mexico.

My contribution in June, 1905, MEDICAL BRIEF, has resulted in such an incredible number of letters, still coming by every mail, that personal replies are physically impossible, hence this once-for-all supplement.

Chloral hydrate and camphor gum are triturated till liquefied, and then crystal acid is added, which quickly dissolves. Kept in well corked bottle. Equal parts of the three drugs are used. Put equal part this mixture with equal of sweet oil to secure catarrh compound, which may be made weaker or stronger, as desired, same as other medication.

In BRIEF article, I stated nearly seventeen parts pure acid was in compound—sixteen and two-thirds exact—which was clear to my mind that above-named part of sweet oil was thus indicated, to make such proportion of acid from thirty-three and one-third in first mixture, as any one may find with a pencil and pad in half a minute.

Absolutely pure dry crystal should be liquefied to use pure, as even five per cent reduced is painful.

This is the remedy *par excellence* for stings and bites of most venomous scorpions and reptiles, applied freely to lesions, with dosage to the limit of diluted spirits of ammonia.

Regret inability to answer letters. Am in pneumonia epidemic; amply taxed with trying labor.

Veratrum Viride, Drug Addiction and a Few Jottings on Typhoid Fever.

BY W. S. ROBINSON, M. D.,
Nashville, Ark.

Where there is a high arterial tension, uncomfortable throbbing sensation in the head, fullness, heaviness, roaring, wavy pulsation in the ears, flushed face, or, in other words, a partial sun-stroke, "overheated," there is nothing better than veratrum viride. It is no sleep-producing medicine, neither does it relieve pain, but it does produce a soothing or sedative effect, not like other preparations that are given to soothe or quiet by its sedative action. The longer it is given the less of the drug will be required to influence the patient. It has no bad after-effects..

With high temperature and full pulse, or any condition in which the patient is disturbed by a feeling of discomfort, due to exaggerated action of the heart, veratrum viride will improve the condition. Children threatened with spasms, veratrum will produce calmness and quietude, prevent convulsions until the fever can be subdued. You will never have convulsions, when your patient is well under the influence of varatrum.

Now, the danger of veratrum has been greatly over-estimated, as there are no deaths reported from its use. When indicated, give until you obtain its constitutional and controlling effects, and this can be done without any danger.

DRUG ADDICTION.

I find, from seven years' experience in the treatment of drug addiction, that the main thing is to eliminate all the effete material with which these patients are surcharged. Then a little common sense, and hyoscine hydrobromate, in very small

doses, as indications require, will put your patient on his feet, so that he can eat and sleep, and will be himself again. I have used hyoscine in something over two hundred cases (most of them physicians) without a single failure to cure satisfactorily.

TYPHOID FEVER.

It must be said that, as yet, unfortunately, no actual specific or antidote has been discovered for typhoid fever. Much might be hoped from the use of certain insoluble intestinal antiseptics, such as salol and the various remedies suggested for their antiseptic effects.

I am partial to the use of sulpho-carbolates of zinc and calcium in the treatment of this fever.

It is my opinion that the antiseptic effects of the sulpho-carbolates are manifested in any other febrile affection, general or local, specific or simple, quite as markedly as they are in typhoid fever.

I give small doses of calomel in the beginning of typhoid fever, especially if there is a dry tongue, to excite the flow of bile, and thus disinfect the bowels by Nature's antiseptic. But it is bad practice to stimulate the organs to action when Nature has shown their need of rest by reducing their work to a minimum during fever.

Poisoning by Kerosene or Petroleum.

BY T. A. JONES, M. D.,

Selfs, Texas.

As I have never seen any account of such a case (and Hare's Therapeutics states petroleum is not poisonous) I will give a case I have just had (May 23, 1905). I was called by 'phone to a near town to see a child two years old who had swallowed eight ounces of coal oil. I ordered by phone an emetic of syr. scillæ, which was given, and vomited the child well. When I got there I found the child in a coma, pupil size of pin head, respirations about sixty, pulse about one hundred and forty; muscles as flabby as a rag, no use of them at all; in state of paresis; bowels distended with gas.

I ordered black coffee, tr. digitalis, castor oil per mouth, and enema of water, glycerine and epsom salts every two hours.

Next day I found conditions same; temperature 104° F. I gave antifebrine one-half grain, calomel one-half grain and podophyllin one-twelfth grain and one-half ounce castor oil every two hours; also, quinine, to be given when fever abated, and ordered hot fomentation to bowels and continued large enemas of epsom salts every two hours.

Third day temperature 100° F., pulse about one hundred, respiration about normal, pupil still contracted, but would respond; not so much coma and could use its limbs; bowels had acted, only two small actions after using enema every two hours, as stated, and taking in twenty-four hours four ounces of castor oil.

I discontinued all the rest of the treatment and made a saturated solution of epsom salts and ordered a teaspoonful to be given every hour for the next twenty-four hours, which caused good actions from bowels, and at my fourth visit, it being the fifth day from the time the child drank the oil, all signs of poison was gone, and I dismissed the case.

I write this as I have not been able to see anything in any of my journals, or medical works, about coal oil being poison. If any of the brother physicians have had any experience in such cases I would like to hear from them.

The Drug Addict.

BY E. FORREST HAYDEN, M. D.,

Shaw, Miss.

There is probably no subject confronting the medical profession to-day freighted with more vital importance than the one of drug addictions, nor is there one upon which there is a greater diversity of opinion in reference to its management and treatment. A great many have offered suggestions, and few have made valuable contributions along this line and toward the permanent and humane relief of these unfortunate sufferers; but yet a great deal remains to be learned of the extreme

gravity of this class of diseases, and of the inevitable debauch and certain physical, mental and moral destruction of these patients, if uncharitably abandoned to their fate.

To-day we feel that we have a method of treatment by which we know that they can be speedily and absolutely restored to original health; we accomplish this, first, by a thorough elimination of all accumulated poisons caused by locked-up secretions and, second, by the use of a drug that places the patient in an anesthetic condition until he or she passes from death unto life almost without the consciousness of pain—vis hyoscine hydrobromate.

[Written for the MEDICAL BRIEF.]

Acute Cholera Infantum.

BY J. I. ALLISON, M. D.,

Bloomington, Tenn.

Age ten to twenty-four months, clean up and clean out patient daily with chloride of sodium baths and enemas, both tepid. Abstain totally from food first twenty-four hours. For vomiting and irritation of stomach and intestinal canal:

℞ Specific Aconite..... 2 drops.
Specific Ipecac..... 5 drops.
Epsom Salts.....10 grains.
Aqua Mint..... 4 ounces.

M. Sig.: Teaspoonful every hour.

℞ Specific Rus-Tox..... 3 drops.
Aqua Mint..... 4 ounces.

M. Sig.: Teaspoonful every hour; alternate with the above.

For diarrhea, pack the entire intestinal canal with three to five-grain doses carboveg. every hour to two hours. Malted milk every four hours.

Physician should be boss of cabin, and master of situation.

Gall-Stones.

BY M. S. DENAUT, M. D.,

Walkerton, Ind.

A woman, aged forty-nine, mother of three children, passed menopause at forty-three years of age. Gave history of periodical attacks of severe pain in right hypochondriac region, jaundiced and clay-colored stools. Could outline a tumor distinctly nodulated. Diagnosis, gall stones. I recommended immediate surgical interference, which she most emphatically refused, but insisted on taking medicine. I prescribed sangcura sprudel salts and sodii salicylas, five grains, three times daily, and other symptomatic treatment, for a period of twelve days, when she gave birth to a gall stone the size of a hickory nut, which was followed during the succeeding ten days by three others of about equal size, each marked by distinct facets, corresponding to the other. This was nearly three years ago, and the patient has manifested no symptoms which would indicate a recurrence of the malady. Adhesions, no doubt, formed between the gall bladder and transverse colon, irritation by the foreign substance caused sloughing, opening up a gateway into the colon and expelled.

A Twenty-Pound Baby.

BY J. H. HUNTER, M. D.,

Ochlochnee, Ga.

A few weeks ago I was called to see a Mrs. J., age twenty-four, white, health good, third child; was called at 3 A. M., four miles in the country. She had been in labor for two days and one night. On arriving at the house I found an arm presentation, the child was flexed posteriorly, with head and feet at the fundus. Under complete anesthesia I tried version, but failed; next I tried to take it piecemeal, but failed. The mother having lost so much blood (depending on a woman midwife) that she was almost bloodless when I first saw her. I then proceeded to take the child through the right abdominal right side. When extracted it weighed twenty pounds. The mother died in one hour afterward. Have any of the BRIEF readers ever delivered one any larger.

Much success to the BRIEF. I always welcome its coming.

I do want the BRIEF. I have not missed a number so far. I do like the BRIEF. Enclosed find one dollar postal order for same.—JNO. T. DAVIS, M. D., Zanesville, O.

[Written for the MEDICAL BRIEF.]

A Good Bracer—Sick Headache.

BY V. E. BOWEN, M. D.,
Farmington Hill, Pa.

To help a "boozer" straighten up, there is nothing better to my knowledge than the following:

℞ Specific Tr. Nux Vomica.....20 drops.
Specific Tr. Capsicum.....20 drops.
Water..... 4 ounces.
M. Sig.: Give a teaspoonful every hour; if indicated, oftener.

This helps to overcome the desire for liquor, restores the appetite for food. I have yet to learn of a single failure. When properly given, I am confident that there is no better bracer known to medical science.

Sick Headache.—Doctor, how often you meet a patient with a headache, and having a broad tongue, pale, and covered with a yellowish white coat. Give all such patients three to five grains of sulphite of soda, two to four times a day, and you will be more than pleased with the result.

[Written for the MEDICAL BRIEF.]

Answers to Contributors.

BY DR. R. D. ENGLAND, PHARMACIST,
Colt, Ark.

I notice in a recent issue of the BRIEF two articles on pneumonia, the first, "Pneumonia Not Necessarily Fatal," by E. V. Pennington, M. D., Mohawk, Tenn. To this article I wish to say, amen. Let us have more common practical sense and less theories; that is why I like the BRIEF. If I want some practical ideas I know where to look for them, in the BRIEF.

The second article, "Is Drug Treatment Useless in Pneumonia?" by G. W. N. Elders, M. D., Hematite, Mo.

I concur in the statement that it does, but not to the extent that some may claim. I have not practiced medicine as long as Dr. Elders, but I follow a different treatment in part. I have never been able to see any good from a blister. Neither is there any theory that can be successfully advanced in its favor. I would rather have one sore to heal than two.

Do you not know when you cause a sore on the surface you open an avenue to septic infection and the only way to heal it is through the blood circulation? So you double the effort of the healing process by the blood circulation. Just stop and think rationally for a moment. Is pneumonia not a collection of serum in the lungs? And if so does it not cause inflammation? If inflammation-heat, so what now? Apply the water-bag with ice water certainly. Use your medicines as suggested and use cold applications instead of blisters and you will reduce your mortality from ten per cent to one or two, as is my record. I am tired of so much theory and so little practical sense. I may be too independent in my course of practice, but I get the results, and as Dr. Elders says, a large share of this practice because of my success in this disease.

Out of one hundred and twenty-five cases during this season I have lost two, one having heart trouble before taking pneumonia, so died with heart failure. My patients get well in from three to seven days.

The article written by Abraham Goltman, M. D., entitled, "The Outlook for the Beginning Practitioner," that appeared in the February BRIEF, is another article to which I wish to call attention. He says: "In order to reduce the overflow of doctors being turned out by the colleges that the course should be raised to five years and the fees so raised that persons with only moderate means could not attend medical colleges." Is this in keeping with the better interest of our country? Is this not a stride (a long one, too) in the direction of monopoly? It is worse—it is creating a money standard, instead of efficiency.

This reminds me of the drummer and railroad agent. Drummer (slapping himself on the stomach): "You ought to be a man like me?" Agent (very small): "Yes, but my brain is not in my belly." Brain is not in money. I hope before such remedy, as suggested by Dr. Goltman, is adopted, that Gabriel will place one foot on the land and the other on the sea, and declare time shall be no more.

[Written for the MEDICAL BRIEF.]

Treatment of Typhoid Fever.

BY E. HOLLAND, M. D.,
Berlin, Md.

Two other remedies vie with baptisia, namely, bryonia and gelsemium. Either one if given according to its specific indications. will either abort or modify the case.

Specific indications:

Bryonia—White coated tongue, constipation, great thirst, dread of malaise, aching in head, back and limbs.

Gelsemium—Muscular and nervous prostration, with general trembling.

Baptisia—Stupid, besotted, drunken expression, brown streak down middle of tongue.

I have repeatedly tried the sulpho-carbolates, but find if the proper remedy is selected in the beginning we have no ulceration.

[Written for the MEDICAL BRIEF.]

Internal Piles.

BY J. L. FENNEL, M. D.,
Waterloo, S. C.

I have found the following formula exceedingly beneficial in internal itching piles:

℞ Ext. Belladonna .....1 drachm.
Pulv. Opium ..... ½ drachm.
Tannic Acid..... ½ drachm.
Ichthyol .....1 drachm.
Vaseline.....q. s. ad.....2 ounces.
M. Sig.: Apply locally morning and night.

[Written for the MEDICAL BRIEF.]

Examination Questions of the University of the State of New York.

Answer any ten of the questions under each heading, but no more. Check the number (✓) of each one of the questions you have answered.

ANATOMY.

TUESDAY—9:15 A. M. TO 12:15 P. M.

1. Give the surgical anatomy of the humerus.
2. What is the cerebellum and where is it situated? What is the size of the cerebellum as compared with that of the cerebrum?
3. Describe the structure of the pericardium and give its blood and nerve supply.
4. Name the salivary glands and their respective ducts.
5. What veins form the portal vein? Where is the portal vein situated?
6. How is the superficial palmar arch formed?
7. Describe the musculospiral nerve.
8. Describe the pleura and its reflections.
9. Wherein does the female perineum differ from the male perineum?
10. Give the origin, insertion, blood and nerve supply of *one* of the following muscles: Quadriceps extensor cruris, pronator radii teres, occipitofrontalis, gluteus maximus.
11. Bound the axillary space and mention its contents.
12. What changes take place in the vascular system at birth?
13. State the differences between the right bronchus and the left bronchus.
14. Give the gross anatomy of the eye.
15. Describe the pancreas.

PHYSIOLOGY AND HYGIENE.

TUESDAY—1:15 TO 4:15 P. M.

1. Describe a protoplasmic cell and its production. By what physical properties is living matter distinguished from dead matter?
2. Give the metabolism of (*a*) proteids, (*b*) carbohydrates, (*c*) fats.
3. Define hygiene, prophylaxis, contagion, infection, zymotic, ptomain, toxin, phagocytosis.
4. State the influence of the blood circulation on the secretion of urine. Explain the effect of division of the renal nerves on the secretion of urine.
5. Describe the functions of the stomach during the process of digestion.
6. How is the action of the heart affected by variations in the rate and force of respiration?
7. What are the functions of the sympathetic nervous system?
8. Give the normal temperature of the body. State how this temperature is maintained and under what conditions it is increased. What is the cause of the *post-mortem* rise of temperature sometimes observed?
9. Describe the physiology of vision with special reference to (*a*) the retina, (*b*) the iris, (*c*) the crystalline lens.
10. Describe the chemical interchange between blood and air during respiration and mention the forces concerned in this interchange.
11. Mention some of the common impurities of drinking water and state how such impurities may be removed. What constitutes (*a*) hard water. (*b*) soft water?
12. Mention the dangers of excessive shade about dwellings.
13. Describe in detail a proper system of plumbing for a dwelling house and point out the characteristics of faulty plumbing.
14. State the relative food value of raw and sterilized milk.
15. How are diphtheritic antitoxins prepared? On what theory are antitoxins applied?

CHEMISTRY.

WEDNESDAY—9:15 A. M. TO 12:15 P. M.

1. Define isomorphous, amorphous, crystalline, galvanic, polarization.
2. Explain the uses of the spectroscope in chemical analysis.
3. State the normal reaction of urine. How is the reaction determined and to what is it due?
4. Mention *five* elementary substances commonly used in medicine in a pure or uncombined state.
5. Describe a method of producing an electric current by chemical action.
6. Give the symbol, valence, occurrence in nature, physical properties and chemical properties of *one* of the following: Bromin, silicon, copper, antimony, manganese.
7. How is carbolic acid prepared? Give the treatment of carbolic acid poisoning.
8. Distinguish between alcoholic fermentation and putrefaction.
9. Give the properties of potassium. Mention five compounds of potassium important in medical practice.
10. What is the chemical name of tartar emetic? Describe tartar emetic as to properties and uses.
11. Mention a secretion of the body that contains (*a*) cholesterin, (*b*) pepsin, (*c*) trypsin, (d) casein, (e) bilirubin.
12. What reaction takes place when chloral hydrate is mixed with an alkali? Illustrate.
13. Give the chemical reaction of (*a*) saliva, (*b*) gastric juice, (*c*) tears, (*d*) bile, (*e*) blood.
14. Mention the most important acetates and give a method of preparing *one* of them.
15. Complete the following equations:

$$BaS+CO_3+H_2O=$$
$$3Cu+8HNO_3=$$

SURGERY.

WEDNESDAY—1:15 TO 4:15 P. M.

1. Classify wounds and give the treatment of *one* variety.
2. Describe teratomata and give their situations.
3. Describe in detail an amputation in the lower third of the thigh.
4. Give (*a*) the predisposing causes of fracture, (*b*) the immediate or determining causes of fracture.
5. Mention the accidents that are liable to occur during the reduction of a dislocation.
6. Give the symptoms and treatment of acute synovitis.
7. Give the causes, symptoms and treatment of stricture of the esophagus.
8. State the special danger of a wound of the femoral vein. Give the treatment of a wound of the femoral vein.
9. Give the differential diagnosis of hypertrophy of the prostate and abscess of the prostate.
10. What are the various forms of abdominal hernia? Describe congenital hernia.
11. Differentiate anal fistula, anal fissure, hemorrhoids and carcinoma of the rectum.
12. Mention in order of frequency of occurrence *four* of the most common pathologic conditions of the cervix uteri.
13. Give the causes, symptoms and treatment of mastoiditis.
14. What is torticollis? Give the causes, symptoms and treatment of spasmodic torticollis.
15. Describe rodent ulcer. Give treatment.

OBSTETRICS.

THURSDAY—9:15 A. M. TO 12:15 P. M.

1. Mention the external and the internal female organs of generation and describe the functions of the more important ones in each group.
2. Define menstruation, describe its function and state its relation to ovulation.
3. State the possible results of gonorrheal infection in the pregnant woman.
4. Mention and describe the principal subjective symptoms of pregnancy.
5. What changes in the uterus does pregnancy effect?
6. What is hyperemesis? Give the symptoms, course and treatment of hyperemesis of pregnancy.
7. State the causes of inertia uteri and give the management of this condition.
8. Describe the management of the perineum during dilatation and during delivery of the head.
9. Mention the indications for manual extraction of the placenta. Give technic of this procedure.
10. Describe the symptoms and give the treatment of asphyxia neonatorum.
11. What chief uterine displacements may affect early pregnancy and how are they treated?
12. What is salpingitis? Give the causes, symptoms and treatment of salpingitis.
13. Define vaginismus and give its causes, symptoms and treatment.
14. What are the causes and symptoms of endometritis? Give treatment.
15. Differentiate prolapsus of the uterus and inversion of the uterus. Give the treatment of each condition.

PATHOLOGY AND DIAGNOSIS.

THURSDAY—1:15 TO 4:15 P. M.

1. What is traumatic infection? How does it take place and how may it be avoided?
2. What pathologic conditions increase vocal fremitus?
3. Define thrombus, embolus, infarct.
4. Mention *five* kinds of bacteria known to be pathogenic in man, and name the disease or diseases with which each kind mentioned is associated.
5. Describe the pathologic lesions in typhoid fever.
6. Give the pathology and the clinical history of locomotor ataxia.

7. What is the Widal reaction? Give the technic of an examination showing this reaction.

8. What adventitious sounds may be heard in auscultation of the heart?

9. In a typical case of diabetes mellitus what is the condition of the urine as to (*a*) specific gravity, (*b*) color, (*c*) odor, (*d*) quantity voided, (*e*) constituents?

10. What diseases may cause occlusion of the common bile duct?

11. Give the periods of incubation, of invasion and of eruption of the acute exanthematous diseases.

12. Describe the value of the microscope as an aid to diagnosis in (*a*) suspected diphtheria, (*b*) suspected gonorrhea, (*c*) suspected tuberculosis, (*d*) suspected nephritis, (*e*) suspected leprosy.

13. What is understood by immunity from disease? Illustrate.

14. Give some of the causes of vomiting. What characteristics of vomited matter may be useful in making a diagnosis?

15. Differentiate abscess of the liver and cancer of the liver.

THERAPEUTICS, PRACTICE AND MATERIA MEDICA.

FRIDAY—9:15 A. M. TO 12:15 P. M.

" * * * in therapeutics, practice and materia medica all the questions submitted to any candidate shall be chosen from those prepared by the board selected by that candidate, and shall be in harmony with the tenets of that school as determined by its State board of medical examiners."

Laws of 1893, ch. 661, § 146.

Questions prepared by the board of examiners representing the Medical Society of the State of New York.

1. Give the therapeutic uses of eucalyptus and mention its preparations.

2. Give the causes of hemoptysis.

3. Of what is lupulin an alkaloid? State the doses of the preparations of lupulin.

4. State the uses of ergot other than its use in obstetrics.

5. Define catalepsy and give its etiology and prognosis.

6. What part of senna is used in medicine? State the physiologic action of senna.

7. Describe the therapeutics of sulfonal. State the dose of sulfonal.

8. Give the symptomatology of scarlet fever.

9. Mention *three* alkaloids of opium and state the dose of each.

10. Describe the therapeutics of oxygen.

11. Define Hodgkin's disease and outline its treatment.

12. Mention the official preparations of ammonia. State the effect of ammonia on the heart.

13. Give the therapeutic uses of naphthalin.

14. Outline the treatment of pernicious anemia. Give the prognosis of pernicious anemia.

15. State the action of medicinal doses of camphor on (*a*) the skin, (*b*) the circulation.

THERAPEUTICS, PRACTICE AND MATERIA MEDICA.

FRIDAY—9:15 A. M. TO 12:15 P. M.

Questions prepared by the board of examiners representing the Homeopathic Medical Society of the State of New York.

1. Differentiate arnica and hepar sulfuris in boils.

2. Give the symptoms of baptisia in typhoid fever.

3. State the therapeutic uses of asafetida.

4. Differentiate the coughs of rumex crispus and bryonia.

5. Describe the headache of sanguinaria canadensis.

6. Describe the headache of lilium tigrinum.

7. Describe the eye symptoms of bryonia.

8. Give the indications for sabina in metrorrhagia.

9. Describe herpes zoster and give treatment.

10. Differentiate lachesis and lycopodium in diphtheritis.

11. What condition in scarlet fever calls for arum triphyllum?

12. Give the indications for *three* remedies curative in orchitis.

13. Give the symptoms and treatment of gall-stone colic.

14. Differentiate measles and small-pox.

15. Describe the diarrhea of croton tiglium.

THERAPEUTICS, PRACTICE AND MATERIA MEDICA.

FRIDAY—9:15 A. M. TO 12:15 P. M.

Questions prepared by the board of examiners representing the Eclectic Medical Society of the State of New York.

1. Give the specific indications for the use of aconite. State the dose of the tincture and of the extract of aconite.

2. Describe the treatment of pneumonitis.

3. Give the treatment of typhoid fever.

4. Mention the preparations of opium.

5. When is belladonna specifically indicated?

6. Give the causes and treatment of jaundice.

7. Give the cause, symptoms and treatment of diphtheritis.

8. Give the treatment of a case of erysipelas.

9. Give the specific treatment of syphilis in the first stage.

10. Give the indications for the use of muriate of ammonia. State the dose of muriate of ammonia.

11. When should crataegus oxyacantha be used? State the dose of the fluid extract of crataegus oxyacantha.

12. Give the symptoms and treatment of urticaria.

13. What are the preparations and uses of serpentaria?

14. Give the medicinal treatment of a case of hemorrhoids.

15. Give the treatment of a case of hysteria.

Max Meyer M.D.

Professor of Chemistry and Toxicology; Lecturer on Histology, Pathology and Bacteriology in the Eclectic Medical College of the City of New York; Ex-Officer of the Health Department of New York City; Physician Macy Mutual Aid, etc. City of New York.

Henry Marion Silver, M.D.

Professor of Clinical Surgery in the New York University and Bellevue Hospital Medical College; Consulting Surgeon to the New York Infirmary for Women and Children; Visiting Surgeon to the Gouverneur and Beth-Israel Hospitals; Fellow of the American Medical Association; Fellow of the Academy of Medicine, etc. New York City.

Editorial.

Asclepias.

Doctor, did you ever try asclepias tuberosa in those conditions where the skin is dry and hot, the secretions all stopped? If not, the next case of this kind which you have, give fifteen to twenty drops of the tincture, or a decoction of the root in tablespoonful doses. You will be astonished, amazed and wonderfully pleased at the results. Asclepias is a perfectly harmless remedy, indicated in all cases where the skin is out of order. It is compatible with any and everything.

There are a great many plants and remedies on the market having equal virtues in their respective spheres, but the doctor and his patient can not get the benefit of them because the doctor has never tried them. That is why we do not make progress in therapeutics faster than we do. The doctor sticks to routine medication. If his patient is helped, well and good; if not, the doctor has done all he knows. No science can ever be built up by any such haphazard method as this. The doctor ought to know about the various remedies. He ought to make his knowledge more and more precise until he can assign each remedy to its exact place in the treatment of disease. He should use it in that place and in no other. We know doctors who use one remedy for nearly everything. Sometimes they get results and sometimes not. There is no accuracy or scientific certitude in such work as this.

Try asclepias, doctor, and your success may pull you out of the old rut by putting you in the humor to try other preparations. The Editor uses Lloyd's asclepias. Some one else may make some just as good, but we don't know it. It pays to stick to what we know is good, and not worry over whether it benefits Lloyd or not.

Vitality.

We read a good deal about vitality. What is vitality? What do we mean by it? Who can answer this? One man tells you that a certain microbe is dan-

gerous. Another man says that that particular microbe has a special mission to perform, and that it is not dangerous to one who has sufficient vitality to offer normal resistance. One man says of another that his vitality is so great as to postpone the inroads of old age indefinitely, other things being equal. Again, we read somewhere of a child who has so little vitality that it is impossible it should live to any great age. A certain man's recovery against enormous odds is ascribed to his vitality. Another succumbs to a most trifling ailment. One man can abuse his powers, indulging freely in food and drink and other habits which we have been taught to look upon as injurious, seemingly with impunity, when in another the slight infraction of the known laws of health is followed by severe suffering. All due to a difference in this mysterious something called vitality.

Now what do these people mean by vitality? What do you mean? It is like asking the question, what is life? It is probably the most interesting and hardest to answer of the thousand and one questions which are constantly staring the doctor in the face.

One man says cultivate your vitality and your system will resist the tuberculous microbe. Now, what we want to know is, what is this vitality which we are to cultivate? We want somebody who has thought about this matter to some purpose to suggest something. Let us all give our views and see what we can make out of it.

"Surgery, Gynecology and Obstetrics."

The above is the title of a new journal just issued. Dr. Franklin H. Martin, of Chicago, is the managing editor, with Allen B. Kanavel, M. D., as associate editor. They will have the valuable services of Drs. Senn, Murphy, Andrews, Beasley, Webster, Dudley, Hollister, Holmes, Bacon, Bachelle, and Cubbins. The first issue was July 1st, and along these special lines we can only predict success to such a journal. This journal has our hearty approval, and we hope our friends will not overlook the fact that it is published monthly, at Chicago, at $5.00 per year.

[Written for the MEDICAL BRIEF.]

Treatment of Chronic Bronchitis in the Aged.

BY H. J. CUMMINGS, M. D., C. M., M. R. C. S. (ENG.), L. R. C. P. (LOND.),
Professor of Diseases of the Chest and Clinical Medicine in the Barnes' Medical College.
St. Louis, Mo.

This common complaint which is, perhaps, the cause of more deaths in temperate climates than all others put together, often taxes the ingenuity of the physician to the utmost. If more care were taken to complete the cure of acute attacks in middle life this dread disease of old age would be greatly minimized. It is only in the early attacks that there is any possibility of a cure if the patient remains in a changeable climate.

In cases which have existed for some time, the only possibility of a cure is in removal to a warm, dry climate during the winter months, such as Florida, California or Arizona. Unfortunately most of the patients are unable to change their abode during the winter months, and are compelled to undergo the increasing discomfort as years go on.

Treatment.—If treated at home, our first attention should be to the general health, especially to the digestive organs, Any diet that produces flatulence greatly increases the patient's discomfort, and any tendency to constipation should be carefully looked after. Warm clothing, the avoidance of draughts, etc., are of the utmost importance, as well as the avoidance of breathing cold air on going out.

Our medicinal treatment will vary, of course, with the character of the distressing cough from which the patient suffers, and our aim should be not to embarrass Nature by checking her efforts, but rather to stimulate and increase the fluid secretions. Of all drugs, perhaps, ipecac best meets this condition, combined with the preparations of ammonia, which have a tonic effect in increasing the force of the respiratory efforts. Iodide of potash or ammonia is of great service, not so much as an expectorant as in causing absorption of the inflammatory products beneath the mucosa.

In cases where the expectoration is too great in amount, a preparation of the dif-

ferent balsams have an astringent soothing effect, limiting its amount. Belladonna and its alkaloid, atropine, also act well, but if pushed too far, gives rise to great discomfort. Moist air will relieve cough and dyspnea, especially inhalations of steam impregnated with turpentine or tincture of benzoin.

It is a great mistake to use the preparations of opium to allay cough and produce sleep. They are absolutely contraindicated, and although they may appear to give benefit, they are really obscuring the symptoms, and interfering with the activity of the secretions. If sedatives are needed, the bromides are much preferable.

Stimulants are practically indispensable in all cases, and should be given freely and regularly. Their benefit will be apparent in slowing the pulse and respiration, improved cutaneous circulation, improved appetite, and a general sense of well-being.

External Applications.—Counter irritation to the chest in any form is beneficial. during acute exacerbations, whether it be of mustard plaster, stimulating liniments or a simple cotton jacket.

Diet.—Diet should be of the most easily digested character; fluids given in small quantities often repeated. Milk, if digested, is, perhaps, the best of all; rich broths, from which all fatty matters have been removed. It is wise to administer nourishment and medicinal expectorants at the same time, thus avoiding disturbing the patient, and any irritation to the stomach. The chances for a cure are very remote, although the patient may be made comfortable for many years.

Yellow Fever.

BY J. H. WHITE, M. D.,

Surgeon U. S. Public Health and Marine Hospital Service; Lecturer on Hygiene and Tropical Diseases in the Medical Department of University of Alabama. Mobile, Ala.

Yellow fever is an infectious disease, characterized in general by one paroxysm of fever coming on suddenly, short in duration, and accompanied by a peculiar nongradation of pulse rate, the most pronounced symptom other than this being the jaundice which gives it its name. As to its etiology, it is conveyed solely by the mosquito known as stegomyia fasciata. This fact was fully proved by the experiments of Walter Reed, Surgeon U. S. A., and which, briefly stated, were the exposure of non-immune individuals in screened rooms to all manner of fomites supposed to be infected by yellow fever, without results; these experiments seemed to prove that yellow fever was not and could not be conveyed by fomites. At the same time he exposed other non-immunes in an absolutely non-infected neighborhood, and again in thoroughly screened rooms, to the bite of the stegomyia fasciata, and in these cases a large percentage of the persons so bitten showed symptoms of yellow fever at the end of from two to six days. It is not desirable to take up the space necessary to go further into Reed's experiments, but pass on to the observations made just before this time by Surgeon Carter, of the Marine Hospital service in Mississippi during the yellow fever epidemic, which observations were made entirely independent of Reed, and exactly agree with all of Reed's findings.

Stated briefly, he found that a man sickening in a certain house, say on September 1st, did not render the house dangerous until about twelve or fifteen days after he became ill, this being illustrated by the entire immunity of persons visiting this house up to the twelfth of the month, but subsequent visitors are almost invariably stricken with the disease in from two to six days after spending a short time in the house, and they in turn becoming sick present the same history.

Now Reed's experiments showed that a mosquito to become infectious must bite a yellow fever patient during the first three days of his fever, that the infection remained latent in the mosquito for ten to twelve days. Note, therefore, if we add these two periods of time together we have the period of from twelve to fifteen days noted by Carter in his observations.

Symptomatology.—The clinical symptoms of yellow fever, while fairly marked in pronounced cases, are not sufficiently distinctive to prevent this disease from being mistaken for malaria or enteric

fever. The onset is generally sharp, a pronounced chill, accompanied by headache and backache. Temperature, from 101° to 103° F.; pulse at the beginning reaches as high as one hundred and twenty, but before the close of the first twenty-four hours there is a recession of this pulse rate which continues until convalescence is reached, when it may be as low as forty.

On the first and second days, venous stasis is pronounced, and the complexion assumes a dull brick red color. The temperature may either remain stationary or rise slowly while the pulse is falling. After the second day there are generally some indications of jaundice, first observable in the conjunctiva, later over the integument. This jaundice is more often of a lemon yellow rather than the deep orange observed in some types of malarial jaundice, and jaundice from hepatic obstruction. On the third or fourth day albuminuria will be found, sometimes merely a trace in mild cases, and sometimes quite pronounced, but if looked for with sufficient care it is seldom or never absent, though it may be very evanescent. In no case should the test for albumen be made so carefully as in a case of suspected yellow fever.

The text-books in most instances convey the idea that yellow fever is a disease characterized by two paroxysms separated by an intermittent. The observation of the writer tends toward the conclusion that the so-called intermittent is the beginning of recovery, and that any subsequent outbreak of the disease, instead of being a third stage of the disease, may be simply a relapse from dietetic or other blunders in treatment.

This was the opinion of Dr. Robert B. Murray, than whom no man ever saw more yellow fever, or had so much knowledge of it, and on whose methods of treatment I base my own. Treatment consists first in an assurance that the bowels are freely opened by whatever means are most convenient, the preference being for calomel or a saline, that the terrible headache and backache which accompany the initial chill, should be met by some reliable analgesic, and the diet confined to practically nothing for the first seventy-two hours, followed by just the barest suggestion of broth containing no solids whatever. And the final return to solid food should be made with even more care than in typhoid fever. It will be observed that no specific treatment whatever has been resorted to, nor is any necessary. Quiet and rest, and particularly rest for the alimentary canal, seems to be the thing most necessary.

It appears to the writer that nothing regarding this disease is of so much importance as prophylaxis, when the spread of the disease can be so readily accomplished. Bearing in mind these premises: 1st, that the disease is conveyed by an insect, infected twelve or more days; 2d, that the insect must receive his infection during the first three days of the patient's fever; 3d, that the insect continues to be infectious until it dies. It is evident then that we must secure the death of any infected insect well within the twelve day limit for which he becomes potent for evil; 4th, that we must prevent any mosquito from biting any fever patient.

These ends can be accomplished by screening off houses, as far as possible, and by making sure that any room in which any fever patient is resident is made a sure prison for any mosquitoes coincidently resident there also, until such time as the patient is well enough to be removed to another room, and the mosquitoes destroyed, as they can be, by burning two pounds of sulphur to every thousand cubic feet of air space, and leaving the room closed for twenty-four hours. Pyrethrum powder may be burned as a substitute, using same quantity as in case of sulphur and carefully sweeping and dusting up stupefied insects. If this is faithfully done, there can be no spread from that room, and it is a duty to follow up this method wherever cases show themselves until ultimately the epidemic is wiped out.

Marine Hospital.

[Written for the MEDICAL BRIEF.]

A New Cap Film Treatment for School Ringworm.

BY DAVID WALSH, M. D. (EDIN.),
Physician to the Western Skin Hospital.
London, England.

Among preventible diseases it would at first sight appear that ringworm would be one of the easiest to prevent in actual practice. Not only is the malady confined to the surface of the body, where it is practically confined to certain definite areas, but its cause is an easily recognizable coarse fungus, with the natural history of which we are now, thanks to the labors of Sabourand and others, well acquainted. Indeed, there is hardly to be found a more interesting chapter in the history of modern scientific research than that which records the gradual evolution of our knowledge of the etiology of ringworm.

The first accurate description of ringworm was given by Willan in 1817, but for many years afterwards it was still confused *with alopecia areata*, eczema, and other affections of the scalp. It was not until the year 1843, however, that Grüby found the fungus which he named *microsporon audouini*. He detected this fungus in the broken-off hairs, noted by Cazenave, in a school epidemic, together with more or less bald patches spreading at the periphery. To this fungus was ascribed alopecia areata, as well as favus and ordinary ringworms.

This confusion was partly cleared up by Matruslen, in 1845, who described the fungus of ringworm under the name of *tricophyton ton surans.*

Duclaux was the first to grow the tricophyton fungus in fluid media, but the main credit of differentiating the small and the large spored varieties rests with Sabourand.

In 1886 Duclaux produced aerial fructification by artificial cultivation of the tricophyton.

In 1894, Sabourand published his classical book, in which he established the plurality of the ringworm fungi.

Our position with regard to ringworm, then, has been revolutionized during the last century. In spite of all this enormous addition to our knowledge, however, treatment has lagged far behind. The outlook for the individual patient, therefore, is little better than it was in the days of scientific darkness, when fungus and antiseptics were alike unknown. At the same time, the medical man called upon to treat ringworm has gained one definite advantage, inasmuch as with the aid of the microscope he is now able to detect certain forms of the malady which are capable of rapid and certain cure.

There is hardly any disease for which more certain "cures" have been vaunted at one time and another. The list of such

remedies includes blistering, Coster's paste, chrysophanic acid, chrysarobin, formalin, glacial acetic acid, goâ powder, iodide of mercury, Harrison's treatment (precipitation of iodide of mercury by use of two solutions), hydronaphthol, oleate of copper, oleate of mercury, resorcin, salicylic acid, sulphur, tincture of iodine, turpentine, and many others. Three cures that have been most popular of late have been salt, formalin, and the X-rays. So far as we can at present judge, there is a future before the X-ray treatment. Of that, however, as of formalin and some of the best of the other methods, it may be said that while all of them cure some cases rapidly, none of them cure all cases rapidly, while sometimes every single one of them fails altogether.

In other words, the specific method of cure of ringworm remains to be discovered. Under careful, skilled treatment we may hope to cure the majority of cases within six or eight months, or, perhaps, within a year, yet there are many which, in spite of skilled and laborious care, last for two or three years or more.

Aldersmith* describes a very chronic form under the name of "diffuse ringworm," in which there are one or more large irregular patches, often extending over nearly the whole scalp, due to coalescence in places. This form is often mistaken for seborrhea or chronic squamous eczema, and its diagnosis can often be determined only by the aid of the microscope. Aldersmith mentions one case that was under treatment for seven years.

Under these circumstances the gravity of the disease becomes apparent when we recall the fact that ringworm is above all things a school malady. Not only is it highly infectious, but owing to the peculiar ways of children it is extremely liable to be conveyed from one to the other. By some mysterious law the interchange of caps seems to be one of the elementary observances of the playground. In any case, the spread of the infection is so rapid in this disease that the introduction of a single case of ringworm into a school is certain to involve a number of the scholars if not at once detected. To some extent the rapidity of extension is determined by the social status of the pupils. Thus the disease is common and widespread in the poor-law and the county council or board schools, whereas it is extremely rare in the private or public schools of the well-to-do classes. In the same way, ringworm is one of the commonest diseases in skin clinics, whereas it is rarely met with in private practice. These facts show that the prevalence of ringworm amongst any set or class of children is mainly a question of environment. But behind all the discouraging facts of the case, we find the redeeming hope of salvation in the preventible nature of ringworm. Sooner or later there can be little reasonable doubt that preventive measures will sooner or later stamp out this scourge from our school community.

The good work has been already begun so far as regards the poor-law children of London. Several large "ringworm schools" have been organized, and affected children are sent thither from ordinary poor-law schools in various parts of the metropolis. Isolation is thus secured without interference with education, while at the same time each patient is placed under constant skilled supervision and treatment. The experiment has not yet been long enough in operation to show whether the bulk of poor-law ringworm is undergoing any marked diminution. The official report of the dermatologist of the ringworm schools, however, proves once again the obstinate nature of the disease, even under conditions most favorable to successful treatment.

For instance: On the 31st December, 1902, there were left in the school one hundred and sixty-four children, and during the year 1903 fifty-five new cases of ringworm of the scalp have been admitted, making a total of two hundred and nineteen cases under treatment during the year 1903. Of these new cases, two were re-admissions, and twelve were transferred from another school. Of the two hundred and nineteen cases, sixty-three were discharged cured, and twelve others were taken out of the institution still uncured.

In the council and board schools, with their scattered scholars and daily attendance, it would be out of the question to

* Ringworm, H. Aldersmith. M. B. 4th Ed., p. 98.

treat the matter from quite another standpoint, and bring constant pressure upon parents to send back to school children suffering from ringworm. Physicians attached to a skin clinique are familiar with the question repeated week after week as to when a "ringworm" patient may go back to school. As a matter of fact it is the exception, according to the experience of the present writer, for the children of the poor to attend hospital until a ringworm is cured. The obvious inference is that the blandishments of the attendance officer have prevailed, and that the child has returned to school to swell the capitation grant of the schoolmaster, and incidentally to spread ringworm to the ultimate loss and damage of the community. Surely, it is the clear duty of school authorities to keep their scholars free from ringworm. Yet experience has shown that the most dangerous of all cases in a school are unsuspected ones, under which heading would naturally fall the partially cured cases brought back to the school by the perverted energies of the attendance officer.

After so much destructive criticism the reader will probably be relieved to find that the situation is not to be regarded as altogether hopeless, and that the main object of the present article is to point out a plan by which the main difficulties in the treatment of school ringworm may be overcome. The mountain may not come to Mahomet, but Mahomet may go to the mountain. If we cannot isolate school children suffering from ringworm, it is, nevertheless, easy enough to isolate their scalps. By encasing the shaved scalp in an impervious envelope, we shall obviously prevent the spread of infection from that particular scalp. Incidentally, we can, at the same time, apply, perhaps, the two most powerful indirect methods of treatment of ringworm yet introduced, namely, X-rays and epilation.

My own plan is to have the scalp shaved and exposed to the X-rays. The bare scalp is then rubbed with turpentine, washed with soap and water and painted with some germicide, such as a weak solution of formalin. The scalp is then painted with several coats of a ten per cent solution of salicylic acid in collodion. On the second or third day a fresh coat of collodion is applied, or sooner, if there be any tendency to crack. After a week or ten days the collodion film is forced up the eighth of an inch or so by the growth of the healthy hair. The loosened cap film can then be cautiously stripped off with little pain, if carefully managed. Its under surface will be found shaggy with stumps of hair, both diseased and healthy. The ringworm hairs will show the irregular, twisted appearance with which one is familiar on the ringworm scalp. In addition, some of the fungus-laden hairs will be whitened, due presumably to the ether in the collodion and possibly also to the salicylic acid. If the cap can not be removed without causing too much pain, a pair of curved scissors can be inserted between the film and the scalp, and removal can be greatly facilitated by snipping through some of the hairs. In this way a wholesale depilation of sound hairs may often be effected, but there need be no fear of permanent baldness, as the hair soon starts a regrowth. A great advantage is that many of the soft short ring-worm stumps come away also on the film, being gently, but firmly, extracted by the traction of the slowly elevated collodion cap.

If desired the cap film can be strengthened by rubber solution, by painting with Unna's zinc gelatine, or by fastening on with collodion strips of jaconet, cotton wool, or sticking plaster. When once the principle of the impervious and adhesive envelope is grasped, details can be readily worked out. In the same way it will be possible to find substitutes for collodion, which is a somewhat costly drug to use on a large scale.

The advantages of the cap film treatment of ringworm are:

1. Infection of other children is prevented by the isolation of the affected scalp.

2. Treatment is shortened by the constant process of depilation attained by taking advantage of the inherent force of growing, healthy hair.

3. Education is not interfered with under this plan.

4. Cure is hastened by the systematic and recurrent removal of affected hairs.

5. Treatment is practically limited to reshaving and refilming the scalp once every week or ten days.

6. X-ray treatment can be cautiously applied through the film.

In conclusion, it may be pointed out that the stamping out of school ringworm under the above or any other plan can not be attained without skilled medical supervision. Microscopical examination is in many instances absolutely necessary for correct diagnosis as well as for prognosis, and to ascertain when a cure has been effected. To carry out the cap film treatment would demand the services of a dermatologist skilled in the observation of ringworm, as well as of a trained staff of nurses and a barber. Whatever form prevention may ultimately take, it is safe to predict that sooner or later educated public opinion will demand of our sanitarians the expulsion of so preventable a disease as ringworm from our school population.

[Written for the MEDICAL BRIEF.]

Morbid Thoughts.

BY T. OUTTERSON WOOD, M. D., F. R. C. P. (EDINBURGH); M. R. C. P. (LONDON),

Senior Physician to the West End Hospital for Nervous Diseases, Welbeck Street, and President of the Medico-Psychological Association of Great Britain and Ireland. London, England.

Some of the most distressing cases of uncertifiable mental disorder are those in which the patient, although perfectly sane in the ordinary sense, is yet tormented with what are called "horrid thoughts." These are generally described as almost unbearable, producing a feeling of misery, uncertainty and depression which impels the patient to seek medical advice. These "horrid thoughts" frequently take the form of a suggestion to do something dreadful, to kill some one, to set the house on fire, to destroy themselves; and they recur so repeatedly that life becomes a burden. Then there comes the thought, "Is life worth living?" and, "why not end it?" This leads to a contemplation of the means to be adopted, till the patient is haunted with the thought of suicide. In all other respects the mental and physical condition presents nothing seriously abnormal, and, fortunately, as a rule these patients sleep fairly well; they take their food and go about their daily work, but in a somewhat absent-minded fashion, during which there is a mental struggle between the recurring morbid thought and the reasoning, self-controlling power. Although as a rule these cases do well, and gradually so far overcome the tendency to give way to the morbid thought as to drive it into the background till it fades out of consciousness, there is nevertheless always a lurking danger of a breakdown of mental control, and the development of an impulse which may end in disaster. It is during the silent watches of the night, and especially towards the early morning, if by chance the patient is awakened from sleep, that the danger is greatest, for the morbid thought is there in all its intensity, and it requires a strong effort of the but partly awakened consciousness to overcome its suggestion. This suggestion, however, does not partake of the character of "self-suggestion" as understood by the hypnotist; it is a morbid thought, which rises into consciousness without any reference to the wish of the individual, and it is more like the implanted suggestion made to the subject when in the hypnotic state. If a person is hypnotized, and the same suggestion is made to him over and over again, on awakening from the hypnotic condition the suggestion will automatically rise into the consciousness, and the patient will act upon it, even after a considerable lapse of time, in accordance with the suggestion made.

The following cases illustrate the kind of morbid thought I refer to:

Case 1.—Miss L. W., age twenty-nine, consulted me on account of a state of mental depression from which she suffered, brought on by a "horrid thought" that was constantly coming into her mind. It mattered not where she was or what she was doing, the thought seemed to force itself upon her consciousness; "Do something to yourself." "Do what?" she would ask herself, and try to reason the matter out. She had so far invariably overcome the suggestion to do something to herself because her reason told her it would be a wrong thing to do. Yet the thought continued to so torment her that

she became afraid she would some day give way to it and destroy herself. She went in daily dread of it, and become so depressed and absorbed in the mental struggle with it that her family became alarmed at her condition, and she was brought to me for advice. She was perfectly sane and sensible, and discussed the matter with me with perfect clearness and coherence. She said she felt confident if she could only get rid of this "horrid thought" she would be as well as ever she was.

Case 2.—Miss A. M., age twenty-seven, the second child of a family of six. She states that in September of last year the thought came into her mind that she might do something to herself, and since then it has constantly recurred, and has made her feel so ill and wretched, because she fears she may give way to this "horrid thought." She has not, however, contemplated any special method of self-destruction, but the feeling is always present, and she seems as if she can not forget it. She says she knows she is quite sane, and too sensible to do anything, but it has made her very depressed and miserable. A brother and sister have suffered from mental depression.

Case 3.—Miss E. S. The thought comes to her "That's the devil," and it mixes itself up with her work, so much so that when engaged with needlework she seems as if she is sewing the words into her work, and she has great difficulty in preventing herself doing so. This thought was started about twelve months ago, and she blames her brother (having then committed suicide by cutting his throat) for starting it. Although she is quite sensible and rational, she feels depressed at the recurrence of the thought.

Case 4.—Mrs. M. K., ever since the Whitechapel murders, has had horrible thoughts, suggesting to her to do something dreadful to those around her, to commit murder or destroy herself. She is a married woman with one child, two and a half years of age. She is neurotic, has nystagmus, as also have one brother and a sister, and her mother's eyes also were "always on the work." I brought these cases before the Medical Society of London in 1896, and they are recorded in the "Transactions" of that Society as three cases of congenital nystagmus occurring in the same generation of the same family.

Causation.—In most of these cases there is a distinct neurotic condition, and the family history generally shows that there has either been insanity, intemperance, or nervous instability in other members of the family. The predisposition to mental trouble is the rule, and easily traced. The exciting cause is usually some sudden mental shock—a fall, a blow on the head, or some strong impression caused by reading of accidents or murders in the papers. Domestic worry, especially in connection with the affections, is a frequent cause. In some cases there appears to have been no exciting cause whatever, the morbid thought arising into consciousness, an unwished-for and an unwelcome guest, which has come to stay there until overcome and forgotten.

Treatment.—In the majority of these cases there is a general disorder of the bodily functions. There is dyspepsia, constipation, and monthly irregularity of the female generative organs. The appetite fails and is capricious, the bowels act spasmodically, and the general health is impaired all around.

The first indications are to improve the general health. If there is insomnia, a dose of twenty grains of sulphonal each alternate night will produce refreshing sleep. A mixture of soda bicarbonate, gentian and ammonia before meals three times a day, and a pill of compound rhubarb, three grains, and blue pill, two grains, each alternate night, will restore digestion and procure healthy action of the bowels. The removal to cheerful surroundings, if possible, and, if that can not be arranged, the introduction of an outside element into the family circle, will stimulate self-control and self-confidence by the interchange of healthy thoughts and ideas, and will tend to strengthen the power of resistance to the suggestion of the morbid thought. Then a nervine tonic in the form of fifteen grains of bromide of ammonium, fifteen minims of spirit of chloroform and five minims of tincture of nux vomica, in an ounce of cinnamon water, an hour after breakfast, and after the mid-day meal, and in the evening, will tend to steady the nervous

centers and improve the general tone, producing a feeling of rest and composure, and allaying nervous irritability. The effect of treatment carried out on these lines is usually all that can be desired, and the usual result is banishment of the morbid thought, and health of mind and body. In some instances I have found hypnotic suggestion of the greatest value in blocking these morbid thoughts out of the patient's mind, and producing a rapid and satisfactory condition of mental tone. The treatment should be continued daily for a week at least, and is well worth the time and trouble expended. Cheerfulness and self-confidence stimulated, and the duration of the case materially shortened.

Diabetes Mellitus.

BY MAX MEYER, PH. D., M. D.,

Professor of Chemistry and Toxicology; Lecturer on Histology, Pathology and Bacteriology in the Eclectic Medical College of the City of New York; Ex-Officer of the Health Department of New York City; Physician Macy Mutual Aid, etc. City of New York.

The morbid anatomy of this disease is obscure, and the following lines may throw some light upon the matter.

Albuminates, carbo-hydrates and fat, the greater part of our daily food, being mixed with the digestive ferments, are conveyed into the blood circulation. A real chemical decomposition of the so-prepared food molecules neither takes place in the intestines nor in the blood, but exclusively within the cells of assimilation, which possess inherited chemical and biological forces to split up the food molecules, selecting those which become necessary for the maintenance of life, and excreting those which are of no use. This cell chemism, highly active in the healthy body, becomes impaired, even ceases under pathological conditions, the result of which is known as disease. Still the body is living, and needs vital energy, but the cell chemism is unable to bind enough energy of the food molecules for the maintenance of the organism, hence it loses in size and increases in tenacity of the tissues.

This condition marks old age, and in diabetes mellitus we find the same state of affairs, *i. e.*, premature senility of the cells.

The healthy, active cell changes the food molecule into nutritive substances, and the waste material as urea, carbon-dioxide, salts, etc., is thrown off, but the presenile cell has not power enough to convert the complex compounds into useful mediums; it labors under the stress of weakness, and is only able to transform starches into dextrin, and then into sugar. Here its strength is exhausted. The cells gradually fill up with sugar, this by osmosis passes into the blood, and is filtered out by the kidneys, and finally we find the sugar now in the urine.

If we compare the symptoms of senility with diabetes mellitus, we find both to be similar.

In conclusion, we can say that the danger does not lie in sugar production, which is a symptom merely, but in the premature senility of the cells, hence in our therapy we must lay stress to bring them back to active normal life, which is the external battle between the free and combined affinities of a non-saturated chemical union.

127 East One Hundred and Fifteenth Street.

An Interesting Case of Fibro-Sarcoma, Involving the Tendon of the Gastrocnemius Muscle.

BY HENRY MANN SILVER, M. D.,

Professor of Clinical Surgery in the New York University and Bellevue Hospital Medical College; Consulting Surgeon to the New York Infirmary for Women and Children; Visiting Surgeon to the Gouverneur and Beth-Israel Hospitals; Fellow of the American Medical Association: Fellow of the Academy of Medicine, etc. New York City.

A. S., aged thirty-six, born in Roumania, did business in Havana, Cuba. Ten years ago he noticed a small swelling in the muscle of the calf of the leg. This increased very slowly for about seven years. During all this time there was little or no pain, when pain suddenly developed, and the tumor began to increase rapidly in size. Another tumor formed towards the popliteal space. In a few months a third tumor formed above the second; meantime all the tumors grew slowly. About six months ago a fourth

tumor appeared, lying in the lower portion of the outer side of the popliteal space.

The patient now began to experience pain of a shooting character in the middle and outside of the leg.

Some weeks ago he consulted three surgeons in Havana, two giving a positive statement that the tumor was of the simple fibrous variety, while the third surgeon rendered a diagnosis of malignant sarcoma. The patient was further advised to come to New York for treatment.

On examination I found a tumor about the size of a small egg, situated in the upper portion of the central tendon of the gastrocnemius, with three tumors above the larger one in a chain extending upwards towards and in the lower portion of the outer side of the popliteal space.

These tumors were hard, and were slightly movable, not painful on pressure; no enlargement of the superficial veins. Very slight enlargement of the inguinal glands in both groins, also in the neck. No history of syphilis. Operation was advised, further treatment to depend upon the report of the pathologist.

On operation, the lower and larger tumor was found to be firmly connected with the central tendon of the gastrocnemius. There was no connection with the muscular fibers. The smaller tumors were found to be connected with the aponeurosis of the muscle, the upper tumor lying in close proximity to the external popliteal nerve. The tissues about the tumors were freely removed, and the wound closed.

A specimen was at once sent to Dr. F. E. Sondern for examination. At the end of three days he reported that the tumor was a fibro-sarcoma.

The report of the pathologist was explained to the patient's friends, as well as the importance of a second operation.

After consultation with Dr. A. Brothers, the patient decided to have his thigh amputated, which was done, the patient passing through the operation and reacting well.

The amputation was advised because there was no evidence to be found in the groins or in any secondary involvement of the tissues.

5 East Forty-Third Street.

[Written for the MEDICAL BRIEF.]

Treatment of Congenital Dislocation of the Hip by the Lorenz Method of Manipulation.

BY SCOTT PARSONS, M. D.,

Professor Orthopedic Surgery, Homeopathic Medical College, Mo.; Surgeon St. Louis Children's Free Hospital.
St. Louis, Mo.

When Prof. Adolph Lorenz demonstrated his bloodless method of reducing congenital hip dislocation at the Polyclinic, in St. Louis, I had the honor of being invited to his clinic, and that I was pleased with the original work of this operator, is to say the least. The ease and grace with which this muscular man manipulated and handled the delicate limbs of his unfortunate little patients was a source of great surprise to me, and to all those present, and also an agreeable disappointment, as my idea of the method, gleaned from the literature on the subject, was that considerable force was requisite to accomplish the reduction. And this idea prevails among those who have not seen this method demonstrated. True, there is a wrenching, stretching and sometimes a lacerating of the muscles, fasciæ and ligaments, which are antagonistic to a restoration of the joint, yet the relaxation and control of these barricades of abnormality are obtained only through scientific maneuvers, with a definition of delicacy. There is not nor should not be the least harshness or roughness in the manipulation, and particularly in the fourth stage, or stage of reduction. In fact, the reduction requires less force than any other part of the procedure, provided the steps preceding this stage have been thoroughly and correctly instituted. To the uninitiated the operation may have a brutal aspect, but the treatment is mild, compared with the methods heretofore employed for the relief of these cases. Up to the time of Lorenz, congenital dislocation of the hip was practically incurable, inasmuch as few cases were ever entirely relieved; more were only slightly benefited, and the balance unimproved or aggravated. Perhaps congenital dislocation of the hip has received as much earnest work and attention as any other condition in orthopediatrics, yet it was

left for Lorenz to devise a treatment pregnant with promise, and that a large majority of cures have resulted, not only at the hands of the Austrian, but others, is

Fig. 1. Showing shoulder and sacral supports, also position of leg during application of cast to unilateral dislocation.

verified by the reports. It might be well to state that the success is not attributed altogether to the manner of reduction, but to the after treatment; the position of the leg after reduction, the dressing and general management of the case, following removal of the cast. Congenital dislocations of the hip have been reduced before Lorenz's time (1), perhaps not in the same way, but, nevertheless, the head of the bone has been returned to its normal position, but from this point the methods of treatment were faulty, and it was found impossible to fix the head in the acetabulum permanently, even after months of immobilization. (2). The best result ever obtained by mechanical maneuvers was by Dr. Buckminster Brown, of Boston. Other cases have been reported as cured, where the treatment has been by extension or immobilized in plaster casts of fixative splints, but the results in the large majority of cases has been negative. Besides the treatment by extension and reduction, followed by a fixative apparatus, operative measures have been resorted to with but little success. Tenotomy was one of the earlier procedures and was not without merit. But beyond the tenotomy the treatment was faulty, and in most cases failed in results. Arthrotomy was another noted method advised (4) whereby the femoral head was freed of the attachments and placed in the cotyloid cavity. Others went a step farther, producing arthrodesis, spiking the head to the acetabular rim. (5) Then came the idea of enlarging and deepening the cotyloid cavity with scoop and chisel (6, 7) and finally excision of the head was resorted to (8), but all these methods utterly failed in positive results in any number of cases. Arthrotomies and arthrectomies have been discarded, except in old and desperate cases, where the bodily deformity in the form of lordosis supervenes. By placing the head of trochanteric stump into the socket, or on the rim, even in a fixed position, the leg is brought into line with the trunk, preserving the perpendicular of the body, and correcting or aborting a progressive lordosis. This is a dernier resort.

Lorenz's method of reducing congenital dislocations of the hip by manipulation, consists in the stretching of shortened muscles, ligaments and fasciæ, with subsequent formation of a stable articulation by functional measures. By that is meant that the patient is made to walk for a time with the affected limb or limbs in the position of complete abduction and hyperextension. The operation, for a matter of clearness, may be divided into six stages: (9).

Stage 1. Treatment of Adductors.—The first step after the patient is anes-

Fig. 2. Plaster cast applied, showing maintenance of leg in position of abduction and hyperextension, also method of everting undergarment to cause non-irritating edge.

thetized is to overcome the resistance of the adductor muscles of the thigh. For this purpose the operator forcibly abducts the limb, while an assistant steadies the

pelvis. Keeping the parts thus on the stretch the operator, by repeated "hacking" strokes, made with the ulnar border of the hand, at a point a little below the

Fig. 3. How cast is worn. The leg in the "Lorenz position" before application of the high shoe.

attachment of the muscles to the pelvis, produces a subcutaneous division, not only of the whole of the adductor longus, but also of parts of the deeper lying adductors.

Stage 2. Treatment of Extensors.—The contractured muscles of the posterior aspect of the joint are stretched by forcibly flexing the hip. In doing this, the knee is kept extended, and the limb is bent upon the trunk with intermittent movement of a swinging character, until the foot can be carried up to the shoulder.

Stage 3. Treatment of Flexors.—The patient is now turned onto face and the muscles on the front of the hip joint are forcibly stretched by producing successive movements of hyperextension of the hip, with the knee fully flexed. At the end of this stage, the heel can be made to touch the buttocks. In order to test when sufficient stretching has been produced, downward traction is made on the limb to see whether the head of the bone comes down, as evidenced by the trochanter being brought to the level of or below Nealton's line.

Stage 4. Reduction of the Dislocation.—This important step for which the previous stages are preparatory, is begun by completely flexing the hip, the knee being bent to a right angle, and the thigh slightly rotated inwards. A wedge may now be placed behind the trochanter. The flexed limb is then fully abducted by bringing it into the position of right angle with the trunk, and the knee and foot are in a frontal plane, posterior to the mesial frontal plane. As this movement is being concluded, the head of the bone can be felt by the operator to clear an obstacle; this is the moment of "reduction." Before the reduction, there is an unnatural hollowness of Scarpa's triangle, but as soon as reduction has been accomplished, the head of the femur occupies its normal position, and pushes forward the psoas and other soft parts, thus filling up the hollow.

Stage 5. Stretching Capsule.—The next procedure aims at stretching the anterior fibers of the capsular ligament. For this purpose the pelvis is raised upon a support, *e. g.*, a sand bag or padded wedge, and held firm, while the operator intermittently strains the abducted limb into

Fig. 4. Anterior and posterior view of a cured case, (unilateral) by Lorenz method, having worn a cast nine months, a postural steel brace, three months, and under treatment in all fourteen months. Notice the symmetry of the two sides. The right leg was the one dislocated.

a marked degree of hyperextension. The pressure is brought to bear on those fibers adjacent to the anterior or inner rim of the acetabulum.

Stage 6. The Application of the Plaster of Paris Apparatus.—The patient is raised, the sacrum resting on a small padded plate supported on a crutch. The shoulders rest on a small padded stool of the same height. The limb, or limbs, if both have been operated on, are held completely abducted and hyperextended. A pair of woven woolen drawers without buttons are put on, and an ordinary muslin bandage, three inches wide, drawn between the skin and the drawers on each side that has been operated on. Next, an ample covering of common dressmakers' wadding, cut into bandages, is applied, so as to envelope the lower part of the abdomen and the whole of pelvic region, and to cover the thigh (or thighs, if both hips have been operated on) to a point just below the knee. Separate additional pads are placed below each anterior superior spine, and above each internal femoral condyle. This investment of wadding is held in place by a few turns of gauze bandage. The nates, perineum and pubes are completely enveloped in wadding. The plaster of paris bandages are then applied over the whole area previously covered. The perineum is completely covered by a figure eight bandage around both legs. Before the plaster has set, the patient is removed from the support and the plaster case is cut down to the shape desired. (See accompanying photographs.) This is accomplished with a sharp cartilage knife and scissors. As the plaster dries, the drawers are cut and turned back to make a non-irritating edge. The bandages that were placed between the patient's skin and the drawers are used for daily friction of the skin; in order to protect the cast along the line of the perineum, soft towels or gutta percha tissue may be fastened to the edge of the cast and changed as often as necessary.

THE AFTER TREATMENT.

Lorenz recommends that the cast be left on for about six months. As soon after the operation as the child is able it should be allowed to get up and made to walk upon the operated leg. A high-soled shoe, from two to four inches, is placed on the foot of the operated leg, and the child given crutches, or allowed to hobble from bed to chair, until such a time as he gains control of the leg sufficiently to walk without support. When both legs have been operated on, the patient can stand by holding a staff in the hand, and can hobble sideways in either direction, or can sit on a small wheeled seat which is moved by the feet. Daily passive and active extension movements are practiced at the knees to overcome rigid flexion. At the end of five or six months when the cast is removed, the glutei muscles are greatly wasted and require daily massage until fully recovered. Passive and active movements of the hip are daily practiced until the leg can be brought into line with the body. This is the most anxious part of the treatment and much depends on the way in which it is carried out. The course of treatment varies from one to two years.

New Features of the Operation.—The most important step in the manipulation is the complete relaxation or severance of the adductor muscles, for without this the leg can not be hyperextended or fully abducted. The manner of dressing and the position of the leg, are entirely original with Lorenz, and perhaps to this feature alone is due the success of the operation. The leg is set in complete adduction and hyperextension. In this position the head of the femur is retained in its socket, and an imaginary line drawn from the trochlea surface of the femur through the head and acetabulum would terminate at the crest of the ilium on the opposite side. The leg is kept in this position for several months, during which time the patient is supposed to use the leg in the act of walking. The theory advanced by Lorenz, and which has been proven correct by hundreds of cases, besides *post-mortem* opportunities upon cured cases, was that the continued use of the leg in this deformed position assisted functionally in developing the acetabulum, which was immature; that the pressure on or in the cotyloid cavity, brought about by the weight of the body on the abducted leg, deepened the cavity, while Nature in her efforts to form a joint, would build up the acetabular rim, particularly the superior border. As long as the femoral head was without the acetabulum, the anatomical structure would cease to develop, and after a certain period atrophy

and disappear from lack of use, and that the presence of the head of the femur in its normal socket would stimulate an activity of development, resulting in a stable articulation.

Age Limit.—With an experience of over one thousand cases, Lorenz places the age limit at nine to ten years for unilateral cases, and six to seven years for bilateral. He has, however, exceeded these limits by preliminary treatment of extension and tenotomies, and in one case was successful at the twenty-third year. (10).

[Written for the MEDICAL BRIEF.]

Notes on Tendon Transplantation in Infantile Paralysis.

BY GILBERT L. BAILEY, M. D.,

Professor of Orthopedic Surgery in the Cincinnati Polyclinic and Post-Graduate Medical School.
Cincinnati, O.

Since Nicolidoni first operated for infantile paralysis by transplanting tendons, a large number of operations have been devised more or less successful in character according to individual cases. There is no one operation which will fit every case, but by combining the experience of the various men who have worked in this field it is possible to improve all cases of infantile paralysis, in which some muscles remain intact. The various operations may be grouped into two divisions.

1. Those in which sound tendons are transplanted into paralyzed tendons; and,

2. Those in which sound tendons are attached to bone, either through the medium of artificial tendon lengthening, or fastened directly to the periosteum.

The first class comprises the majority of the paralyses involving the muscles of the foot. In the second group the muscles of the leg and thigh will be found most applicable. Taking the foot after the plan of Lange of Munich, we find it is capable of four movements—dorsal and plantar flexion, and inversion and eversion. These movements are performed by groups of muscles, which may be weakened or strengthened by taking one or more muscles from an intact group, and transplanting it so as it will perform the function of the weakened group. The transplantation may be readily accomplished in the majority of cases by simply exposing the tendon by a long incision, and transplanting directly to the side of the foot where it will have the desired action.

For this purpose I have found the method of Lange to be of great service. This method consists in exposing the tendon to be transplanted, under aseptic precautions, running a heavy silk thread through it, holding it firmly and transplanting it under tension at the point where the desired force is to be exerted.

The wound is then closed with small gauze drainage, put up in plaster, and allowed to remain undisturbed for three weeks, except for the withdrawal of the drainage which is removed at the end of twenty-four hours.

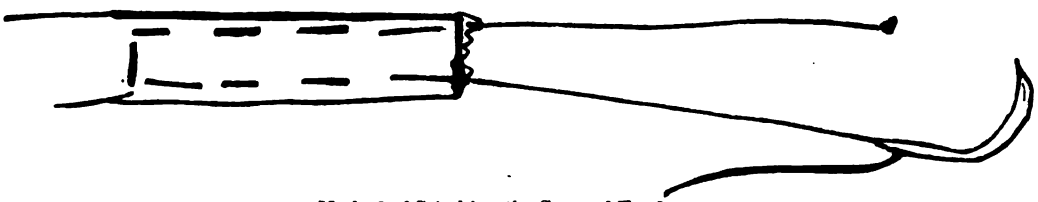
In the case of the knee in which usually the anterior flexor muscles are involved, it is often necessary to transpose the hamstring tendons to the front of the leg, causing them to become flexor. This is accomplished in much the same way. The hamstring tendons are exposed and severed as near their insertion as possible, the No. 12 silk thread is stitched into them, as in the accompanying diagram. (See following.) The double threads are then brought up from the back of the thigh subcutaneously to the wound previously made just above the patella on the anterior surface of the thigh. The same procedure is accomplished with the other hamstring and the four strands of silk appearing at the anterior opening are now braided together firmly. Another opening is made over the anterior tuberosity of the tibia and this braided silk string is carried subcutaneously over the opening above the patella to the one below it. The

tendons are now drawn taut and held so by an assistant while the operator with a heavy curved needle stitches the strand firmly into the tuberosity of the tibia, boring forcibly into the bone. The wounds are then closed, gauze drainage inserted if necessary, the gauze drains being fastened by threads which afterward protrude through windows in the plaster cast. The wound is now firmly encased in plaster, plenty of padding being used to prevent rubbing. The gauze threads are removed through windows of the cast at the end of twenty-four hours and the cast taken off at the end of three weeks.

These little patients may be allowed to walk at the end of four weeks following the operation, care being taken to prevent contusions or other injury to the skin overlying the artificial silk tendons. These tendons may be allowed to remain in place indefinitely, the history in the majority of cases being that they become a framework for the deposits of embryonic connective tissue cells which subsequently become organized. At the fifth or sixth year the silken strands will be found to have been absorbed. In some cases the silk tendons, either through strain or injury, prove a source of irritation under the skin and may have to be removed at a later date. This happened in two of my cases in which the artificial tendon was removed at the end of sixteen months, another at the end of twelve months. This removal, however, did not interfere with the efficiency of the result, as the connective tissue formation at this time became strong enough to carry out the function of the silk alone.

The following five cases have been under observation for more than a year after operation and amply demonstrative the feasibility of the artificial tendon.

J. C., aged thirteen, had an anterior poliomyelitis involving both legs, the left less in degree than the right, although the left foot had no movement in the ankle. The right knee was flexed from contraction of the hamstring muscles. The right foot had intact the tibialis anticus and the Achilles tendon. Operation performed January 27, 1904. An attempt was made to shorten all of the anterior tendons of the left foot to prevent "foot drop." The tibialis anticus was divided into two parts, one part being left in the normal situation, and the other half attached to the perineus longus. The right Achilles tendon was also divided, one-half being inserted into the tibialis posticus. The biceps femoralis was divided above its insertion, the artificial silk tendons introduced as above described and elongated with the No. 12 silk. These artificial tendons were carried up to the front of the thigh, braided and inserted into the tuberosity of the tibia. The patient made uneventful recovery; no suppuration apparent, and six weeks afterwards was able to disregard the crutches he had used all his life and walk with two canes. He is now able to walk about the house without artificial aid, but feels safer in walking out of doors with the aid of a cane. In this case the artificial tendon over the right knee became a source of irritation following a fall, which weakened the skin over it. The artificial silk tendon was removed July 2, 1905. This extension is perfect, however, at the present time.



Method of Stitching the Severed Tendons.

D. H. (operated July 6, 1904), aged five; had infantile paralysis at the age of two, involving the right leg, which cleared up, leaving only the perineal muscles paralyzed. The tibialis anticus was split over the instep and half of it carried subcutaneously into the os navicularis at the outside of the foot. In this case the foot was very much inverted, the patient walking on the dorsum of the foot. After the operation, which was followed by an un-

eventful recovery, the foot remained in perfect position for five months. She then struck her foot on the point of a rocker, causing the old wound to break down and the stitches had to be removed. This is the only failure among the five cases reported.

M. B. (operated June 23, 1904), aged nine; had infantile paralysis at the age of one. The principal muscles involved were the extensors and adductors of the right thigh. These partially regained their function, but the child threw out the right leg in walking, creating quite a noticeable deformity. The hamstring muscles were intact, as well as the sartorius. The sartorius was severed at its insertion and carried up and stitched to the patella at its upper border. Extension was much improved and the child now walks with very little deformity.

G. H., aged ten, was afflicted at the age of three with anterior poliomyelitis, leaving him with complete paralysis of the muscles of the left foot and of the extensors of the right foot, but the Achilles tendon of the right foot was preserved. Shortening of the tendons of the left foot was performed to overcome the left "foot drop." The Achilles tendon of the right foot was lengthened by the Bayer method. The right hamstrings inserted into the tuberosity of the tibia, as reported in the case of J. H. The result was eminently successful, as he is now able to walk with a cane, where he was unable to walk at all before. The artificial tendon over the right knee had to be removed on June 11, 1905, but extension is still perfect.

K. S., aged eleven, was operated on July 9, 1905. Anterior poliomyelitis at the age of two months; inversion of the right foot. Half of the tibialis anticus was inserted at the tibialis posticus and the extensor longus pollicis was inserted into the periosteum at the head of the first metatarsal bone. The results were eminently gratifying, the deformity of the foot having entirely disappeared and walking is almost perfect except for a genu recurvatum which was present before the operation and which we hope time will relieve.

In these cases I have demonstrated beyond doubt the success of tendon transplantation and also demonstrated the ability of the body tissues to tolerate such a foreign body as the artificial tendon for an indefinite length of time.

It was the writer's privilege to see thirty cases which had been operated on in the above manner by Dr. Lange of Munich, at from three to seven years after the operation. All of these cases presented favorable results. The writer also saw several specimens of silk which had remained in the tissues from three to five years and they presented under the microscope varying stages of organization. The embryonic cells seemed to penetrate the meshes of the braided silk and became organized there, forming in time ideal tendons. Too much care can not be used to protect the tendons from injury in the first year or two after operation, but the cases cited above show that the silk may be removed without special harm after a period of one year has elapsed. Whether in these cases there has been a true formation of cicatricial tissue to take the place of the tendon or whether the separated tendons have become adherent to the tendon of the quadriceps femoris the writer is unable to state. The result, however, is a great improvement over the previous condition.

Before leaving the subject of the treatment of infantile paralysis it is well to emphasize the importance of early and prolonged massage, electrical treatment and hydrotherapy in the early stages of this disease. Braces should not be applied if it is possible for the patient to walk without them, as the brace in a great measure prevents the development of the uninjured muscles. In suitable cases nerve transplantation may take the place of the tendon transplantation, possibly with far better results, but not enough data is at hand at present to enable us to compile any statistics on this operation.

[Written for the MEDICAL BRIEF.]

Electricity in Medicine.

BY A. D. ROCKWELL, A. M., M. D.,

Formerly Professor of Electro-Therapeutics in the New York Post-Graduate Medical School and Hospital; Ex-Electrotherapeutist to the Woman's Hospital, New York, etc.; Author of "Medical and Surgical Uses of Electricity," "Treatise on Neurasthenia," etc.; Fellow of the Academy of Medicine; Member of the New York County Society, Neurological Society, etc. New York City.

Unfortunately for the general and successful utilization of electricity in medicine, a far more intimate acquaintance with its physics and physiology, and with the laws which govern the action of its various manifestations on living tissues, is demanded of the general practitioner, than he can claim to possess. In the first place he must recognize the fact that electricity is not simple, single manifestation of force, but a generic term, susceptible of so many modifications of its units of measurement that we get various currents so called, differing so widely in their effects that these currents may be almost said to differ in kind as well as in degree.

For this reason I have always held that to correctly differentiate between the various manifestations of electricity, and select the form most suitable, is one of the most important and difficult problems in electro-therapeutics. The foundation principles on which must rest the use of electricity in disease is the recognition of the fact that electricity, or rather electrization, besides being a local stimulant or sedative, according to the method of its application and the pathologic condition that prevails, exercises at the same time an influence over general and local nutrition at once unique and unrivaled.

To make our applications exclusively local is both illogical and inconsistent, since in the use of electricity, as in the use of every other remedy, constitutional diseases should be treated constitutionally. The best method of bringing the whole system under the direct influence of electricity is by some form of general electrization. If the faradic current is used by general faradization; if the galvanic, by central galvanization—or by the use of static electricity or of the high frequency currents of D'Arsonval. In this way the success of electro-therapeutics is materially enhanced, and its sphere very greatly widened, so as to include a variety of frequent and distressing constitutional morbid conditions for which merely local methods of treatment are but imperfectly indicated. To those who adhere to the long accepted theory that electricity is merely a means for local stimulation, and, as such, chiefly indicated in conditions of paralysis or chronic rheumatism, or who hope to reduce electro-therapeutics to an exact science on the basis of a complete physiology or pathology, these statements may seem quite erroneous, and especially so if they have studied the action of electricity on the body merely by localized applications. The narrow doctrine of merely local stimulation is being rapidly abandoned, and the fact accepted that we have in electricity an unsurpassed means of improving the general nutrition in the immense variety of chronic morbid conditions where such results are chiefly indicated.

Now, in determining the differential indications for the use of local and general methods of electrization, we need to consider several things. In the first place, general electrization with whatever electric modality, directly affects the whole body, while localized electrization is mainly confined to the part to which the application is made.

Then, again, general electrization may by sympathetic or reflex action, indirectly, have a special therapeutic influence on some special part or organ; while localized electrization of any part, but especially of the sympathetic or cerebro-spinal axis, by sympathetic or reflex action, may indirectly have a general therapeutic influence on the whole body. Electrization, where judiciously attempted, very rarely injures and usually more or less benefits even those parts which are in comparative health.

This consideration has an important practical bearing, especially in the use of general electrization, in case of doubt as to the seat of the disease. Still, again, in nearly all cases it is important, and in many cases it is indispensable that the applications should be made to the seat of the disease as well as to the locality of the symptoms.

Scientific electro-therapeutics therefore requires the most accurate preliminary diagnosis; above all, it is important to rigidly discriminate between the diseases which are of a constitutional, and those which are of a local origin. From these fundamental considerations, we logically derive the general law that constitutional diseases are better treated by general and local diseases by localized electrization.

We have here an interesting point in connection with what are termed localized and general methods of electric treatment.

With the so-called dynamic forms of electricity—the galvanic and the faradic currents, with which were first associated the terms, localized and general electrization, approximate localization of effects is readily accomplished. The threads of current widely diverge, it is true, as they pass from pole to pole; but if the electrodes are placed in close proximity, with the locus morbi between them, the electric force is, for the most part, only locally expended, and the general system, little if at all directly affected. With static electricity and the high frequency currents of D'Arsonval, it is difficult to obtain this absolute localization to the exclusion of constitutional effects. Whether this might not be in certain conditions a disadvantage is, perhaps, a question. In a few exceptional cases we are inclined to think it a disadvantage.

As an illustration, reference is made to a case of chronic arthritis of long standing, in which the static vibratory or wave current relieved the pain, and seemed likely to prove of permanent service, but the general vibratory influence, which it is impossible to suppress, caused such nervous disturbance that the treatment had to be abandoned, and the galvanic current substituted. Fortunately such cases are very rare; the general effect of the wave current, instead of being harmful, is distinctly beneficial, supplementing and reinforcing the local effects.

For this reason, in cases of doubtful pathology or doubtful location of the disease, the constitutional nutritive effects of static electrization or of the static wave current may improve both the local and general condition.

If the faradic current is used, the method of general faradization acts in the same way; if the galvanic, the method of central galvanization.

Much of the discouragement that has followed the use of electricity in disease has been due to the fact that constitutional diseases have been treated locally. Morbid constitutional conditions, such as hysteria and neurasthenia, anemia and rheumatism, which, as all are agreed, demand remedies that affect the system, have been treated electrically only through their local symptoms, such as peripheral paralysis, and gastric disturbance, or neuralgia and inflammation of the joints. These local symptoms may often be relieved undoubtedly by simple local treatment, but permanent relief can scarcely be expected from any treatment that is not general or constitutional.

When only the galvanic and faradic currents were at our command, it was far more simple and easy to give local than general treatment. Now, however, in the use of static and high frequency currents, local includes general treatment; consequently, the results are, in numerous instances, better than when the other modalities only were in use.

[Written for the MEDICAL BRIEF.]

Management of the After-Coming Head.

BY J. BUNYAN STEPHENS, M. D.,

Emeritus Professor of Obstetrics and Clinical Midwifery in the University of Tennessee. Nashville, Tenn.

In discussing the management of the aftercoming head, we must distinguish between those cases, first, in which the head has entered the pelvis and has only to overcome the resistance of the peritoneum; second, cases where the head is retained at the brim by pelvic contraction; third, where retained by stricture of the os uteri; fourth, by extension of the anus and chin; fifth, by insufficient expulsive action of the uterus and abdominal muscles.

The subject, as I take it, means the proper and most successful measures used in the delivery of the head after the body of the child has been expelled in cases presenting by the breech, feet or

knees, and since the mechanism and management of these differ but little, we class the two latter with the former. And since a proper understanding of the mechanism and management of the body which precedes the head has much to do in the successful management of the aftercoming head, I would therefore call attention, first, to the management of breech cases, at least to the particular points which we should remember are preparatory to the delivery of the head. We have, as we regard it, three causes, one or more of which, if the case is not managed according to Nature's mechanism, may result in the death of the child, viz., pressure on the umbilical cord; secondly, the severing of the utero-placental attachment while the head is delayed in the pelvis, or at the brim; thirdly, compression of the placenta between the fundus or walls of the womb and the head of the child; and may I not add another cause, viz., that of the too early pulling upon the body of the child by the physician in his haste to deliver, and thus dislocates the neck. By hastening the body through the pelvis, too, the uterus failing to contract as rapidly as the body advances, the arms by friction on the uterine walls are extended above the head, and by the same cause normal flexion of the head is lost and extension is produced, causing the chin to hitch on the pelvic brim, and a lesser diameter of the head exchanged for a greater one, one wholly unable to engage in or pass through the diameters of the pelvis.

None of the foregoing causes can result in the death of the child if the case can be so managed as to prevent the delay of the head, so on finding we have a breech case to contend with, the first point to be considered is the need of thorough dilatation of the soft parts preparatory to the easy delivery of the head; therefore, the liquor amnii should be preserved until it has done its full work in that respect, for another one of the dangers to which the child is exposed and which should have been mentioned in the foregoing list, is the defective dilatation of the os, which contracts about the head and neck of the fetus at the moment of delivery, causing death by asphyxia. In the management of all breech, foot or knee cases, presenting spontaneously, or made to do so by version; in order that the aftercoming head may pass the excavation in the best possible way the mechanism of both breech and shoulders, as well as that of the head, should be conducted in such a way as will, if possible, bring the head, well flexed, with its longest diameters (which when normally flexed is the suboccipito bregmatic) into the longest diameter of the pelvis. To do this we prefer the first position of the breech, in which the sacrum is found at the left ileo-pectineal eminence, or cotyloid region (left sacro anterior). In this the longest diameter of the breech (bistrochanteric) engages on the left or shortest oblique diameter of the pelvis, with the toes, after having passed, pointing towards and under the right thigh of the mother. And when such is the case, if not interfered with by meddlesome midwifery, the aftercoming head will meet with but little, if any, trouble in passing, from the fact that in this case the long diameter of the head on reaching the pelvis will engage in the longest of the pelvic diameters, the right oblique—it being the general rule for the head to take the opposite oblique diameter to that of the breech. In breech cases, therefore, it is best to do nothing but patiently wait until the birth of the breech, refraining from trying to hasten matters by bringing down the feet. Delay during early stages of labor is not dangerous, but prepares the parts by prolonged dilatation for subsequent easy passage of the aftercoming head.

When the body has passed to the umbilicus, gently pull down a loop of the cord and place it in that part of the pelvis where it will be least likely to pressure, viz., in the first and third position of the breech; if possible, in the left sacroiliac region, and in the second and fourth in the right. Its pulsations must be watched, its increased feebleness proclaims danger to the child. The body must be held in such a manner as not to impede rotation of the shoulders into the antero posterior diameter of the outlet, but, if necessary, rather favor it. When the shoulders are born, the back of the child is directed to the pubic symphysis and thus promote anterior rotation of the occiput and during the birth of the head lift the body

of the child towards the abdomen of the mother. That is to say, let the child be laid astride of one forearm, and the hand which belongs to it passed into the vagina until its first and second fingers rest upon the malar bone of each side, while the other hand is hooked over the shoulders, with the neck between the first and second fingers and their tips upon the supraclavical region. Let an assistant then press the head downwards by suprapubic pressure in the axis of the superior strait and both hands of the operator make simultaneous traction, as nearly as possible in the same direction, the internal hand at the same time exerting itself to preserve the necessary flexion of the head. As the head emerges let the line of traction sweep forward in the curve of Carus, until at the end the child rests upon the abdomen of the mother. I should add that when the mouth appears at the vulva all hurry should cease and the operator's efforts should be directed to the preservation of the perineum. All traction should cease and with the upper hand promote flexion by restraining the descent of the occiput, and the other used to shell out the head by pressure on the forehead through the perineum, or if necessary by passing two fingers into the rectum. This method (Deventer's, introduced in 1715, subsequently fell into disuse, only being brought into notice again three or four years ago by several prominent American obstetricians), is a simple and rapid procedure and is worthy of trial in any case where the shoulders can be readily brought into view. By this method the aftercoming head, even with the extended arms, can be extracted together by simple traction on the feet and shoulders.

The method is this: As soon as the shoulders have appeared at the vulva the body of the child is swung well backward, the feet being grasped by one hand and the shoulders by the other and both hands make traction simultaneously and directly downwards towards the floor. By this maneuver the arms, which lie by the side of the head, are pressed against the yielding and elastic sacro-sciatic ligaments, the chin being arrested by the pelvic floor; extension occurs, the occiput appears at the vulva, the head is born by extension, the occiput in front and chin in the rear, and the arms easily follow.

The advocates of the method believe that it never tears the perineum and my own rather limited experience with it certainly supports this somewhat astounding claim. The ease and rapidity with which the delivery of the aftercoming head can sometimes be affected by this maneuver is surprising. Further experience may develop contra-indications to it, such, for instance, as in dealing with a pelvis under normal size, or a head above normal in its diameters. In advising this method, reference is only made to those cases where the shoulders have appeared at the vulva and the head already in the pelvic cavity. Of course, it is inapplicable when the head and arms are arrested at the superior strait, for when the child is large or the transverse diameters of the pelvis is diminished, the wedge formed by the head and arms is often too large to pass the superior strait. In such a case the release of the arms must be effected before the head can enter the pelvis. The extraction of the arms from the superior strait is a much more difficult matter than their release after they have entered the pelvis and is effected by a different maneuver. Such an arrest occurs at or about the time when the points of the scapula appear at the vulva and before the back is wholly turned to the front; and unless it can be overcome by very moderate efforts, all traction should cease and the thorax should be grasped by both hands, pushed slightly upward to relieve the impaction and rotated, if necessary, until the antero-posterior diameter of the child is nearly, if not quite, transverse to the pelvis. The feet should then be seized by the hand which corresponds to the back of the child and drawn firmly upward and to that side toward the groin of the mother. This answers the double purpose of drawing the posterior arm further into the pelvis and of making room for the passage of the operating hand into the vagina. The free hand is then rapidly passed along the abdomen of the child to the posterior shoulder and one or two fingers are passed along the arm and hooked into the bend of the elbow, which is then drawn downward and across the face into

the vagina. The hand is then swept out of the vagina pressing upon the forearm, applied as near the wrist as possible, thus bringing the arm down and out. The feet are then drawn downward or backward, and the same hand is passed over the abdomen to the anterior shoulder and the attempt made to pass two fingers behind the symphysis to the bend of the elbow, which if reached is to be drawn downward across the face, as was the posterior arm. But if the attempt is not speedily successful, the hand should be withdrawn, and the hock of the child rotated across the front, that the retained arm may become posterior. This rotation can be effected in the interval of pain by grasping the thorax of the child with both hands, pushing the child slightly upwards and then rotating the thorax, or it can be done by traction in the proper direction upon the prolapsed arm. And when the retained arm is thus made to occupy a posterior position, it is then brought out, precisely as the first. In rotating the child it should always be remembered that the articulations of the neck are such that if the point of the chin be carried behind the point of the shoulder, dislocation of the atlas upon the axis is the result. For this reason the thorax should be pushed strongly upward whenever an effort at rotation is made, in order to free the head from the superior strait.

Should the circular fibres about the cervix, or an imperfectly dilated os, close down upon the neck of the child, which occasionally occurs, especially if ergot has been given, then the circumstances become much more embarrassing, and any attempt to overcome the obstruction by force exposes the woman to the most imminent danger of rupture of the uterus; and though steady and gentle traction should be given, which may effect dilatation in time to save the child, it is in these cases that the application of forceps to the aftercoming head is most often indicated. There can be no doubt of the truth of Lusk's observation that the forceps, which should always be at hand in such cases, will sometimes bring the head rapidly through the cervix, when traction upon the feet only serves to drag the uterus to the vulva. Care should, however, be taken that this rapidity be not too great as in itself to cause serious laceration.

Most German and American obstetricians believe that the use of continued traction upon the face and shoulders is the best method to adopt in arrest of the aftercoming head at any point in the pelvis, and it should certainly be the first method tried in any given case; but as cases frequently occur in which the head can be delivered with far greater ease by a rapid alternation between different methods than by the continued use of any one alone, it is for this reason, if for no other, well to be familiar with all the methods which have been found to be of value.

Prague's method is to seize the feet with one hand and draw the body backward as far as the perineum will allow; the other hand is hooked over the shoulder and traction made with both hands simultaneously; as the head enters the excavation the body is swung rapidly upward and the remainder of the delivery is accomplished by upward traction upon the feet, while the hand upon the neck promotes flexion by retarding the descent of the occiput. If by any clumsiness of the operator the abdomen of the child is directed to the front during the liberation of the arms, or otherwise, and the chin therefore arrested at the symphysis, the Prague method should be used throughout, only differing from it in this, when occiput is front, and at the brim, traction is first made backward; but in chin front and at symphysis traction is first made horizontal, and as the occiput descends the body of the child should be raised until, when the head emerges from the vulva, the line of traction is nearly parallel to the mother's abdomen. The only disadvantage to Prague's method lies in the fact that all the force exerted by the operator is expended on the child's neck, therefore less force can be safely applied than in the combined method.

At the present time many believe the use of the forceps to be the most certain means of overcoming difficult cases of high arrest of the aftercoming head. The operation, however, is often difficult and the time occupied in the application of the forceps may be of vital importance to the

child. Moreover, there are but few cases in which a skilled operator, especially if aided by supra-pubic pressure, fails to deliver by manual extraction; but as such cases do occasionally occur, the forceps should always be at hand before podalic version is attempted, or when we find an aftercoming head has to be dealt with. Fortunately, the arrest of the head by extension is rare, unless as the result of improper traction, and when it does occur may often be overcome by internal pressure on the face of the child, aided by suprapubic pressure on the forehead; but if this fail traction should be upward, over the mother's abdomen, combined with traction upon the shoulders; at same time with the opposite hand will draw the occiput over the perineum.

If forceps are necessary, they should be applied under the child's body and to sides of the head and should then be extracted by the same mechanism. When the aftercoming head is arrested at or near the lower strait it is extremely rare that the combined method will fail to extract it, but if forceps be required the application and extraction are both simple and easily performed. In ordinary forms of pelvic contractions the arrest of the head is always at the brim. A breech presentation should never be allowed to persist as such in a justo-minor pelvis. If the child is not under the usual size the head will always be arrested at the brim, unless extreme flexion is kept up, which is not likely to be the case. Cæsarian section would bring the best means of relief. Only in flat pelvis the head enters the superior strait in the transverse diameter and the passage of the strait is most easily effected in a slightly extended position, so that one pole of the bi-parietal diameter may be received by one of the sacro-iliac notches, while the lesser bimastoid diameter opposes the contracted conjugate. Then, if on passing the hand into the vagina for combined traction finds the head transverse, we should allow extension to go on until the face begins to approach the side wall of the pelvis, or until the greatest diameter has passed the superior strait, and when this has occurred flexion should be promptly effected, and rotation and delivery will promptly follow.

In using forceps for the delivery of the aftercoming head the axis traction appliances are particularly serviceable. In all cases of aftercoming head every means necessary for the restoration of suspended animation in the child should be provided beforehand.

[Written for the MEDICAL BRIEF.]

On the More Frequent Use of the Aspirating Needle as a Means of Diagnosis.

BY TRAVIS CARROLL, B. A., M. D.,

Professor of Surgery in the Cincinnati Polyclinic and Post-Graduate Medical School, Cincinnati, Ohio.

In this era of medicine, when the whole trend of things is toward the exact, where diagnosis of disease is not considered established until verified by chemistry and the microscope, it behooves the surgeon to follow the steps of his medical colleague, and before resorting to the use of the knife to fully confirm his opinion by every means possible.

As for instance, in the case of suspected abscess, it is not well to rely simply upon the local symptoms of pain, fluctuation, swelling, etc., but to make use of any more accurate means, notwithstanding how simple the case may appear to strengthen the diagnosis. It can hardly be denied that one of the most important instruments in attaining such an end in all cases of fluctuating tumors is the aspirating needle.

The use of this instrument in this connection is not new by any means, but how seldom, except in the most obscure cases is it resorted to? How often are we satisfied with the seeming correctness of our surmises, and jab a knife into a soft, fluctuating tumor without any thought of the possibility of a mistake, and sometimes to our great sorrow.

I know of two instances, in the hands of good surgeons, where axillary aneurisms were opened for supposed abscesses, and the patients' lives, in both cases, only saved by the employment of prompt and imperative measures.

It was once my misfortune to open a traumatic aneurism in this manner. The

patient on this occasion was an old woman, who, while drunk, had fallen and received a lacerated scalp wound extending down to the bone on the upper and posterior aspect of the head. The wound after being drawn together, healed nicely without suppuration in a few days. About four days after the patient's discharge, she presented herself again, complaining of a painful, inflamed, non-pulsating and fluctuating swelling at the site of the original injury. Thinking, as it so often happens in scalp injuries that it was a pus formation due to the early union of the superficial structures, thereby shutting off all drainage, I, without further thought, plunged a knife into the tumor, and was rewarded by a gush of blood that spurted at least three inches from the wound. It was a diffused aneurism. Because of my not being able to find from within the sac, the opening of the bleeding vessel, hemorrhage was arrested by understitching the artery through the scalp. Bleeding during the six succeeding days recurred five times from the sac, each time coming from a different artery, and was only finally and permanently controlled by the complete encircling of the wound with interrupted sutures, and by turning out a partly organized clot, curetting the interior, and packing the cavity.

While the result was all that could be desired in this case, the writer would have escaped a very unpleasant experience had he made use of the precision advocated in this article. Now, I make it a routine practice, no matter how evident the presence of pus in a certain locality may appear, to substantiate it by the use of the aspirating needle.

In opening an abscess, the advice generally given is to plunge the knife in quickly, thereby overcoming the resistance offered by the abscess wall, for it is well known how difficult it is, when this quick movement is not employed, to penetrate a soft pus cavity. This sudden stabbing motion has always seemed to me a very unsurgical procedure, which, in certain regions becomes extremely dangerous, as after the instrument is once started in this way, all control of it is lost until the limit set is reached.

In order to do away with the quick movement of the knife, and to minimize as much as possible the danger of injury to neighboring structures and organs, I have, for a number of years, made use of the following method in opening up pus collections:

An aspirating needle, made as thoroughly aseptic as possible, and attached to a hypodermic syringe, is inserted into the suspected abscess, and the presence of pus confirmed by its appearance in the barrel of the syringe upon withdrawing the piston. The needle is then partly withdrawn, so as to leave the point within the abscess cavity, then turned and made to transfix that part of the wall and the overlying structures, emerging again on the cutaneous surface.

Now we have the intervening tissues and that portion of the abscess wall held firm on the transfixed needle, so that now the incision can be made with care, and precision, excluding the possibility of cutting anything but the structure between the needle and the skin. If the pus is not deep, and so situated that no organ or structure of any importance is included between the skin and the needle, a knife is merely pushed along the needle as a guide, and the abscess laid freely open. In doing this, it is not necessary to extend the cut to include all tissue on the needle, thereby freeing it entirely, but simply make the incision as long as is necessary.

If, however, the abscess is in a region where there is a possibility of some important structure having been included in the transfixion, a careful dissection on the directing needle can be made down to the pus, and the wounding of such organs avoided.

It is well here to add that in making the transfixion, the needle should be directed so as to run parallel, as nearly as possible, to all neighboring nerves and vessels. The objection to the above method suggested by several surgeons, is that the lifting up and holding rigid of the tissues makes it more liable to injure important structures within them. This objection does not hold good, because any structure that must be divided or avoided can be better managed when held thus than if treated in any other manner. In

addition, any artery included can easily be felt pulsating on the needle, and thereby avoided.

In very deep collections of pus, it may not be possible to turn the needle and make the desired transfixion, then the incision may be made, simply using the needle as a guide. In one instance, in this manner, in a very old woman, whose family had always refused an operation, I was able to open an appendiceal abscess quickly and safely without an anesthetic.

In asking attention to the above methods of dealing with pus formations, it may seem like inviting one back to the rudiments of surgery, but when the many mistakes, often dangerous, that are made by disregarding the means advocated in this article of verifying one's diagnosis, are borne in mind, this subject will appeal as one worthy of serious consideration.

Epithelioma of the Skin.

BY J. M. KING, B. S., M. D.,

Professor of Clinical Dermatology, Medical Department, University of Nashville.
Nashville, Tenn.

It is unfortunate, indeed, that cancer of the skin is not more readily recognized by the general practitioners throughout the country. So often a patient having a suspicious looking growth on the face, lip, or hand, goes to his family physician for diagnosis and treatment, with utter disappointment. The physician will tell him that he can do nothing for him, and allow him to drift untreated, and even fails to direct him to a physician who makes a specialty of treating cancer along the line of ethical medicine. The patient, like hundreds of others, finally drifts into the hands of the quack. This is common report. It is our duty as practitioners of medicine, if we can not treat these cases, to direct them to men in our profession who have had a special preparation for this kind of work, instead of allowing them to fall into the hands of quacks.

No longer than this morning (May 23, 1905), I read the following, typewritten from the back of a slip of paper, upon which the physician had left his name, at my office:

"Personal: Send us names and addresses of all persons in your community who have cancer or cancerous growths. We will give you one dollar for each patient that we get from your list. ——— Co., Box 167."

Presented with such facts as the above, I consider it timely to review points to be observed in diagnosis of cancer of the skin, and to describe the best methods of treatment with their results.

Let us then first recognize that there are four clinical varieties of cancer of the skin: (1) flat, (2) papillomatous, (3) tubercular or deep seated, and (4) rodent ulcer. While practically the tissue changes with slight exception are the same in all four varieties, the clinical features differ somewhat more widely. Typical epithelioma of the first three forms most frequently begins at a muco-cutaneous junction, but may begin on the mucous surface or on the free skin. The dermatologist most often meets with it on the lip, nose, eyelids, or somewhere on the face. Rodent ulcer more often occurs on the free skin surface on the upper part of the face.

I. The flat epithelioma may begin in several ways: As a small, firm, pearly-looking papule; as a simple wart or mole; as a small keratosis; as a crack in the skin; and on the lip it may commence as a small abrasion, crack or small papule.

A beginning papular lesion on the skin becomes scaly and enlarges vertically and peripherally; at first it is movable with the skin, but finally it becomes adherent to the subjacent tissue, and ultimately within months or years breaks down and ulcerates in a characteristic form. The wart or mole, becoming cancerous, gets red, tender and painful, finally the surface breaks and bleeds, and becomes covered with bleeding crusts; this process continues, and is followed by ulceration. The crack in the skin of the lip oozing, becomes covered with crusts which are easily removed and readily reformed. Finally, the characteristic ulcer develops.

II. The papillomatous variety differs from the flat variety, in that it presents a more elevated, ulcerated, fissured, and warty-looking surface, and this appear-

ance is produced by an exaggerated development of the papillæ of the skin. This variety may begin in a warty growth, or may arise in the flat deep-seated varieties. In its slow growth from any source it usually becomes elevated above the surface, is red, with uneven surface, and may be pedunculated. Finally, the subjacent tissue becomes involved and the deep-seated variety is established.

III. The tubercular type may begin as a nodule located in the chorium or subcutaneous tissue, or it may arise from the other two varieties and from lupus vulgaris. When it begins as a nodule the nodule increases in size in all directions; the covering over it is a livid red and crossed here and there with dilated capillaries. After a few months, when it reaches the size of a cherry or larger, it breaks down and ulcerates. This variety progresses more rapidly than the others, and lymphatic involvement ensues very quickly.

IV. Rodent ulcer begins as a small, flat nodule, with dilated capillaries crossed over it, and it may remain in this condition for years before breaking down and ulcerating.

Sooner or later all the varieties ulcerate, and in the majority of cases some ulceration has taken place before the physician is consulted, and clinical diagnosis then depends upon the recognition of the type of ulcer together with its history and location; we should then possess a mental picture of these different forms of ulcers in order to make a diagnosis from the clinical appearance.

In the shallow typical epitheliomatous ulcer, the growth of the epithelioma is very slow, or the ulceration is chronic and usually covered with crusts, which are readily removed, leaving the red granular base, which readily bleeds upon disturbance, and is bound by an elevated firm rolled border. Sometimes this border has a whitish, pearly appearance, due to the crowded, round-celled infiltration shutting out the blood flow.

The ulcer of the deep-seated variety is more rapid in its growth, as the epitheliomatous development, the essential process, being more rapid. The border of the ulcer is more everted than elevated, but some parts of the edge may be undermined and irregular on account of the greater resistance of the integument. The base is irregular. The products of inflammation are too excessive to allow the formation of crusts; usually the discharge is sanious, but in some cases, probably on account of the secondary infection, there may be a heavy flow of pus; the neighboring lymphoid glands become quickly involved and there is usually neuralgic pain.

The papillomatous epithelioma fully developed presents an elevated, ulcerated, fissured, cauliflower-like surface. The discharge is scanty and there may be crusts in it.

A rodent ulcer is very characteristic, the white, pearly papules from which it develops spread outward, becomes depressed in the center and there ulcerates, and thus the ulcer from the very beginning is surrounded by the characteristic elevated, firm, waxy-like, rolled border. It spreads vertically and laterally, the rodent process slightly in excess of the new growth process attacking the tissue within the band, and in eight or twenty years may destroy one-half the face and eventually the patient's life. There is no pain, odor, no glandular involvement and very scanty discharge.

An early diagnosis and thorough treatment is of the greatest importance to the patient with epithelioma of the skin. The disease in the superficial forms is limited to the chorium for some years, because proliferation of the epithelioma is very slow, and the resistance offered by the fibrous layers of the chorium is so strong, but in time it breaks through this barrier and enters the subcutaneous tissue and develops the deep-seated variety with its lymphatic involvement, thus entailing much greater difficulty in treatment.

The chronic scaly patch on the face of the patient past forty, accompanied with but little itching, should be regarded with suspicion. I would advise in this case that the patient be treated with X-rays. An elevated cone-shaped mole, if it should get red and a little sore and painful, and continue so for some time, should be removed. The pearly, firm, flat papilloma, the size of a pea, developing after forty, and enlarging slowly, should be treated at once. A cut or crack or an

abrasion about the lip which oozes and becomes crusted, and repeats this process until it reaches the chronic state, should be treated without delay.

Superficial epithelioma may be treated successfully by one of three methods—surgical, caustics and X-rays. The X-rays produce the least disfigurement. The removal of all diseased tissue, outlying cells and involved glands is the object of surgical treatment, and anything short of this is not curative but more or less aggravating. If there is glandular involvement or deep-seated epithelioma of the skin, it is generally agreed upon at the present time that removal of the growth and the glands by X-rays offers the only hope of successful treatment.

Caustics, such as Bogars' paste, Marsden's paste, caustic potash, are used with success and good cosmetic results.

Rodent ulcer in the majority of cases should be treated with X-rays alone, as they offer the best results. In some cases, however, it will be necessary to remove some very thick rolled edges with caustics or curette, but we should depend upon X-rays as the curative agent. After considering the advantages of all the methods of treatment for this superficial variety of epithelioma of the skin, I would choose the X-rays. I believe we have in them an agent with which we can come nearer to destroying the outlying cancer cells than with any other means, and that by careful and thorough application the percentage of recurrence can be reduced.

The results obtained by me in three recent cases have been apparently satisfactory, and this is in accord with general reports.

The first case was in an old lady, aged sixty, with a superficial epithelioma on the forehead, near the edge of the hair. This growth had been twice removed by caustics with recurrence. I applied X-rays vigorously without producing any ulceration, with the result that the thickened rolled margin disappeared and the place looks at present perfectly healthy.

The second case was one of a young man aged twenty-one, with a small epithelioma of the size of a pea on the face to the left of the nose. This patient was treated with X-ray to the point of ulceration. Upon healing the surface was left perfectly smooth, a little red with pigmented area.

The third case was a lady forty years of age with epithelioma of the face just in front of the ear. This was removed apparently satisfactorily with the application of the X-rays.

Pusey and Caldwell (page 517), after reporting sixty-nine cases of epithelioma of the skin, with eighty-eight per cent symptomatically cured, the time ranging from two months to two years, say: "There is no reason to believe that there was any other method of treating any of these cases which could have shown as good results. There is less scarring than follows any other method of treatment. Again, the scars that are left are usually soft and smooth, the color of normal skin, or white and entirely healthy looking."

With reference to recurrence after X-ray treatment I refer to Sequeira, of the London Hospital, who has had an experience with more than one hundred cases. He says: "Recurrences are by no means rare, and the question that still is to be decided is whether relapses are due to the fact that some of the outlying cells have escaped the action of the X-ray, or whether they are true recurrences. Some of the cases we have met support the former contention. * * * As a matter of practical import, the recurrences are easily removed by further application of the rays."

Early diagnosis and thorough treatment by whatever means may be used while the disease is yet superficial, are the points to be insisted upon in epithelioma of the skin.

Minor Details of Physical Diagnosis.

BY L. C. STOCKING, M. D.,
Professor of Physical Diagnosis in Barnes Medical College.
St. Louis, Mo.

Many physicians lay great stress upon auscultation and percussion to the almost entire exclusion of other and important diagnostic factors. The day for superficial and "snap shot" diagnosis is past,

and we can not neglect the minor features of diagnosis, even though those features may seem at first vague or of little importance. To the observant doctor the little details which might pass unnoticed by a less carefully trained mind, will give the key to a situation otherwise impossible of accurate diagnosis. We should, therefore, not only drill ourselves, but teach the young aspirant, to know the importance of these minor details. Inspection and palpation are too often hurried over, while percussion and auscultation occupy the whole attention, and thus it happens that such important diagnostic points as pallor, pinched expression of the face, pulsation of the arteries and veins, and position of the patient, seldom receive any attention.

Physical diagnosis does not mean merely to pound and listen; it involves the aid of all the senses to a minute degree. The patient's expression and physique must be studied, his temperament is not a thing to be forgotten. The day for looking at the tongue and feeling the pulse and uttering an immediate diagnosis is past. We must study the physiognomy of our patient; the facial signs are valuable diagnostic agents.

Emaciation, in case of shock, is, for instance, almost the first diagnostic sign which attracts our attention; the oscillating pupil readily diagnoses another condition, and so on indefinitely. The position of the eye is almost a pathognomic symptom in certain conditions.

How characteristic is the position of the lung in certain phases of pulmonary diseases. In asthmatic conditions the patient is unable to lie down, but sits up and grasps the side of the bed chair to assist in bringing into use the auxillary muscles of respiration.

In spinal troubles, the position is also characteristic.

The skin may often give a clear knowledge of the condition of the circulation, and the character of the secretion.

The eyes need to be carefully watched. Here at times we can obtain signs which give us a diagnosis that would otherwise fail. The unconscious man will at first tell us of his condition by an examination of the eye. In opium poisoning we have the pin-point pupil; in uremia we have the dilated pupil; in other conditions we have the unequal pupil, etc.

In giving an anesthetic we must carefully examine the eye for danger signs.

The condition of the tongue will tell us of impaired mobility, one-sided or unequal activity tells us of brain lesion. The dry tongue tells us of deficient secretion; the excessive use of mercurials will cause the opposite effect, salivation. The coloring and coat of the tongue should also demand our attention.

Boiling Water vs. the Knife.

BY R. G. COPELAND, M. D.,

Professor of Operative and Clinical Surgery in the Birmingham Medical College; Surgeon to the Hillman Hospital; Local Surgeon for the Southern Railway Co.; Surgeon-in-Chief for A. G. S. Ry.; Professor of Oral Surgery in the Birmingham Medical College, etc., Birmingham, Ala.

This subject is selected to advocate the boiling water treatment in non-malignant growths, and the destruction of veins and sinuses. There are numerous applications to the surgeon for relief from varicose veins, small aneurisms, ranulæ, venous angiomata, and capillary angiomata. From fear of the knife, these patients, both in the adult and child, refuse to be operated on, the individual in the first and the parent in the second instance. This includes a class of patients that can not be reached or cured except by the promise that a knife will not be used, and is contraindicated, but an almost positive guarantee that they will be cured by the injections of boiling water.

These patients do not object especially to an anesthetic, either local or general, but believe that the knife is injurious.

To illustrate: P. G., referred to me by Dr. M. for varicose veins of the left leg. All superficial veins of the leg, internal and external, were really sinuses. This man objected to any operation involving the use of the knife, although he was told that cocainization and ligation of the veins at various points would effect a cure. The entire leg and foot was an eczematous and annoying mass.

Boiling water was used after an Esmarch bandage was applied in the lower

third of the thigh where the veins began to show varicosity. About eight injections were used, one in the lower portion of the thigh, about four on the inner, and three on the outer side of the leg.

As on former occasions, the skin blanched, and the surface became very warm, and it was freely noticeable to all present the change that was taking place in the vein as the boiling water was forced in.

Several sloughs appeared at the site of injection. This patient was in the infirmary twenty-four days; after leaving his recovery was rapid and uneventful. The eczema at the present time has almost entirely disappeared, and he is no more annoyed by the itching and burning sensation that was always present, to say nothing of the "weeping," which is very annoying in these cases.

Oral Disturbances from Pyorrhea Alveolaris.

BY HERMANN PRINZ, M. D., D. D. S.,

Professor of Oral Pathology and Therapeutics, Washington University.
St. Louis, Mo.

"Nothing is permanent but the change." The truth of this aphorism holds good in all existing conditions of living organs. A standstill of bodily activity means death—a final dissolution of all organs concerned. Health and sickness, viz., ease and disease, are interdependent upon the perfect working order of all the organs of the body. Imperfect activity as a result of disturbance of the organism, in part or as a whole, will find its expression as local or general disease, which may assume an acute form, and if continuous for a longer period, a chronic type.

At present it is generally recognized that the breaking down of highly organized bodies, when subjected to proper conditions, is brought about by the activity of minute vegetable organisms, the bacteria, producing what is generally known as fermentation; or, under other conditions, putrefaction. The presence of bacteria is primarily instrumental in producing various severe vital changes, which are known as infectious diseases.

One of the diseases which is exclusively confined to the oral cavity, and perhaps the most prevalent type of local infection, is "pyorrhea alveolaris." This disease, next to syphilis, has received the greatest variety of names, which is largely due to the fact that its etiology is still veiled in mystery. The definition, as set forth by Miller in his text-book, is about as satisfactory a one as can be presented under the present pathological conception of this disease. He defines it as a chronic, destructive inflammation of the peri-dental membrane, accompanied by more or less severe inflammation of the gingivæ, and a necrosis of the alveolar process within the area of the affected tooth. That we have no definite explanation of the true causation of this disease finds its explanation largely in the following factors:

1. We still know very little about the pathology of the disease. The material for such experimental work is very difficult to obtain.

2. We have absolutely no critical starting point of the disease. The ordinary symptoms by which it is recognized are the presence of pus, the formation of the pocket, the loosening of the tooth, etc.

3. The incorrect conception of the pathology of the disease has led to a whimsical adherence to old established methods of empirical treatment.

In recognizing an infectious disease it is of importance to remember that two predominating factors are responsible for its existence, the cause of the disease and the action of the disease. From a clinical standpoint we may classify the predominating factors of pyorrhea alveolaris into predisposing causes, local disturbances and bacterial invasion. As predisposing cause we may mention such diseases as scorbutus, rickets, locomotor ataxia, dyspepsia, rheumatism, tuberculosis, anemia, chlorosis, etc. Local disturbances are usually resultant from mechanical or chemical causes or from traumatism. As has been stated, the disease manifests itself in a more or less severe inflammation of the gingivæ, flowing of pus from the alveolus, and the loosening of the tooth. If the tooth is still solid,

tapping with a metallic instrument induces a peculiar sound, and a fremitus which is easily felt by placing the finger over the affected root. The deposit of calcareous material about the tooth is probably the most prominent factor in the production of the disease. This "tartar," as it is called, is not of the soft, yellow, salivary variety, however; it is most likely a special product of crystallization, derived from the exudations of the mucous glands, or some other liquids derived from many sources, which hold lime salts in solution; these deposits are very hard, with sharply-defined edges, of a deep dark color and clinging very tenaciously to the root. They are usually found beneath the free margin of the gum, and the irritation produced by these sharp spiculæ lessens the resistance of the gum to microbic infection, and, consequently, pus infection with all its sequelæ will follow. No distinct micro-organism has so far been found as being productive of this disease. The pus is the result of a mixed infection, the strepto- and staphylococcus are always present in this pus.

As far as the treatment of this disease is concerned, surgical and local therapeutical applications are most important in bringing about an arrest of the progress of the disease. They consist primarily in the mechanical removal of the calcareous deposits. Easy as this seems to be, special training and a thorough knowledge of the anatomical arrangement of the parts is required. Perfect articulation of the teeth should be established and splinting of loose teeth should be obtained by proper bandaging; necrosed tissue should be destroyed, and a stimulating drug applied to influence cell proliferation. General treatment is often indicated, particularly if a general disease is the underlying factor. This, however, is usually of secondary value. The general hygiene of the mouth should be scrupulously maintained, and the masticating apparatus should be in perfect order, for well-chewed is half digested. The harmonious nutrition of the body depends, not upon the quantity of food swallowed, but upon its proper mastication and digestion. Disturbances of the digestive apparatus and many of the more obscure diseases, especially those of the jaws, ears, and the extremely painful neuralgias, can be only too frequently traced to diseased teeth. The preservation of the teeth by prophylactic means should become an unalterable part of the daily toilet. Suitable antiseptic dentifrices are necessary. The full effect of a dentifrice, however, can only be derived when it is employed in the form of a wash. Powder, paste or soap can not do this work satisfactorily, although they are helpful for mechanical cleaning. The destruction of the disease-producing organisms and their removal can only be accomplished by a liquid which will penetrate into the interstices between the teeth. Especially potent in this respect is the presence of free oxygen, which, when brought into contact with decayed matter, will be accompanied by the production of a heavy foam, which forces the material from between the teeth to the surfaces, and from places where the brush can never reach. An effective germicide should be added to the solution. It should be borne in mind that such washes must be absolutely harmless to the hard and soft tissues of the mouth. Absolute cleanliness of all the parts must be maintained and visits at stated intervals to the dentist or physician are necessary to prevent a recurrence of the disease.

Cholera Morbus.

BY ROLLA L. THOMAS, M. D.,

Professor of the Principles and Practice of Medicine in the Eclectic Medical Institute, Cincinnati; Dean of the Faculty.
Cincinnati, O.

Cholera morbus is an acute affection characterized by nausea, vomiting of serous material, frequent watery stools, colicky pains, and severe muscular cramps, and attended by great prostration.

Etiology.—This is a disease of hot weather, beginning in June, increasing in frequency during July and August, and usually disappearing in September. Bad hygienic conditions predispose to cholera morbus, though the exciting conditions are unripe or overripe fruit, indigestible vegetables, such as cucumbers, radishes, eggplant, etc. Drinking large quantities

of ice water when overheated, or tainted milk or water may also be considered as excitants. It is more frequent among males than females, and among adults than in children, though cholera infantum may be considered the cholera morbus of infants.

Pathology.—No characteristic anatomical changes take place. In some cases, catarrhal changes peculiar to gastro-enteritis are found, while in others no morbid changes are seen.

Symptoms.—The attack generally comes on suddenly, not infrequently in the night, and is announced by pain in the umbilical region attended by nausea, which soon terminates in vomiting. At the same time the patient has an urgent call to stool, which is large, copious and feculent in character. In a short time the retching and call to stool is almost constant and the pain in bowels is intense. The stools vary in character, at first of greenish or yellowish brown color, copious in quantity and of a fecal character; as the disease progresses, however, they early lose their fecal character and consist of a dirty water, even resembling the rice water discharges of cholera.

Very early cramping of the muscles of the legs, toes and sometimes of the abdominal muscles ensues, which is exceedingly painful and causes the patient to cry out with his great suffering. In extreme cases the spasmodic contraction of the muscles amounts to episthotonus.

The prostration is now extreme, the pulse is small, feeble and frequent, the eyes sunken, the face blue and pinched, the extremities cold, the skin becomes relaxed and bathed in a cold, clammy perspiration. If not arrested the patient's strength is gradually exhausted, the patient becomes dull and careless as to his condition, then finally coma and death result. Fortunately this is a rare result, and before the alarming symptoms appear, the disease seems to have expended its force, the vomiting and diarrhea subside and the patient makes a speedy and uneventful recovery, so that after twenty-four or forty-eight hours he is seemingly as well as ever.

Diagnosis.—We diagnose the disease by the large, copious, watery evacuations, pain in the abdomen, retching and vomiting, great prostration and cramping of the muscles. Unless Asiatic cholera was prevailing at the time it could hardly be mistaken for any other disease. Arsenical or ptomaine poisoning would be recognized by the history of the case.

Prognosis.—The prognosis is nearly always favorable, if seen reasonably early. When the patient is old and feeble or a sufferer from Bright's disease, or structural heart lesions, the prognosis must be guarded. If not seen till the stage of collapse, a fatal termination may occur. The only fatality I ever knew in this disease was of this character.

Treatment.—Direct a mustard plaster to the abdomen and hot water bottles to the feet. Internally from a half to a teaspoonful of the comp. tinc. of cajeput every fifteen or twenty minutes will afford speedy relief. If the pain be severe one teaspoonful of chlorodine may be added to ten teaspoonfuls of water and a teaspoonful of the mixture given every fifteen, twenty, thirty or sixty minutes. Or what is better and much quicker in its results, a hypodermic injection of sulphate of morphia—the dose will be from one-fourth to one-half grain, according to the severity of the symptoms. This will not only relieve the pain, overcome the cramps, but generally allays the vomiting and diarrhea.

For the diarrhea, nux vomica and subnitrate of bismuth both prove beneficial. When there is coldness of extremities, a relaxed skin and threatened collapse active measures must be used. Hot applications are to be made to the feet and legs and trunk, or the limbs are to be rubbed vigorously with dry mustard. In extreme cases the patient should be rolled in a blanket wrung out of hot mustard water. Internally, comp. tinct. of cajeput should be given, and strychnia, one-thirtieth grain, be given hypodermically, or what is better still a five per cent solution of camphor and ether administered hypodermically. The dose will be from twenty to thirty-minims as often as the heart's action demands its use.

At the same time a pint of normal saline solution should be given subcutaneously. The diet should be restricted for a few days following convalescence.

Treatment of Yellow Fever.

BY GEO. H. TICHENOR, JR., A. B. (TULANE), M. D. (TULANE),

Yellow Fever Expert for Louisiana State Board of Health, 1905; Nominated by Nicaraguan Minister to United States for Membership in Yellow Fever Institute, etc.
New Orleans, La.

Treatment for First Three Days.—Bowels must be flushed to the extent of fifteen to twenty-five actions per day with saline purgatives, preferably either thiosulphate of soda or epsom salts. Fever reduced by hypodermic injections and enemas of saturated solutions of common table salt, one every three or four hours. The hypodermic injection to be made in the same spot, thus avoiding pain to the patient.

Treatment for the Fourth Day.—Vegetable drugs, combined with ipecac, given in small and repeated doses to act on the liver. The liver must be well purged of bile. Use a good heart remedy to stimulate and prevent hemorrhages, when such is required.

Patient must be allowed to drink plenty of water at all times, as this flushes the secretions, especially the kidneys. Patient must not be allowed to eat anything for the first five days of sickness, only water to be given, not even milk. To eat means sure death.

During convalescence food must be given in liquid form for the first few days, afterwards solid food, at the discretion of the physician.

Physicians must use their own judgment as to dosage of drugs mentioned and when required. Drastic cathartics are especially harmful. Calomel, except at the very commencement of the disease, is harmful. Any form of arsenic must be especially avoided. There is no indication for any use of any form of arsenic during the whole course of the disease, or afterwards. Peroxide of hydrogen has been used in South America with some success on the third day of fever to remove contents of stomach and bowels, but care must be taken that it does not inflate the bowels too much, thereby rupturing them.

I have found sulphate of soda too inert and slow in action to be of any benefit in yellow fever.

Patient must be kept cool, having all the windows open, and under no circumstances must he be bathed, either with hot or cold water, during illness.

The sanitary regulations of the Marine Hospital service regarding mosquitoes must be enforced.

There is no prophylactic against yellow fever, other than such drugs that tend to flush the stomach and bowels, such as thiosulphate of soda.

Spasmodic Laryngitis.

BY KENT O. FOLTZ, M. D.,

Professor of Otology, Rhinology and Laryngology in the Eclectic Medical Institute, Cincinnati; Author of "Diseases of the Nose, Throat and Ear." Cincinnati, Ohio.

Spasmodic laryngitis is always an inflammation of the laryngeal and tracheal mucous membrane, with an associated spasmodic contraction of the laryngeal muscles. This causes a cough, difficult respiration, stridor and sometimes dyspnea. The spasm is not dependent upon the amount of inflammatory action. When supraglottic there is often spasm, while if subglottic, a true or membranous croup is the condition, but both forms may exist. A neurosis may cause laryngeal stridulus without inflammatory action.

Etiology.—An inherited tendency is often present, and any state of the system causing a lowered vitality will predispose to this condition. Colds are the most frequent exciting factor. It is not infrequently found as a precursor of children's diseases.

Symptoms.—The attacks may occur at any age from a few months to ten or twelve years old. Usually there is some cough and symptoms of coryza preceding the attack, but often there are no premonitory symptoms. The attack is most frequently between ten and two o'clock at night. After a natural sleep, varying in duration, the child awakes with a loud, rasping, wheezing, asthmatic cough, the

respiration is very labored, and on inspiration there is a peculiar whistling sound. The face is markedly flushed, and there is an anxious and terrified expression. The child will usually cling to the attendant as if in terror. The pulse, on account of increased vascular tension, the result of the impaired respiration, will be rapid and hard. The duration of the attack varies from half an hour to two or three hours. Infrequently there may be two or more attacks the same night, but usually they are repeated on successive nights. As a result of the coughing and forced respiration, there is usually a decidedly inflammatory action following the paroxysm. A hoarse, croupy cough, with an excessive catarrhal secretion, often lasts for several days, and if a decided cold has been contracted, a catarrhal pneumonia may result.

Diagnosis.—Not infrequently this is mistaken for pseudo-membranous croup, but in the latter the disease is insidious, the cough, which is present increasing gradually, and does not abate during the day. In spasmodic laryngitis the paroxysm is sudden and rapidly reaches the climax, and invariably occurs at night. The cough is loud, wheezy, and dry, and change in the voice is simply the result of impaired respiration, and is sudden. There is slight or no inflammatory action of the faucial structures. In true croup, on account of the membrane, the cough is harsh and rough, and increases in severity. The voice is changed, owing to the presence of the membrane, but it is gradual.

Prognosis. — Usually favorable, as rational treatment will generally effect a cure. Fatal results may follow in some cases, so the general condition of the patient must be considered.

Treatment.—The relief of the spasmodic action of the laryngeal muscles and alleviation of laryngeal inflammation are important. Placing the child in a bath, I consider barbarous. The treatment I have found most beneficial was employed by my father in over forty-five years of active practice, a large proportion of his work being among children. The child should be allowed to remain in its crib or bed. No extra clothing should be placed over it. Plenty of fresh air admitted to the room, but the temperature should not be allowed to drop below 60° F. Emesis is seldom if ever required.

The following is given:

℞ Sp. Aconite.....3 to 5 drops.
Sp. Ipecac.....8 to 15 drops.
Aquæ, q. s.

Mix. Teaspoonful every fifteen minutes for an hour, then every half hour or hour.

In the majority of cases, the child will be sleeping quietly before an hour has passed. The medicine can be continued during the waking hours, giving it every two hours, and it will relieve the irritation of the mucous tissues, preventing a recurrence of the attack in many cases. The production of emesis simply takes the strength of the little patient, and renders it more susceptible to subsequent attacks, and often with a fatal termination. During the intervals of the paroxysms, or following a single attack, such hygienic and medicinal measures should be instituted as will lessen the susceptibility of the patient to climatic changes.

Report of a Case of Subcutaneous Rupture of Femoral Artery.

BY JULES LAZARD, M. D.,

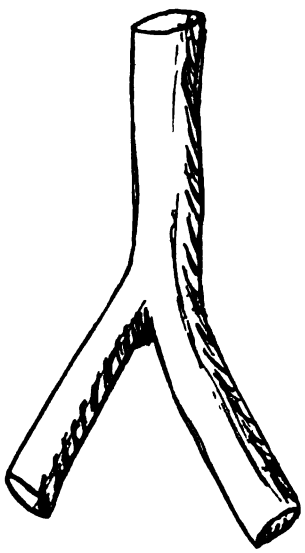
Visiting Surgeon, Charity Hospital, New Orleans; Professor of Physiology and Urinology in the New Orleans College of Pharmacy.
New Orleans, La.

The following case illustrates a condition which seems to be rather rare, and is, therefore, considered of sufficient interest to report:

A young white man, robust, healthy, was admitted to the hospital at 11.15 P. M., having sustained serious injuries in a railroad accident at 10.30 P. M. He complained of great pain in his feet, and thirst, though he had been drinking water constantly on the train the thirst was not relieved. His pulse was weak and skin pale. He was given strychnine and digitalis, and morphine hypodermically.

Hospital examination revealed a compound fracture of all the toes of the right foot excepting the little one a lacerated wound over the outer malleolus; and a large lacerated wound of the left popliteal space, dissecting up the skin for two

inches. This wound bled freely. Under chloroform anesthesia they were thoroughly cleaned and sutured, and the second toe of the right foot amputated; in the meantime a constrictor was applied over the left femur to control bleeding of the left side, which was subsequently sutured. Infusion at this time was thought unnecessary. Nothing abnormal was noticed in the upper part of the left thigh. He was under chloroform for an hour and twenty-five minutes. Strychnine and digitalis were ordered to be given every four hours. He was seen again at four A. M. There was now extreme pallor and sighing respiration, great restlessness and insatiable thirst. Pulse almost imperceptible. The foot of the bed was raised, and warm bot-



tles placed around the patient. At nine A. M. his pulse was imperceptible. The restlessness and thirst increased. His left arm was quickly prepared, and three pints of normal salt solution (saline) 112° F., injected into his venous circulation. His pulse became stronger, and some general improvement followed. A large swelling with much discoloration on the upper surface of the left thigh was noticed for the first time. He gradually sank and died at 11.40 A. M.

Autopsy showed besides the other wounds related above, quite an extravasation of blood in the intermuscular plain and subcutaneous tissue, especially over the sartorious muscle of the left side, the sheath of the femoral muscles was filled with blood as low as the knee, and as high as Poupart's ligament.

Careful dissection for the removal of the femoral artery showed that the vessels had ruptured in the angle of the superficial and deep femoral arteries. (See drawing.)

A Preliminary Study to Urinary Analysis.

BY W. R. INGE DALTON, M. D.,

Former Professor of Dermatology and Syphilology, New York School of Medicine; Dermatologist and Syphilologist, Metropolitan Hospital and Westside German Dispensaries; Member of the American Medical Association and President of the Medico-Pharmaceutical League, New York City, Seattle, Wash.

A concise and definite analysis, in order to find the etiologic factors of disease so that remedies may be prescribed intelligently, is now regarded by up-to-date physicians as essential—absolutely necessary—to effect a cure. Previous to a chemical analysis there are certain physical properties which are presented for study. The first characteristic physical property is color. The average distinctive color of a healthy adult's urine is a light amber, rather inclined to a yellowish hue, deriving its color from the pigment deposits of urobilin, entirely separate from those pigments formed by the liver, which last are parts of the biliary excretions. Urobilin is always elaborated from the hematin of the blood—a conceded fact. Where this fluid is of an excessively high color, with a low specific gravity, we may look for a greatly lessened quantity of urea, and right here we may be led astray, jump to an erroneous conclusion, and ascribe the condition to an excess of urea in cases of this kind. Look out for a rheumatic tendency, an inadequate functionizing by the liver, and numerous skin lesions in specimens of this order.

The amount of coloring matter, then, will determine several diagnostic features; when in augmented amount, we know it denotes urobilinuria. The liver is over-

taxed in work; it refuses to perform its physiological function of transforming the degenerative red blood corpuscles, the ptomains, toxins, the free blood pigments and the other poisonous elements of the blood into normal bile fluid, which flows into the duodenum, thence into the intestines, and, through the lacteals and absorbents, into the general circulation, whereby, in consequence of this increased labor, the liver cells become impaired, causing a decrease of physiological metabolism. From this condition of the liver we may note a protean number of skin diseases, chloasma, leucoderma, furunculosis, etc.

As to the light color, it is generally due to an increase in the output of water, demonstrating some disease of the kidney. This kind of urine, by its color, shows it to be of alkaline reaction. When the color assumes a blackish tint, unless caused by carbolic acid, we may infer that we have to deal with cancer of a melanotic variety. When the color is greenish, it proves biliary jaundice (icterus), hence, follow a large number of cutaneous affections. When we note a markedly light color on examination, with high specific gravity, we may confidently expect to find eczema, psoriasis, urticaria, erythema, etc., following glycosuria, or diabetes. On the contrary, a highly colored sample, with low specific gravity, taken with an increased amount of urea, infers urobilinuria, caused by a liver disease. Thus, the color of the number of pigments to a specified sample will certainly determine great knowledge of its pathology. As to the acidity or alkalinity of the sample to be examined, if it is highly acid in reaction, upon the application of heat, the earthy phosphates will not form deposits, and the sample will be clear and transparent! These phosphates are soluble in acids; when the specimen is alkaline, they may be precipitated, even before heat is applied. Specimens may differ from day to day, owing to this change from acidity to alkalinity, and vice versa. If we wish to have a precipitation of the phosphatic deposits, the addition of potass. liquor, or liquor ammoniæ, will show them. When due to the phosphates we have a cloudy urine and a phosphaturia results. Nearly all diseases of the skin, which are caused by this condition, are associated in their etiology with neurosis of some kind. When we add an acid to our specimen after subjecting it to heat, and the transparency is lost, it assumes a cloudy appearance, due to serum-albumen, pus, or blood, and if it is not affected in any degree by the acid addition, it may be, and most likely is, due to micro-organisms or to mucus. They may be readily discriminated on microscopical examination. When we find tube-casts, we may rightly infer them to be due to serum-albumen.

The specific gravity ought to range from 1014 to 1025 or 6. In interstitial nephritis we have a low specific gravity, and if continued, uremia surely follows; if of high specific gravity, diabetes ensues. We must seek the cause of turpidity or cloudiness in urine, to arrive at right conclusions, in order to ascertain by these analyses the physiological significance of the abnormal conditions. When the urine becomes viscid, and of a tenacious consistency, there is sure to be varying amounts of pus, fibrin, or mucus, and if, after some hours, it becomes of a jelly-like character, there is some inflammation of a fibrinous kind in the kidney, ureter or bladder. From the basic phosphate of sodium in the blood we get the normal acid reaction of the urine. Acid salts, by osmosis, permeate animal membranes readily, which explains why an acid urine is secreted from alkaline blood. We must differentiate, however, when it is truly alkaline, and when due to ammonia (caused by a volatile alkali), or to a fixed alkali caused by the phosphates of sodium or potassium. It is quite important to make these distinctions because of the innumerable skin diseases springing from conditions of the blood, when due to a fixed alkali.

It has been my practice, based upon the theory I enunciated at Atlantic City before the American Medical Association five years ago, to effect the cure of all skin diseases by a rigid treatment of the blood, from the stomach contents down, and through the absorbents and lacteals, into the circulating current. I now still more confidently adhere to that theory of

"The Causes of Skin Diseases Due to Hyper-Acidity"—that the chyme, as it reaches the duodenum (transformed into chyle), is so hyper-acid that it prevents physiologic metabolism.

[Written for the MEDICAL BRIEF.]

Pregnancy Complicated with Inflammatory Disease of the Pelvic Organs.

BY HENRY C. COE, M. D.,
New York City.

This division of the subject is such a broad one that I can do little more than touch upon its main features in order to keep my paper within proper limits.

I shall discuss briefly: (1) inflammatory conditions of the uterus; (2) of the adnexa; (3) of the peritoneum and pelvic connective tissue; (4) of the urinary tract; (5) of the rectum, with a few remarks on the important subject of appendicitis complicating pregnancy. As I shall draw entirely upon my personal experience, references to the literature will be omitted, also the discussion of etiology and pathology.

Uterus.—Acute endometritis is certainly a rare complication of pregnancy. It has been described in connection with infectious diseases and the acute eruptive fevers. A streptococcus infection may follow unsuccessful attempts at criminal abortion. I recall one case which terminated fatally at the sixth month, but as the fetus was macerated, I was unable to say whether the condition of the endometrium was primary or secondary. Acute gonorrheal infection of the pregnant uterus is fortunately infrequent, though the subacute or chronic form of inflammation is often met with in hospital practice, and is, in my experience, a cause of premature delivery which is often unrecognized. Its bearing on puerperal endometritis, mixed infection, etc., must not be lost sight of.

Chronic catarrhal endometritis (with accompanying watery discharge, sometimes very profuse) cystic endometritis and diffuse hyperplasia of the decidual endometrium, all deserve mention. I have always regarded them as representing the exacerbation of previous affections of the endometrium under the influence of the increased congestion of pregnancy. That they are important from a clinical standpoint is evident from the frequency with which they lead to premature expulsion of the fetus.

The treatment of acute endometritis (whether septic or gonorrheal) would follow the ordinary rules. An infected pregnant uterus should be emptied without delay, since there is no chance for the fetus, and the safety of the mother demands prompt treatment. Acute cervical gonorrhea requires strong injections —sulphate of zinc, or bichloride, and applications of nitrate of silver within the cervical canal. The interests of the child are to be considered, especially during the latter months of pregnancy. But the best treatment is prophylactic—thorough curettement and cauterization of the uterine cavity as a preparation for a subsequent pregnancy. The good effects of the treatment are shown in the case of patients who have repeatedly miscarried previously. The lighting up of a latent gonorrhea under the influence of impregnation I have noted in several instances.

Diseases of the tubes and ovaries complicating pregnancy I would classify under two heads—acute inflammation, and the exacerbation of previous trouble under the influence of pregnancy. It is not easy to decide under which category a given case belongs, especially if a clear history of former disease of the adnexa can not be obtained. That acute oöphoritis of a severe type may complicate pregnancy has been shown in a previous paper of mine. In one case reported the patient, after receiving a blow in the left groin, developed local pain and tenderness with fever ranging from 103° to 107° F., for six weeks before I saw her, when she was at the fifth month of pregnancy. An abscess in the left side (doubtless ovarian) emptied into the bladder, and after a long convalescence she went on to full term and had a healthy child. The patient has since had another child and is now quite well.

The diagnosis in this case was based on the history of traumatism, the localization and severity of the pain and the virulence of the inflammatory process, which I have found to be characteristic of

acute ovarian abscess. The prognosis in this, as in similar cases, was grave. That the patient did not miscarry and succumb to the prolonged strain upon her vital powers was due to her excellent condition.

The question of operative intervention must always arise, and if the abscess can be clearly located the surgeon's duty is clear. The lateral incision is naturally preferable, as it may be made without interrupting pregnancy. If a celiotomy is done, it would seem wise to make the incision along the outer border of the rectus rather than in the median line. Certainly a median section after the fifth month of pregnancy would be attended with serious risks of infection (even if the abscess has not ruptured), and a miscarriage would doubtless occur and still further complicate the situation.

Regarding the vaginal incision of an ovarian abscess, I admit that the risks of infecting the uterine cavity is great, but from my experience in a few cases I believe that with care they can be avoided. With pus clearly pointing in the posterior vaginal fornix the patient stands a better chance if it is evacuated per vaginam, the cavity thoroughly disinfected and a T-tube is inserted, than if the abscess is allowed to rupture spontaneously.

Peculiar interest is attached to the question of the influence of pregnancy upon pre-existing disease of the adnexa, especially when viewed from the standpoint of modern conservatism. The prognosis is naturally uncertain. How often do we regard conception in some of our old ovarian or tubal cases as a veritable calamity, yet pregnancy is attended with minor disturbances and labor and the puerperium run a physiological course! The way in which exudates sometimes soften and disappear, adhesions are stretched and imprisoned adnexa rise up out of the pelvis with the growing uterus, upsets all our theories and prognostications. I recall one instance in which a multipara, married several years, had a narrow escape from hysterectomy. She bore two children in the most normal way, her adnexa having been supposed to be hopelessly diseased. But such exceptions do not justify too great hopefulness. Even the simplest varieties of cystic or hyperlastic oöphoritis, with limited adhesions, may be attended with more or less constant pain, with a distinct exacerbation of the trouble after delivery, or abortion or premature delivery may result from the imprisonment of the uterus. The pain alone, unless constant and unbearable and attended with considerable enlargement of the uterus, I would not regard as an indication for laparotomy, though I can conceive that there might be cases in which it would be proper to empty the uterus. That a cystic ovary may become a true ovarian cyst under the influence of the increased pelvic congestion I have noted in several instances, in which celiotomy was performed without disturbing the pregnancy. I would not hesitate to open the abdomen or to break up periuterine adhesions if the indications were clear.

Tubercular disease of the adnexa is distinctly aggravated. In one instance the pregnancy and labor were normal, but the patient developed acute tubercular peritonitis and died three weeks after delivery. In subacute inflammatory conditions the outlook is more serious. Here the influence of pregnancy is decidedly bad. The probability of a fresh infection from the side of the intestine to which diseased ovaries and tubes are adherent should always be borne in mind, hence the importance of careful attention to the bowels in these cases. This point is still more important in connection with the next inflammatory condition which may complicate pregnancy.

That acute appendicitis may develop during pregnancy is unquestionable, still I believe that the recurrent cases are far more frequent. There is little doubt that the chronic constipation so common in women at this time is a potent factor. I am sure that I have aborted several attacks by free purgation, by irrigation of the bowel and the use of an icebag. One of my patients had a mild attack with three pregnancies, and eventually had an internal operation. Another went through her pregnancy, terminating in a difficult instrumental delivery and had an acute attack and a successful operation when her baby was six months old. In a third case (first attack) I was prepared to operate upon a primipara in the fifth month, but the acute symptoms subsided and she

miscarried a few days later, her physician informing me that she has since been quite well.

I have had under observation a primipara four months pregnant, who was operated upon successfully, a suppurating appendix being removed without disturbing the pregnancy. Some years ago I assisted in a similar case in a woman at the seventh month. The uterus formed the inner wall of a large abscess, which was incised and drained, the woman miscarrying a few days later, but making a good recovery. The prognosis as regards the subsequent course of pregnancy and labor is naturally somewhat uncertain, but judging from the results of celiotomy I feel considerable confidence in Nature's power to stretch adhesions and melt away exudates.

As regards the treatment I would say: Temporize as far as is safe in view of the risk of interrupting pregnancy, but when the indications are clear operate without delay, choosing the incision parallel with the outer edge of the rectus, and drain as in any other case. The after treatment requires more than ordinary care, and it will usually be necessary during the first forty-eight hours to depart from the common rule of withholding opium.

Inflammations of the urinary tract presents many phases. Doubtless they are mostly of gonorrheal origin, though some are septic and a few traumatic. I recall one fatal case of pyelitis, and another of inflammation of the ureter so severe that I was inclined to empty the uterus, when labor came on naturally and the patient was relieved as soon as the pressure was removed.

Rectal troubles—proctitis, ulcers, fissures, and inflamed hemorrhoids—frequently assume importance during pregnancy, when they are apt to be greatly aggravated, but their treatment does not require special consideration.

I would like to call attention to certain obscure cases of high fever during pregnancy, attended with local tenderness, in which the diagnosis is difficult. Some of these turn out to be cases of grippe, malaria, typhoid, intestinal trouble, late pelvic thrombo-phlebitis, etc., but in many the cause of the symptoms is not discovered.

[Written for the MEDICAL BRIEF.]

Fatty Degeneration of the Heart.

BY W. E. PUTNAM, M. D.,
Surgeon-General, State of Vermont.
Bennington, Vermont.

Is there any sign, or group, or succession of symptoms, by means of which we can determine definitely the presence of fatty degeneration of the heart? I will answer that question with one word—no.

The disease is one in which a true diagnosis is very difficult, many times impossible. When fatty degeneration exists, and depends upon a local cause limited to the heart, it is always associated with other changes of an earlier date, and its proper symptoms, if it has any, are they mixed up and confounded with those of an earlier structural disease. When it proceeds from some general cause, we may be more sure of our diagnosis.

In this disease, the pulse has been observed to be weak, or irregular, or very slow. One, two, or all these symptoms may be present, but, of course, this group may be observed in other lesions, so we have nothing definite here.

There are no peculiar ausculatory signs to the pulsations of a fatty heart. The same may be said of shortness of breath, syncope, which are common, of coma, and of precordial pain, which are less common.

It is always well in a suspected case to take the age into consideration, as the fatty change, when due to general decay, is prone to begin between the ages of sixty and seventy; some observers say about the sixty-third year.

In twenty-one instances out of sixty-eight, syncope was followed by death, and of the whole number (eighty-three) sixty-eight died suddenly. Death usually followed some unusual exertion or excitement, such as climbing hills, stairs, running for train or car, or to escape shower, anger, fright, etc.

The principal character which these cases seem to present is that the victims are fit enough for all the ordinary events of a quiet and peaceful life, but are wholly unable to stand any severe extra strain, mental or physical, especially accident, operation, or fright.

I stated at the beginning of this paper that the symptoms of fatty degeneration of the heart, are purely presumptive, or words to that effect, but if there are evidences of feebleness of the heart, yet no symptoms of valvular lesion, if the patient has attained the age of sixty, has a tendency to grow more fleshy, with pale and sickly complexion accompanied by a marked arcus senilis, then you may reasonably conjecture that the heart is yielding. The presence of the arcus senilis, alone, is entirely insufficient evidence upon which to base a diagnosis of the fatal disease mentioned above. Perfectly healthy people apparently, and in reality probably, some of them quite young, carry a distinct arcus.

In my own case, I have had an indistinct arcus since I was a boy, and yet, so far as I know, have a perfectly healthy heart. I am still, however, on the sunny side of fifty, and although beyond the Oslerian age of my best endeavor, am still a long way this side of fatty degeneration, as far as age is concerned, at any rate.

Death is usually preceded by rupture of the septum, followed by sharp pain at the time of its occurrence. The scene closes usually in a few minutes after the tissues give way, although some have lived one, two, or even three days.

The disease of which we have been writing is incurable, but much may be done in the way of medicine, and especially good advice, to add to the patient's comfort and safety.

Fairly generous diet should be allowed, very moderate exercise, avoiding all excitement, cultivating peace of mind and quietude. These are cardinal principles. Inculcate temperate habits. Give diffusible stimulants freely when syncope threatens, such as spirits etheris nitrosi, spirits ammon. arom., or hypodermics of spirits camph. ether, or spiritus frumenti. Strychnia sulph., one-thirtieth to one-fiftieth grain, three or four times a day, is often of great benefit, also caffeine, spartein sulph., and tr. nux vomica.

Digitalis ought not to be given. An exception is sometimes made in regard to this drug early in the disease.

Note.—The eighty-three cases referred to in this paper were in the service of Sir Richard Quain, more than half of them being over sixty.

Practical Bandaging of the Scrotum and Perineum.

BY FREDERIC GRIFFITH,

Surgeon, Fellow of the Academy,
New York City.

There are two portions of the body which not only the general practitioner, but the surgeon as well, oftentimes finds difficulty in bandaging, namely, the perineum in both sexes and the scrotum in the male.

Perineal Binder.—While nearly everyone is familiar with the commonly described T-bandage for the support of dressings in the perineum it is a special work of a sewing woman to produce this bandage, and when away from the hospital

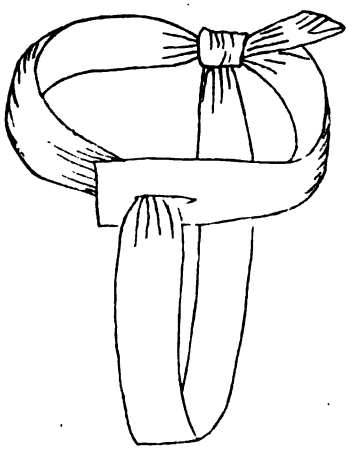

Fig. 1. Improvised T-bandage.

precincts may become impossible to procure one in emergency. An improvised T-bandage may be made from a yard and three-quarters length of a four or six-inch roller bandage.

The bandage is applied by passing one end through a longitudinal cut near the other extremity after passing around the patient's waist. Drawing the slip taut it is placed in position at the middle of the back. The tail is passed down and drawn up first between the patient's legs, the dressing to be supported having been placed in the perineum, and is completed by fastening to the waistband in front.

In male patients two tails are made by tearing up the middle of the free end of

the bandage to a point opposite the base of the scrotum. It will oftentimes be of advantage to confine the scrotum in the dressing, which may be accomplished by tearing up simply to the peno-scrotal junction. The penis being free urination is unhampered. This bandage is useful in bed-ridden cases, where a simple dressing is required, which must be frequently changed.

The best perineal bandage or binder for use in bed cases, as after rectal operations, where secondary hemorrhage may occur if firm support be not accorded, and in all walking and office cases where the patient's comfort as well as insurance against derangement must be made, consists of a binder simply prepared as follows: A four-foot length by eight to

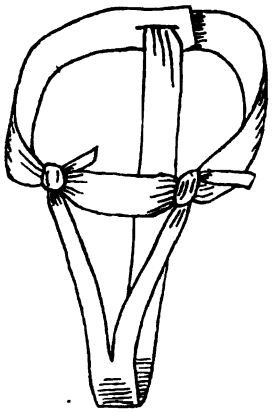

Fig. 2. T-bandage split in front for use in male patients.

twelve inches in width of bandage muslin is provided with a waistband made from a four-inch width roller bandage of sufficient length to pass around the patient's waist. The band is fastened in front or at the side with one or two safety pins, or it may be tied, the perineal cloth being suspended at the back. Finish the dressing by bringing the tail forward beneath patient's thighs (two tails are made when used for males), passing up and over the waistband in front, where it is drawn snug, smoothed and pinned.

Suspensory Bandages.—So positively inadequate are the ordinary forms of suspensory bandage sold in the shops that I frequently tell my gonorrhea patients that they might just as well slit their trousers pockets and use them as suspensory bandages as to employ any of the common varieties of jock straps or supporters. The primal requisite of a suspensory bandage is does it "lift" the scrotum? A new snugly-fitted suspensory

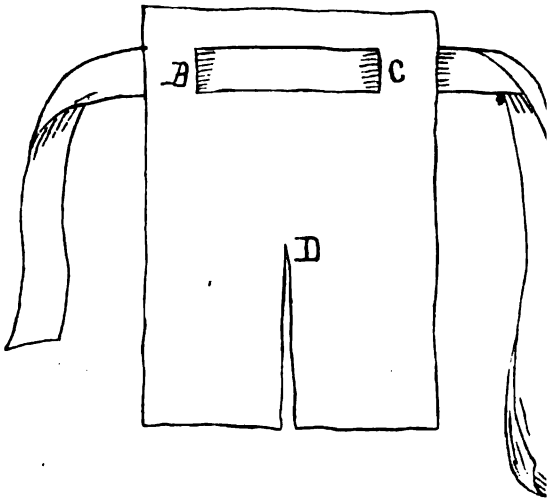

Fig. 3. Perineal binder fitted with a waist band by passing the end of a four-inch bandage through longitudinal apertures (B C). Two tails are made when used for male patients (D).

may seem to be of service in a given case of epididymitis, but the virtue will be found to lie in the compression afforded and not from any suspension of the diseased organ. Pressure of the scrotum against the perineum is not suspension, as a study of the various forms—almost without exception—of supporters in the market, after being placed carefully in

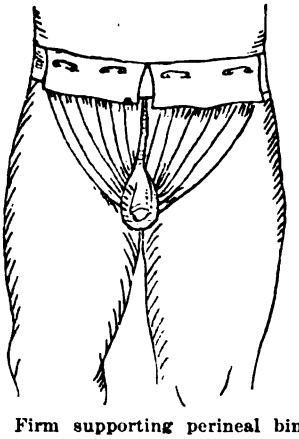

Fig. 4. Firm supporting perineal binder in position.

position upon the patient's body, will make clear. A simple yet adequate suspensory bandage suitable for any case, operative or medical, where true suspension of the

testicles is desired with or without compression may be readily made. From a four-inch width roller bandage cut off a twenty-four to twenty-eight-inch length.

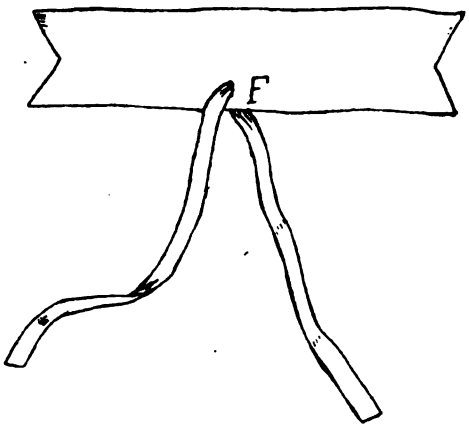

Fig. 5. Simple but firm supporting suspensory bandage.

Double it and near one edge of the fold, cut a small transverse opening. Tear a one-inch bandage and thirty-six to forty inches long down the middle after clipping the end to start it. Pass the end of one of these torn strips through the aperture in the broad bandage and draw it through to the middle of its length. To prevent slipping it may be tied in a single knot at (f, Fig. 5).

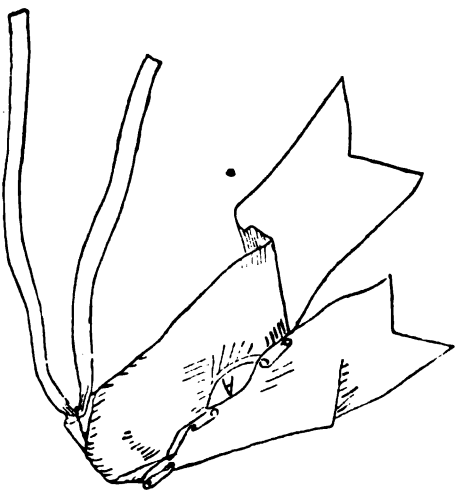

Fig. 6. Improvised suspensory formed by folding and held by means of safety pins. Note the aperture for the penis at (A).

By folding and fastening with three safety pins form a pouch, leaving space for an opening at (a, Fig. 6), through which the penis is to be passed. Apply the bandage over the scrotal application or the dressing, which may have been used by pinning the two tails of the pouch to a waistband (use the other narrow strip left

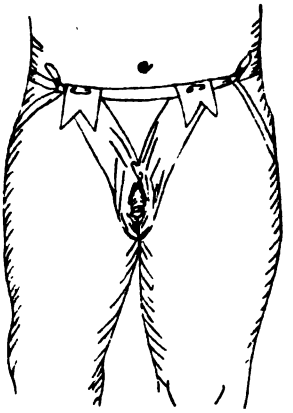

Fig. 7. Improvised suspensory bandage in position.

after tearing through the middle of the inch bandage) at a proper height after passing the penis through the opening provided and elevating the scrotum and dressings to the desired height. Pass the two tails at the bottom of the pouch backward between the thighs and tie to the waistband, drawing them up upon either side in the crease of the buttocks.

To modify any of the ordinary-shaped bandages to make them of more practical value for the surgeon's use it is only necessary to apply the scrotum straps

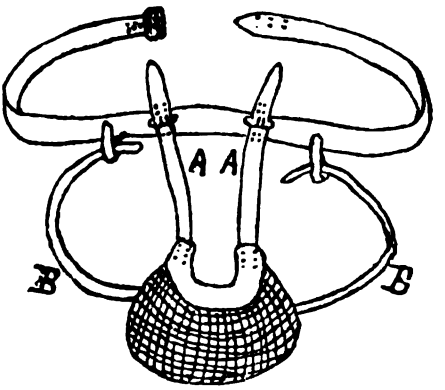

Fig. 8. Improved suspensory bandage with adjustable scrotum straps (A A), thigh tapes (B B).

(aa, Fig. 8), adjusting them with buckles and the thigh straps (bb) when these have not been provided.

"Cimicifuga"

BY PITTS EDWIN HOWES, M. D.,

Associate Editor of "The Eclectic Review." Boston, Mass.

Cimicifuga racemosa—or macrotys—is among the oldest of the valuable remedies of the eclectic school. The time spent upon studying the curative action of this plant will be amply repaid. Its range of action is wide-reaching. Those who have prescribed it the most frequently are the most persistent in sounding its praise.

Its sphere of action is largely upon the brain and spinal cord, hence, it should be remembered as a cerebro-spinal remedy. Without doubt the effect produced by this remedy upon the muscular system is not direct, but is due to a reflex action from the brain. It should be looked upon as a depressing irritant in large doses. Indirectly, the vegetative system receives some benefit from its administration. It is a potent remedy in all diseases of the mental system when melancholy is prominent among the symptoms, especially when accompanied by sleeplessness. This latter symptom is one of the keynotes for its use in nervous affections, and should always be remembered. For the removal of such conditions it should be prescribed in small doses. Excessive doses will produce a very strong effect upon the nerves of sensation, and develop all the symptoms of neuralgic rheumatism. The pains are aching, pressing and remitting. They are attended with great restlessness and a weak, exhaustive feeling.

It is one of the most remarkable remedies in all diseases of the cerebro-spinal system. This is especially true when the motor tract is excited, and yet, notwithstanding, there is manifest an atony in the muscular and nervous systems. Hence, this gives us a clue to its wonderful efficacy in some forms of chorea. Cimicifuga is indicated when this disease is produced by irritation of the spinal cord, uterine ailments, or purely psychical causes.

The movements abate or are absent during sleep. They are increased by the emotions, at the menstrual period, or as a result of suppressed menstruation. They are often attended by depression of spirits and wakefulness.

Cimicifuga occupies a large place in the treatment of muscular affections. By preference it seems to act upon the belly of the muscle, and is especially indicated when the trouble has appeared suddenly. The form of rheumatic fever, for which it is curative, is characterized by three prominent symptoms, namely, suddenness, the severity of its manifestations, and its location in the large muscle.

In cases of chronic rheumatism, when the pain is situated in the large muscles and the history of the attack elicits the fact that the onset of the disease was markedly quick and severe, cimicifuga should be given with great confidence in its curative power.

Night sweats, which are due to the degeneration of the nervous supply to the cuticle, will be arrested by the administration of this remedy.

There are conditions of the abdominal structures in which cimicifuga will be used with advantage, namely, rheumatism of the muscular tissues, also the neuralgic pain—frequently taken for peritonitis—which occurs after confinement.

Cimicifuga finds, perhaps, its most important place in many of the ailments peculiar to women.

In amenorrhea—in young girls—from deficient nervous energy in the ovaries, and when the abnormal nervous influence is directed to other organs, giving rise to chorea, hysteria, nervous headaches, etc., etc., the cimicifuga will restore the functions of the reproductive organs to a normal state. Should there be, at the same time, with the above conditions, a chlorotic state, helonias should be prescribed in conjunction.

In retarded menstruation, when, instead of the ordinary flow, there appears a dull, heavy headache, melancholy, palpitation of the heart and other reflex symptoms, this agent will produce a normal tone to the system and cause a regular return of the menses.

In suppression of the menses from a cold, mental emotions, a febrile condition with rheumatic pains in the limbs, an

intense headache with uterine cramps, this remedy will be curative.

Many cases of dysmenorrhea are also relieved by cimicifuga, when they are accompanied by the rheumatic or neuralgic symptoms before described.

As a parturifacient cimicifuga was in general use among the Indians at the early settlement of this country. Many writers have testified to its efficacy in facilitating parturition. It has been stated that cimicifuga exerts a specific influence upon the uterine tissue. That these contractions last longer than those produced by ergot, are followed by less torpor and a greater susceptibility and capacity for action in the uterus than before its employment. Its action, also, is not attended by that deleterious and stupefying influence upon the fetus which often follows the administration of ergot.

After delivery this remedy has been successfully used for the purpose of inducing firm uterine contractions, expelling the placenta and checking *post-partum* hemorrhage. After-pains will be checked by its administration, especially when the patient is inclined to be despondent and is wakeful.

Ovarian neuralgia will be cured by cimcifuga when the ovarian pains are reflected, or change their location to other portions of the body, as the leg of the same side, the region under the breast, or extending up the side to the shoulder.

In puerperal mania, where melancholy and sleeplessness are prominent symptoms, the agent under consideration should be given with the greatest confidence.

In the promotion of easy labors this remedy holds an important position. Given for a few weeks before the expected confinement, it will influence that occurrence in a marked degree. Many times by means of its use the woman is enabled to do without the aid of the anesthetic. Those who have not used it in this manner will be much gratified by the results produced.

It will also be found useful in many nasal and throat affections, especially if these troubles have been preceded by rheumatic symptoms.

Many times the most brilliant results are obtained in those persons who are overworked—completely tired out.

It is best adapted to those pains—rheumatic or neuralgic, which occur below the waist line. When above that part of the body bryonia will produce better results.

Frequently combining gelsemium with the cimicifuga, especially if there is much irritation, will yield a more lasting effect and the cure will be more rapid.

Arsenization.

BY REGINALD B. LEACH, M. D.,
St. Paul, Minn.

On the 29th of March, 1905, I was requested to and delivered, in St. Paul, Minnesota, an address upon the subject of tuberculosis. On the 2d of April, 1905, *The St. Paul Pioneer Press* did me the honor to reproduce said address, together with eight pictures and two charts. The subject-matter of said address, together with the pictures, occupied fourteen columns of said paper, and was accompanied by an editorial and followed on April 3d, 1905, with a touching cartoon.

Among those to whom copies of this address were sent was a Mr. E. L. Prescott of New Orleans, who, being personally interested in the subject, called a member of his family from Arizona and sent her to me for such professional service as I might judge expedient. Through this party I had the pleasure of several times corresponding with Mr. Prescott at New Orleans, and, upon one occasion (July 31st, 1905,), believing that I might help protect him against yellow fever, through arsenization prophylaxis, I addressed him a special communication upon the subject, inclosed the following prescription, and gave him permission to give same to his friends or acquaintances:

"*How Arsenization Is Performed.*—Take a tablet, granule or powder, containing one one-hundredth grain each of arsenious acid, three times daily for the first week, twice daily for the second week, and once daily thereafter until the remainder of one hundred tablets, granules or powders are taken, or until the epidemic closes by virtue of sanitary and

hygienic precautions or weather conditions."

This prescription is from actual, practical experience of Dr. Rego Cezar and hundreds of his colleagues of Brazil during the yellow fever epidemics of Rio, Para and Campanias, Brazil, in '92, '96 and '97.

Mr. Prescott, believing that what was good for himself and friends should be made known to all, published my letter to him in the *Times-Democrat*, of New Orleans, August 3d, 1905. The prescription seemed to meet with almost universal approval and I was notified that before noon of that same day all of the arsenious acid tablets at that time in that city had been purchased and were being taken by the public.

Mr. Prescott's office, in the Hennen Building, at once became the Mecca of the populace, who desired more enlightenment upon the subject. He was asked whether to take the remedy before or after meals, what dose was best for children, etc., and if it were not possible for him to induce me to come to New Orleans and there make practical test demonstrations of what they called "Dr. Leach's Arsenization Preventive of Yellow Fever," as first alleged, theoretically, by me in the U. S. Senate, June 4th, 1898, and first practically, though negatively, tested in Brazil by Dr. Rego Cezar in 1876.

Having for fifteen years been before my colleagues of the medical profession, trying to induce them to investigate my allegations of the protective properties of arsenization, I naturally grasped this opportunity to visit a plague-ridden city, believing that, if ever, I should now have an opportunity to "make good" or fail.

August 6th, Mr. A. W. Blakely, proprietor of the New St. Charles Hotel, wired me: "Will arrange for transportation and guarantee hotel expenses while here, if you care to come to New Orleans." August 7th, I replied as follows: "Your invitation appreciated. Only awaiting Prescott's notification before accepting." August 8th, Mr. Prescott wired me: "Matter of expense all arranged. Come at once. Wire just when you leave." August 10th, Mr. Prescott further wired me: "Bring medical credentials addressed to Orleans Parish Medical Society." To this I replied: "Will bring Dartmouth diploma, Minnesota registration and Medical Society credentials, though their utility seems superfluous if I 'make good,' and useless if I don't."

Thursday evening, August 10th, I left for New Orleans and arrived at said city at 9:15 A. M., on the 12th inst., to find myself surrounded by friends, who began bestowing favors which I can never forget nor be able to repay.

Within a few minutes of my arrival, the Western Union Telegraph Co. sent me their compliments and the freedom of their wires in communicating with my little family at St. Paul. The proprietor of the St. Charles Hotel notified me that the hotel was mine, and that if I wanted anything not in sight and went without it, it was my own fault. Hardy & Ayer, liverymen, sent me word that any carriage in their barn was mine for the asking, gratis, and I found my money worthless during my entire stay in that city, excepting in tipping bell-boys and waiters. The courtesies of all clubs and exchanges were extended me and all time limits wiped out; and physicians of all schools of medicine (excepting those of the Marine Hospital service and what was known as "The Bunch" in the Orleans Parish Medical Society) called upon me and offered their best wishes and professional assistance in making the practical demonstrations of immunity for which I went to their city.

I was welcomed to the State by a letter from Governor Blanchard, who, under date of August 16th, said: "I have yours of the 14th inst., enclosing a letter from the Hon. John A. Johnson, Governor of Minnesota, introducing you as a physician of high standing, etc. I am glad to have this letter from you and also the one from Governor Johnson. We welcome you to Louisiana, and are glad that you have come for the purpose of testing the virtues of arsenization as a preventive against attacks of yellow fever. I will be glad to extend to you, both personally and officially, every courtesy possible, and all the assistance in my power, to aid you

in making practical tests of the aforesaid theory."

"The Orleans Parish Medical Society" met in regular session on the evening of the day of my arrival, August 12th. By messenger I presented said society with my credentials from my home society, together with my diploma from Dartsmouth Medical College, my endorsement from Belleview Hospital Medical College and my Minnesota registration, accompanied by a personal letter, stating that I had not come to their city for the purpose of practicing medicine, but solely for the purpose of making practical test demonstrations of immunity, through arsenization, against the bite of the segomyia fasciata: the pest-bearing mosquito just then augmenting the epidemic of fever in that city.

The reply from said society came to me before twelve P. M., that same day, in the form of a set of resolutions, which had been passed, as the secretary stated, that same evening unanimously. These resolutions were couched in language so contemptibly discourteous as to merit and receive only oblivion. They have not to this day been given publicity. Had said society decided to rid itself of an outsider and a "heretic," it would seem that the surest and quickest way would have been to have appointed the committee requested and that said committee at once produce the infected stegomyia and place same upon said "heretic," that he be for once and all destroyed.

So far as I am aware, a similar certified, positive, practical test demonstration has thus far never been made of a similar prophylactic; though thousands of negative tests of arsenization have been made in Brazil since 1876, and are now being made by the hundreds of thousands, with arsenization versus yellow fever, in our Southern States.

Before I had been two days in New Orleans, I received calls from two ladies and six gentlemen, all laymen (one from Alabama), alleging their non-immunity by virtue of previous attack of yellow fever; that they had confidence in arsenization and that they desired to offer themselves to undergo, with me, the proposed demonstration of immunity through arsenization prophylaxis.

Having paid no attention to the rebuff of the Parish Medical Society, its members began to tell of what they had done. They offered as one excuse for their position the excuse that, in supervising my demonstrations they would be lending countenance to a suicide. That if I came through it all right, it would prove nothing; and that if I made the same tests upon my volunteers in their presence, they would be countenancing murders. That all volunteers would die and that, thereby, the death rate of New Orleans would be augmented. They knew that there was nothing in arsenization; so "what's the use?"

Their solicitude for my welfare was so great that every day some new excuse emanated from their ranks. How the public judged these excuses is best told in the following from the "funny-man" of the *Times-Democrat:*

"DR. LEACH."

"It wouldn't do for Dr. Leach to arsenate the town;
The thing might be effective and the doctor bills go down.
No self-respecting doctor could afford to be unjust;
But then, you know, this Dr. Leach might represent the trust.
Another thing to think about in dealing with this Nemesis,
Is that we can't afford for Leach to die upon the premises."

Among other excuses offered against my tests was one to the effect that "Arsenization has already been tested, along with the mosquito theory, and been found wanting."

If this were true, they failed, when asked by me to do so, to produce evidence to that effect; and the fact that Gen. Wyman, in the following letter to Mr. Blakely, of the St. Charles Hotel, omitted to mention those alleged "tests," is somewhat conclusive of negation of their assertions:

"WASHINGTON, D. C., Aug. 19, 1905.

"*Dear Mr. Blakely.*—About Dr. Leach: He tried very hard to have the service take up his theory and make the necessary expenditures to investigate it. It was turned down by the scientists of the Bureau several years ago. He is certainly enthusiastic and unselfish, but I think he is on the wrong track."

If the theory of arsenization prophylaxis had been proved "N. G.," is it likely

that the Surgeon-General of our Marine Hospital Service would have failed to mention same in his letter to the man who was paying my hotel expenses; a personal friend of Dr. Wyman? Hardly.

All this becoming public property, the people were up in arms. Thousands who had not, up to this time, sided with me, at once did so. "The under dog," you know. The fight was on.

The mayor of the city and other distinguished citizens had, before I left St. Paul, petitioned this medical society to supervise my proposed test demonstrations, providing I would agree to go to that city. The governor had welcomed me to their commonwealth, the mayor and his counsel had called in person, as had hundreds of the most representative citizens, and I had already been the guest of honor at the Pickwick, the Chess Club and the Sugar Exchange, and had invitations to other clubs and exchanges.

The newspapers, up to this time, had made it their business to herald my every act and word. "Letters from the Public" began to make their appearance in their columns. One, signed "Fair Play," will do as a sample for all and show the spirit of the people who were and are still taking arsenious acid:

"*Editor New Orleans Item.*—The treatment accorded Dr. Leach in this community was probably conformable to the ethics of the medical profession, but is widely at variance with the laws of hospitality and manly appreciation.

"He came into our midst at our solicitation, bringing with him the highest credentials. He asked for no remuneration, but merely the privilege, under medical supervision, of subjecting himself and other arsenicized persons to the mosquito test. What were the doctors afraid of? Was it the fear of his acquired immunity or the apprehension of a theory to be by him demonstrated to be a fact?

"There are produced the highest testimonials in support of the mosquito theory. He brings certificates equally convincing of arsenization. Why do they unhesitatingly accept the evidence of Cuba and Mexico and reject, without trial, the evidence from Brazil? There is one fact most clear, and that is, that if we do escape a more serious outbreak of fever, that some thousands of the population will attribute their immunity to arsenization, and not to those who primarily are thought to be responsible for its introduction. I am no arsenic convert, but do believe that no one has a right to condemn that which he refuses to investigate."

A "Mass Meeting" was called in the Palm Garden of the St. Charles Hotel on the evening of August 17, at which time I presented the people the theory of arsenization, amplified from the following, which appeared in *The Wisconsin Medical Recorder* in 1900, viz.:

"Arsenization is the act or art of arsenicizing; the introduction of arsenious acid into the human frame with the view of protecting it against Asiatic cholera or yellow fever (and, presumably, against bubonic plague), or rendering those diseases less formidable."

Arsenization, or the immunizing of the human against the diseases referred to, is accomplished either by inoculation from an ivory point or by the hypodermic injection or the ingestion of arsenious acid; and from experience it has been learned that a dose, ranging from one one-hundred and fifteenth to one one-hundredth of a grain of arsenious acid, repeated as above described, sufficiently immunizes any one versus the diseases mentioned.

This is the experience of Drs. J. P. da Rego Cezar and Ismael da Rocha and at least fifty others in Brazil against yellow fever; and of Drs. P. C. Majumdar and U. C. Bagchi, of Calcutta and Bombay, India, against Asiatic cholera.

The probable prophylaxis of bubonic plague by arsenization is analogically reasoned because of the intense (if I may be allowed the term) analogy, or likeness, or similarity, between the stage of collapse in this disease to that stage in Asiatic cholera and in yellow fever. At this "Mass Meeting" a committee of seventeen of the most representative citizens of New Orleans was formed, with Mr. Sidney Story as chairman and Mr. F. M. Welch as secretary. A resolution was unanimously adopted to again petition "The Orleans Parish Medical Society" to supervise the test demonstrations for

which I had gone to New Orleans. It was decided by the committee that as soon as this set of resolutions was presented the secretary of said society, that the action of said "Mass Meeting," together with a copy of said resolution and petition, should be made public through the daily papers.

Within an hour of the meeting, the petition to the medical society was delivered to its secretary, and the sub-committee on publication had visited the offices of the various morning dailies and had requested that the proceedings of said "Mass Meeting" be given publicity.

But they were too late. A committee from the local medical society, together with Dr. White of the Marine Hospital Service, had already visited those same offices and had obtained their promise that nothing more from me or from any citizen favoring arsenization would be made public; and in the afternoon of the same day, *The States*, the afternoon member of the newspaper combine, closed its columns to any person interested in anything but the killing of mosquitoes.

The public at once "sat up and began to take notice." They wanted to know why an alleged preventive against yellow fever, with almost universal adoption, even to its being prescribed surreptitiously by their local doctors, was not permitted by "the powers that be" a practical, positive test demonstration against that disease which was destroying their business and the lives of many loved ones.

A committee of local doctors called upon His Honor, the Mayor, and demanded that he request me to leave their city. This, of course, His Honor refused to do. He is not only too much of a gentleman to have obeyed such a request, but he had headed the petition requesting me to go to New Orleans.

Letters began to pour in to me from all over the State; in fact, from all over the South, from as far east as Baltimore and as far west as Dallas, Texas, requesting me to "stay and fight it out if it takes all summer." This, of course, I was ready and willing to do, and did, so long as my committee found it expedient and possible.

Another "Mass Meeting" was decided upon, and was called for the evening of the following Wednesday; and paid advertisements for same were inserted in all daily papers in the city. This meeting was for the purpose of reporting back to the people the acts of their committee appointed at the former meeting, and for the purpose of protesting against the action of the local medics and U. S. M. H. S. doctors in "muzzling" the press, and in thus far making impossible the proposed test demonstrations of immunity under arsenization.

From the previous Thursday morning up to the morning issue of this day, Wednesday, August 23d, 1905, *The Times-Democrat*, *The Picayune* and *The States* had made no mention of myself or efforts; but on this Wednesday morning, *The Times-Democrat* gave me a column and a half of the most beautiful "editorial roast" such as no one, to my knowledge, not in politics or a mountebank of the first water, had ever before received.

They quoted Gen. Sternberg, former Surgeon-General U. S. Army, as their authority for the fact that I had been so laudibly ambitious to help humanity that I had four different times been impertinent enough (and successful enough) to importune and foist upon the credulous U. S. Senate my nostrum which can be, and was in New Orleans, purchased at any retail drug store in the world, almost, for "two bits."

They even went so far as to quote Gen. Sternberg's reply to the Committee of the Senate on Public Health and National Quarantine, to the effect that, in his opinion, I did not possess the requisite scientific attainments for membership on a commission I had requested the President to appoint for the purpose of investigating into the cause and prevention of Asiatic cholera, yellow fever and bubonic plague; and they accepted Gen. Sternberg's "think," shell and all, *quid pro quo*, for the truth and a fact. And yet Gen. Sternberg is the same one who denied that the icteroides bacillus of Sanarelli was the specific morbid germ of yellow fever; that his, the bacillus X, was the only specific morbid germ of this disease, while all now know that both are

wrong, that what they called the specific morbid germ of yellow fever is not the cause of yellow fever, but the specific morbid germ of hog cholera, and that all now admit that "We do not know the cause of yellow fever." (See Bulletin No. 14, U. S. M. H. Service.)

Gen. Sternberg's opinion of the writer is public property in what is known as Senate Report, No. 1215, May 7th, 1900.

In this same issue of the *Times Democrat* is reproduced what they term "Dr. Leach's Record." This record displays, at the worst, a laudable ambition to help our fellows and, maybe, to "be somebody," and for this the writer is held up as "Thou Shalt Not."

On page eight of Senate Document, No. 111, Second Session of the Fifty-fifth Congress, February 2d, 1898, you will find what others know of "Dr. Leach's Record." This was not published in New Orleans, but can be had at any time by any person sufficiently interested to ask for same of the Secretary of the U. S. Senate, Washington, D. C.

At this last "Mass Meeting," Wednesday, August 23d, I took occasion to reply to the said editorial, as well as to a similar one which appeared on the same day in *The Picayune*. My reply can be seen in the columns of *The New Orleans Item* of August 24th, 1905.

In 1896, when appealing to my confreres through the medical journals to assist me in properly presenting and practically proving arsenization against Asiatic cholera, one would-be facetious colleague of Philadelphia made the statement that "There is lots of cholera in Egypt; let the Doctor really prove the assertion he makes." At that time I attempted to prove same in Egypt, but before I could leave America was notified by Rogers Pasha, Health Officer of Egypt, that their cholera epidemic had closed. I have never since had the chance to make said practical test demonstrations, though I certainly expect to do so in Europe unless the present epidemic there closes before I can make necessary arrangements for the care of my family during my absence.

The action of my Philadelphia confrere, and the action of the local medics of New Orleans (in their effort to have their mayor ask me to return to Minnesota and here make the tests they refused me the privilege of making there), their action reminds me of a similar position in which our British ancestors found themselves upon one occasion, and which in history is known as the "Groans of the Britons," in which they are said to have exclaimed: "The barbarians, on the one hand, drive us into the sea; the sea, on the other hand, throws us back upon the barbarians; and we have only the hard choice left us: to perish by the sword or by the waves."

Previous to the last "Mass Meeting," the Marine Hospital authorities had notified my committee that if, at this meeting, the proposed call for volunteer physicians to supervise my test demonstrations was carried, an injunction would be served the following day and the tests thus stopped. At said meeting, therefore, the chairman, after consultation with the balance of the committee, announced that the proposed tests would not be made, just why they would not be made, and that "Dr. Leach will leave for his home on Sunday."

At once this announcement was made, and the meeting had closed and I had bid good-bye to the many who had loyally stood for the tests which had taken me to their city, I repaired to my room at the hotel and, not wishing to leave a single stone unturned, indited a letter to the Governor of Louisiana. In this I related the many and sundry excuses offered for not permitting the desired tests. Told of the excuse that probably none of my non-immunes were such in fact. That I had rescinded all desire to make the tests upon those who had volunteered to me, and would gladly accept any volunteers Dr. White or his cohorts could and would furnish; to all of which the opposition demurred. After relating the facts to His Excellency, I recalled his letter of welcome to me and his offer of "personal and official assistance," and requested that he offer a pardon to fifteen State's prisoners, whom he or his authorities knew to be non-immunes against yellow fever, said offer to be for volunteers who, should they undergo the tests under ar-

senization and survive, would be free men again. To this the Governor, under date of August 25th, 1905, wrote me (and same was received by me at St. Paul, Minnesota, on the 30th of August, 1905,) to this effect:

"I have yours of the 23d inst. Your proposition to demonstrate the efficiency of your system of arsenization by having some of the State convicts to volunteer as subjects for the test under promise of pardon by the State, is not practicable.

"The Chief Executive of Louisiana has no power to grant pardons, except upon the recommendation of the State Board of Pardons, which consists of the Lieutenant-Governor, the Attorney-General and the Judge who presided at the trial of the prisoner. Nor would public sentiment sustain such a thing."

Having done all possible, it is "up to the people."

On arriving at Chicago on Monday, I had the unique experience of meeting one of the editorial writers of *The Journal of the American Medical Association*, and of being requested by him to read his "write-up" of my endeavors at New Orleans and give him my opinion of same as soon as possible. This is my first opportunity to do justice to his "write-up," known as an "Unwise and Untimely Experimentation," and I take pleasure, therefore, in replying herein and now as follows:

In said editorial I find the writer takes occasion to say that: "If Dr. Leach's claims are valid, why were not reports made through accredited medical channels, and why has he delayed until now, in the midst of an epidemic, to give forth to the world the results of his experience and experiments?" My reply is, that if said editorial writer had read more, or remembered better, he would have written less hastily and with more justice; for arsenization has appeared on an average of once a month in some medical journal in the United States since September 3d, 1892 (and in many in Brazil since 1876—in the same country, by my pen, since 1900); that it has also been made public through daily papers and lay magazines since 1892, and that I most respectfully refer him particularly to Senate Documents and Reports above referred to as well as to his own journal—*The Journal of the American Medical Association* for 1895, under the title of Asiatic cholera, as presented at the Atlanta, Ga., meeting by Dr. Elmer Lee, to the *Medical Arena*, of Kansas City, the *American Homœopathist*, of Cleveland, the *Medical Summary*, of Philadelphia, the *St. Louis Medical Era*, the *Wisconsin Medical Recorder*, *Moody's Magazine of Medicine*, the *Southern Journal of Homœopathy*, the *Philadelphia Recorder*, the *Cincinnati Lancet-Clinic* (article by Ishmael da Rocha), and many, many others discussing, pro and con, both yellow fever and Asiatic cholera in relation to arsenization—both from the homeopathic and the "old school" standpoint.

This same Chicago editor quotes from the August 17th, 1901, *Journal of the American Medical Association*, to the effect that "Arsenic acts by stimulating the reproduction of cells, increasing the number of red blood corpuscles, rejuvenating the tissues and conferring on the economy an extraordinary degree of resistance to morbid influences."

This said editor seems to think something new; whereas, away back in 1881, Bartholow tells us that "Arsenic promotes constructive metamorphosis when administered in medicinal doses," "checks retrograde metamorphosis," and "promotes the appetite and digestive functions," while Prof. William Henry Porter of the New York Post-Graduate School, later says that "The arsenites are intensely irritating and poisonous to all forms of both animal and vegetable germ life; and that they produce in the system a new, normal or healthy activity of the liver."

While this is in no sense my reasons for believing in the protective virtues of arsenization, I have the honor to respectfully submit the above as something referred to by our editorial writer, but evidently thought by him to be something new.

My personal reason for believing in arsenization as protective of Asiatic cholera or yellow fever is that, as no two bodies can occupy the same space at one and the same time, so no two diseases,

being similar and therefore requiring the same centers of the economy through which to demonstrate their similarity, can simultaneously demonstrate their signs and symptoms; and that yellow fever and Asiatic cholera being, in my judgment, the analogues, if you will, of the physiologic effects of arsenious acid upon the human frame, neither disease can, simultaneously, affect a person deleteriously who is previously arsenicized to the proper degree; and this proper degree, from the experiences of our Brazilian colleagues, has been decided as above given.

One other point I would like to call to the attention of the editorial writer above referred to: If Dr. Leach has not for many years been presenting arsenization to our colleagues, how comes it that said writer knew of the book written by Dr. Eduardo Magalhaes of Brazil, and which said book is dedicated to the said Dr. Leach of St. Paul? It looks as though that writer might try it again and this time style his editorial, "Unwise and Untimely Comments."

If one would like to see why, in my judgment, arsenization will protect against Asiatic cholera, I would refer him to Bartholow, who quotes Virchow to this effect: "Virchow has pointed out the similarity in the *post-mortem* appearances of arsenic and cholera." Also, in the same volume: "It is a curious circumstance, first demonstrated by Virchow, that some cases of acute arsenical poisoning are not distinguishable by their symptomatology or morbid anatomy from cases of epidemic cholera;" and still again: "In still other cases the gastro-intestinal disturbance, the rice-water discharges, the collapse, simulate the algid stage of cholera."

I left for New Orleans August 10th, with a feeling best expressed by an experienced one, who said:

"Thus every man of real learning;
Is anxious to increase his store;
And feels, in fact a greater yearning;
The more he knows, to know the more."

I wanted to know, from actual, personal, practical test demonstrations, under unequivocal circumstances and surroundings, that arsenization would do what I believed, from reasoning, my way, it should do. I wanted to prove in New Orleans where they had yellow fever what our expert Brazilian friends had proved in Brazil under similar circumstances; and I, naturally, I think, thought every physician in the Crescent City would but too gladly welcome either a proof of prevention or a proof of negation. I believed, with Confucius, that:

"He who from day to day recognizes what he has not yet
And, from month to month, does not forget what he has attained to,
May be said, indeed, to love to learn."

I wanted to learn more of the prevention of yellow fever; and by actual personal test demonstrations; and I believed that my colleagues of New Orleans would only too gladly grasp the opportunity, so long as it was my funeral, if I did not "make good," to join me in making the proposed tests; especially as they were to be first made upon me.

It is a sad commentary upon the ordinary opinion entertained by the laity of our profession that arsenization as a protective against yellow fever still remains a mooted question in the United States, and that no amount of talk, for or against it, can ever decide the question; nor any amount of opposition of any kind prevent its eventual acceptance and universal use by the people, once it is proved, as I went to New Orleans to prove it, and as it certainly will be proved.

In closing, it is a pleasure to add that not less than half a million of our fellow citizens south of "Mason and Dixon's Line" have taken advantage of arsenization, and that they are today using the prescription as given above and, as intended, for all humanity.

This, as anyone can see, will give us, even if no more "converts" are added, one of the biggest, if not the very biggest, negative demonstrations of any prophylactic remedial ever made anywhere in the history of medicine during a similar length of time.

As you will have noticed above, the credit for having first discovered the prophylactic properties of arsenic against yellow fever belongs to and has been given to Dr. Rego Cezar of Brazil; and, as I wrote, in a certain noted place in New Orleans, before leaving there, so I

will close this with the following paraphrase on Bill Nye, in paying further tribute where said tribute belongs:

God speed Arsenization,
And Rego Cezar's fame;
"'Till everywhere that you have went,
They're glad that you have came."

[Written for the MEDICAL BRIEF.]

Spinal Irritation—Its Cause and Cure.

BY VIRGIL P. ENGLISH, M. D.,
Cleveland, Ohio.

Spinal irritation is an irritated or incapacitated condition of one or more of these nerves, due to pressure upon their roots, or upon the spinal cord. The pressure causing this condition is produced by inflammation and the resultant expansion of the surrounding tissues, or by a displacement of one or more of the vertebræ. Usually the latter.

In most cases this pressure upon the roots of the spinal nerves results from a weakness and compression of the cushions of cartilage between the vertebræ. This compression of the intervertebral cartilages permits the vertebræ to approach so near together that the nerve roots between them are compressed.

Symptoms.—Spinal irritation may cause any or all of the symptoms in the following list:

Headache, pains or oppression in the head, especially in posterior part or at base of brain; noises in the head, confusion, inability to think effectively or to stop thinking, dizziness, nervous headache, sensations that seem to the patient like a pulling or stretching of cords in the neck; functional disorders of the eyes, connected with pain or aching in the occiput or cervix, or both; aches or pains in the eyes or back of them, specks or spots before the eyes or blurred vision (a thorough examination by the oculist may not reveal anything abnormal); a frequent, instinctive desire to sigh or yawn, or take a deep, full breath (in some cases there is inability to do so, or but partially, owing to inability to fully expand the chest); palpitation or irregularity of the heart; pains, oppression, difficult breathing, or very peculiar, almost indescribable feelings in the region of the heart, lungs, stomach, or other parts of the chest or abdomen, that may have been diagnosed as neuralgia, rheumatism, digestive derangements, cardiac affections and various other disorders; aches or pains in the region of the kidneys, backache, sensations of oppression, constriction or pain like a belt around the body,

Fig. 1. The human spine is a curved column, consisting of thirty-three bones and intervening cushions of cartilage.

or around the right or left half; partial paralysis of the arms, shoulders, hands, lower limbs or feet, causing pains in these members, or a feeling of numbness, coldness, heaviness, or a tingling, or sensations that the patient may describe as the pricking of pins or needles, or as if the parts were asleep; sometimes the fingers feel too large; it is difficult to pick

up small objects, such as a pin or needle, and, unless looking, patient might not be able to ascertain whether holding the object or not; pains or burning in the heels, big toe or plantar region; sore, tender or burning points along the spine or in the limbs or feet; pains resembling sciatica or neuralgia; chills up and down back, sensations resembling the crawling of insects, creeping sensations, coldness or numbness; pain, soreness, tenderness or sensitiveness between the shoulders or along other parts of the spine; creeping or grinding pains, nervousness, sleeplessness, insanity, fugitive pains in a part or all of the viscera, impaired function of the heart, lungs, stomach, liver, kidneys, bowels or other vital organs.

Symptoms are usually aggravated by standing, walking, running, riding or twisting the body—anything that causes the vertebræ to settle down closer together, thus increasing the pressure upon the nerve roots.

Many cases of spinal irritation are diagnosed and treated as nerve exhaustion, neurasthenia, nervous prostration, rheumatism, neuralgia, nervous collapse, and various other disorders. And not infrequently, one or more of these disorders actually do exist in connection with the spinal irritation.

The foregoing list does not include all the symptoms caused by this disorder. It is seldom, however, that any one patient will have all of those mentioned. Usually one patient will have part of them and another patient will have others, according to the location and number of the nerves affected in each case.

The spinal column is a sort of tent pole, supporting the upper portions of the body. When the body is in an erect position each vertebra supports the weight of that portion of the body that is above it. The same is true of each inter-vertebral cartilage. Those in the cervical region support the weight of the head. Those in the lumbar region support the weight of the head and shoulders, the ribs and the contents of the upper part of the trunk. Upon the sacrum and the cartilage first above rests the weight of all the upper portions of the body. Each of the lumbar cartilages supports almost as much. In many persons there is the weight and pressure of a hundred pounds or more whenever the body is in an erect position. Whether standing or sitting this weight and pressure is constant.

The inter-vertebral cartilages are an elastic, compressible, India-rubber-like substance. They act as cushions or springs, responding to the shock in walking, running and jumping, thus decreasing the jar to the brain and all parts of the head and trunk. They have the same effect upon the body that the springs do beneath cars and carriages, and the rubber tires of bicycles, automobiles and other vehicles.

To accomplish the very function for which they are intended these cartilages must be, and are, readily compressible. So much so that the length of the body is considerable less when standing than it is when in the recumbent position. In Gray's Anatomy, page 304, we find the following: "In two hundred and eighty-seven soldiers measured by M. Robert the measurement in the erect posture was on an average 65.28 inches, and when in the horizontal, 65.79, a difference of half an inch."

It should be borne in mind that the compression of the cartilages just mentioned takes place in perfect health, and that it is perfectly normal. But there are a great many cases in which the cartilages become weakened and are abnormally compressed. Compressed so much that the vertebræ above and below them are close enough together to squeeze the roots of the spinal nerves that lie between them.

This pressure upon the roots of the spinal nerves gives rise to numerous symptoms that vary greatly, according to which are the nerves compressed, how many of them are thus affected, and whether the pressure is mild or severe. From the very nature of the conditions and principles involved these symptoms are very deceptive and misleading to those not familiar with the disease. A little light will be thrown upon this fact by considering what the laity call striking the crazy bone. As every physician knows, this consists of an impact upon the trunk of the ulnar nerve at the point where its covering of tissues is not suffi-

ciently thick to protect it from external violence.

The point in this to which I desire to direct particular attention is the fact that among the most noticeable sensations produced are those at the terminal filaments of the nerve branches. These filaments are distributed in the little finger, the adjacent half of the ring finger and the

Fig. 2. Through this column is a canal, in which rests the spinal cord.

corresponding side of the hand. These are the parts in which the sensations are most distinct. Along the trunk of the nerve in the arm and forearm, except at the point receiving the blow, usually, no sensation whatever is noticed.

What is true of this nerve is true of all others. When the root or trunk of a nerve is affected the most noticeable sensations are in the area reached by the distribution of its terminal branches.

Another illustration of this principle is seen in what is commonly called the "feet going to sleep." These sensations are caused by pressure upon nerve trunks in the thighs, usually arising from crossing the legs or from their weight pressing the thighs against the edge of the chair or other seat upon which the person is sitting.

Passing out of the base of the skull through the foramen magnum, the spinal cord extends down through the canal in the spinal column. Corresponding with every joint in the spine a pair of nerves is given off. These spinal nerves—branches of the spinal cord—extend to the right and left, through the inter-vertebral notches or foramen, a pair lying between every two vertebræ.

Together with the surrounding tissues these nerves pretty well fill the foramen. Not so nearly that they are affected by the ordinary compressions of the inter-vertebral cartilages. But so nearly that they are readily compressed and their functions interfered with by the pressure that results when the cartilages are abnormally compressed.

When the nerves are compressed that distribute their branches over the base and posterior portions of the head, there are the well-known aches, pains and distress so often attributed to reflex symptoms caused by uterine displacements and consequent pressure upon pelvic nerves.

When the nerves supplying the cervical muscles are compressed, the patient experiences those sensations that are so often spoken of as a drawing, pulling or stretching of cords in the neck.

When the roots forming the brachial plexes are compressed the shoulders, arms or hands are affected. There is often a partial paralysis of these members; the hands are often cold or numb, fingers feel too big, sometimes the hands and fingers feel as though they had gone to sleep—as though pins or needles were pricking them. Often there are pains in and through the shoulders.

When the thoracic nerves are compressed, there are neuralgic pains or distress that are often called intercostal

rheumatism or neuralgia. The patient is often unable to determine whether the distress is in the walls of the trunk or within its cavity.

When the upper lumbar region and lower dorsal are affected, there are often sensations that not infrequently are described as feeling as though there were a belt of pain or constriction around the waist, or around the right or left half. One patient thought she felt as though the lower part of the body was separated from the upper part, at the waist.

When the roots of the nerves leading to the lower extremities are compressed, the feet often feel as though they had gone to sleep, or as though pins or needles were pricking them. Sometimes there is a severe pain in the heel, sometimes the great toe is affected.

In some cases there is pain or aching between the shoulders, or a tender, sensitive condition; sometimes these conditions are experienced in the region of the kidneys or in other parts of the spine. In other cases none of these symptoms can be detected.

As the spinal nerves give off branches to the sympathetic system, a pressure of the roots of the spinal nerves often affects the vital organs. Not infrequently there are functional derangements of the heart; sometimes there are very serious digestive derangements; sometimes the kidneys are affected. Any of the vital organs, in fact, may be and often are, affected. Sometimes the bowels are affected. Many obstinate cases of constipation are due to this cause and can never be cured until the spinal irritation is relieved.

It is quite evident that the ordinary methods of treatment are entirely useless in all of these cases.

As nearly every part of the body is reached by the spinal nerves, either directly or by connection with other nerves, there is but a small area of the body that may not be affected by spinal irritation. Very many of the obscure cases of chronic disorders, in which the patient suffers year after year in spite of the best efforts of the physician, are cases of spinal irritation. Many cases called hysteria, cases in which the patient complains of sensations that seem too unreasonable to explain, except as a delusion, are spinal irritation. The sensations are exactly as the patient describes them to be, and they will disappear as the spinal irritation is cured.

As so many different parts of the body may be affected, so many different organs distressed and incapacitated, and, as the symptoms are often so varied, and, not infrequently, contradictory, it is not strange that this disease is so generally

Fig. 3. Between every two of these bones (the vertebræ) a pair of nerves pass out, one nerve extending to the right and one to the left. The spinal nerves or branches of the spinal cord (Fig. 3.—1, 2, 3, 4, 5, 6.)

misunderstood, and the patient permitted to suffer year after year.

But few physicians who are not very familiar with this many-headed monster will fully realize how many of their patients suffer from this disease in a greater or less degree.

More than half the satisfactory results given by osteopathy are secured in the

treatment of this disorder. This branch of the healing art is thriving upon a partial success in this class of cases. There are several thousand osteopaths in the United States, many of whom have no small following. Yet my methods of treatment will cure these cases in less than half the time required by any method of massage, with but a fraction of the expense, and will cure many cases that can not be cured at all by those methods.

The reason that medical treatment has usually been a failure in these cases, is because there has almost always been an attempt to do something that should not be done, and the very things that must be done in order to effect a cure are neglected. Most physicians attempt to treat effects. My methods are directed against the causes. When many would use strychnia, assafetida, etc., to stimulate the nerves, and tonics to improve digestion, I endeavor to strengthen and invigorate the inter-vertebral cartilages by the use of sulphur, lime, silica and other chemical constituents of the body, in connection with hygienic measures.

I attempt to supply the chemical elements of the body that are deficient in these patients. The chemical elements, a lack of which in the cartilages, leaves them soft, weak, inelastic, deficient in tonicity, and too easily compressed.

By hygienic measures I attempt to so direct the vital energies of the body that the fullest appropriation of these elements is secured. I teach the patients how to stretch the spine and relieve the pressure upon the nerves, thus securing temporary mitigation or relief of their suffering, even at the beginning of treatment.

By gradually building strength and tonicity in the weak parts, a cure is slowly, but positively, effected.

[Written for the MEDICAL BRIEF.]

Small-Pox.

BY CARL PUCKETT, M. D.,

Pryor Creek, Ind. Ter.

It hardly seems possible that anything new can be written about small-pox, and I suppose every physician knows from reading, if not from experience, how to recognize the disease; but, nevertheless, I will attempt to reiterate what has been said and possibly give a few new points from observation of the disease. Having recently had considerable experience, I may at least bring to my readers a review of variola.

This article is based on the observation of thirty-five cases, and a close study of twenty-two cases that I treated during a recent epidemic among a force of lime kiln laborers. The type of the disease was unusually severe compared to some of our former epidemics. I have had three cases of confluent form, but all recovered, although slower than usual.

The symptoms were, as a rule, definite and easily recognized. The incubation was from ten to twenty-three days, with an average of about fourteen days; only one case of twenty-three days, however. The invasion was usually with slight chill, followed by a rapid rise of temperature, severe frontal headache, lumbar pains and aching limbs. Vomiting was present in about twenty-five per cent of the cases. There were two convulsions among the initial symptoms of one case, a child of four years. The tongue is coated, white, brownish posteriorly and the breath has a very bad odor. The eruption appears in three to five days from the appearance of the initial symptoms. Begins first on the forehead, about the clavicles and on the wrists, and rapidly extends over the rest of the body, till it is complete in the next twenty-four hours. The eruption begins as small pin-head papules, which impart a shotty feel to the hand, especially on the forehead; the temperature subsides at this time and the patient feels fairly comfortable. Within another day the papules change to vesicles, which are round, elevated, and have a small impression in the center. About the eighth day the vesicles change to yellow pustules. The temperature now rises a second time, and the symptoms may be very severe with delirium caused from fever and absorption of poisons from the pustules. The pustules appear over the scalp, on the eye-lids, and among the eye-lashes, and frequently on the lip, extending as far as the mucous membrane, as well as all other parts of the body. In the ma-

jority of cases there was sore throat, sometimes very severe, caused by the appearance of vesicles within the pharynx. By the twelfth day the pustules began to dry and form crusts and convalescence was established. By this time the patients usually felt fairly comfortable, and were anxious to be up unless their feet were too painful to walk, which they were usually for several days in severe cases. It is from two to three weeks from the beginning of the encrusted stage before it is safe to release the patient from quarantine. The complications were few compared to the severity of the disease. The eyes required constant attention in severe cases, and especially those in confluent form; the eyes of two of my patients, males, in confluent form, were completely closed for three or four days, due to the swelling and eruption about the eyes. It looked as if the eyes would be lost, but with constant treatment there was only a severe conjunctivitis in the worst. The pharyngeal complications were severe in these cases, and there was marked swelling of the lymphatic glands of the neck; one of these cases developed a light attack of pleurisy about the time of being released from quarantine, following a cough, from which he had not been free since the beginning of convalescence. Another case of confluent form, female, four months pregnant, primipara, recovered with lighter complications than either of the males and had no symptoms of abortion. Boils and carbuncles were very frequent during convalescence, usually following the more severe cases.

At the onset, and before the eruption appears, a mistake in diagnosis might easily be made if small-pox was not known to be in the community, but by close observation, with symptoms already mentioned, I think a mistake can usually be avoided.

A prognosis can scarcely be made till after the appearance of the eruption. Very severe initial symptoms sometimes preceded a mild attack, in which the eruption was very light. The greatest danger and most severe symptoms were present in the pustular stage. If the eruption is very intense, the symptoms are usually much more severe and the prognosis should be guarded; there is danger of the disease becoming confluent, which also makes it more uncertain.

In the treatment I sometimes used opium if pain was very severe at onset, but usually Dover's powders with salol answered the purpose, five grains of former to ten grains of latter every two or three hours till symptoms abated, then salol alone in ten-grain doses is better, which is good to be used up to second or third day of pustular stage of eruption. It is analgesic, slightly antipyretic, with very little depression to heart's action, and modifies pustulation; in fact, this is where it does the most permanent good.

I used chloral hydrate and cold sponging for restlessness and delirium; also cold sponging alone for fever. Carbolic acid, one drachm to pint of water, is very good as local application for itching, burning and pain during height of eruption. At the beginning of desiccation, I used carbolated petrolatum locally. For the eyes I used a boric acid solution as an irrigation and instilled nitrate of silver solution, two grains to the ounce, five to ten minims three or four times daily, according to severity, where eyelids were swollen so that there were accumulations of pus between and under them; it quickly cleanses the eye-ball of all accumulated secretions, etc.

I may say a few words here relative to vaccination. We usually consider vaccination as only lasting or conferring immunity from seven to ten years. It probably does not confer immunity longer than that as a rule, but will make variola much lighter on a person even as late as forty years after vaccination. All of those that had ever been vaccinated in their lives had the disease in much milder form than those that had not; in some instances only varioloid where vaccination had been forty years previous or during the Civil War, so we see that even though immunity is passed we are in a measure protected.

Vaccination four to six days after exposure will prevent small-pox. One case, for illustration: A married man, who was in the latter part of the vesicular stage when I vaccinated his wife and two children, who had been in the same room

with him from the first appearance of symptoms, and stayed there throughout the attack, while none of the other members of the family contracted the disease. There were a number of similar instances, and I am quite sure that the spread of the disease can be prevented by vaccination after exposure.

I used vaccine tubes and had ninety-seven and five-tenths per cent of successful vaccinations; the failures were only on those that had been previously vaccinated twelve to fifteen years before.

As a last few words on small-pox, I can truthfully say it is justifiable of all the horror, dread and fear with which it has been looked upon. Those in confluent form and many others during the height of the eruption present a terrible picture of suffering. These few points have been written as observations and opinions formed from waiting on the disease during a recent epidemic. I hope they may be of some help to the readers of the BRIEF.

[Written for the MEDICAL BRIEF.]

Rivals of Germs.

BY JOSEPH D. HARRIGAN, M. D.,
New York City.

The old rivalry between germs and chemicals for recognition as the primary cause of disease should, it seems to me, take on new life with the recent discoveries in radio-activity.

Causing, as they have done, a revolution in the scientific world generally, these discoveries have apparently in medicine been utilized hitherto merely in an extremely narrow and limited field.

Restricted to their therapeutic effects, the radio-active substances have been discussed most voluminously in all the medical journals on the globe. The number of cures wrought have been remarkable.

Nowhere, seemingly, has the sinister side of these interesting substances been deemed worthy of very deep investigations. As a cause of disease they have been more or less neglected. The fact that most infinitesimal quantities of these chemicals are capable of producing most disastrous consequences to the animal economy when brought into what might be called "striking" distance, should give one food for profound thought. The fact that they have the faculty of producing molecular disturbances in other bodies at distances of several feet from them, imparting to them at the same time some of their own individual activity, should be a strong incentive to us to review the claims of chemicals and other forces produced through them as positive causes of disease.

According to reports concerning radio-active substances generally, they possess, apparently, all the peculiar properties of which, seemingly, in the minds of many, germs have had hitherto a monopoly, and, moreover, are capable of duplicating all the achievements of the latter.

Thus, for instance, were a small piece of polonium displayed in a room darkened for the purpose, as was done recently by Prof. W. Markwald of Berlin, and pieces of barium, platinum and zinc-blende placed near, the latter will glow with a bright, greenish light. They do not require to be in contact in order to develop these effects. They need only to be in the room in order to be affected.

This opens up such a wide field for speculation and investigation as applied to medicine, that it surprises me that nothing has been developed hitherto along the lines of chemico-activity in its relation to the etiology of diseases.

With a thorough realization that health is merely a perfect adjustment of the chemical and electro-chemical relations of the body, it would appear to me criminal neglect to permit the years to pass along without a thorough investigation of the various chemico-active substances that, diffused throughout all nature, must have an effect upon this delicate adjustment of the organism, resulting at various times and in different places in widespread epidemics of disease.

The tendency of the present day to ascribe all diseases of an epidemic nature to germs has become so universal almost that it seems to have become forgotten that great epidemics of diseases have visited whole communities at times directly traceable to a deviation alone in the chemical adjustment of the body.

Take, for instance, scurvy, that scourge of the sea at various times, and of the land as well, in various of the great wars. No suspicion of germs in that disease is entertained. On the contrary, clearly and unmistakably proven to be due to the deficient supply to the body of such chemicals as are found generally in potatoes and green vegetables, such as, for example, the carbonate of potassium; it may be set down emphatically as a chemical disease, or rather, speaking more correctly, as a negative chemical disease.

History is replete with harrowing tales of the ravages wrought both on sea and land by this dread disease, due simply to what? To a mere matter of an absence of something from the every-day diet. And yet, examining the clinical histories of cases of the disease, one must be struck with the remarkable similarity in the symptoms existing in this disease, as compared with those of many of the so-called germ diseases.

Running through all the stages from the initial or prodromic period of malaise to the rheumatoid pains in the calves of the legs and in the back, the purpuric efflorescences, the eruptions of a decidedly hemorrhagic character, the nodular eruptions, as, for instance, lichen scorbuticus, lichen lividus, acne scorbutica, purpura papulosa; or vesicular eruptions, such as herpes scorbutica, purpura vesiculosa, etc., they present appearances for all the world almost identical with those of the so-called germ diseases.

And all of these symptoms, it is to be borne in mind, due to an absence of a certain chemical ingredient.

In other words, it might be termed a negative chemical disease. Per contra, we should be led to expect positive chemical diseases, due to the presence of certain chemicals in the body, producing even more pronounced disturbances of the system, and also occurring in endemic and epidemic forms of more or less widespread nature.

That such diseases do occur epidemically is not only probable, but is also an actual fact, as testified to by several authors—Liebermeister among others.

As a rival to germs in causing disease, the absence of chemicals can simulate the incubation period and also disease produced by this absence can attack vast numbers of people at almost the same time, but the rivalry apparently stops short when it comes to contagion and also to the conveyance to distances.

But does this hold good with regard to positive chemical diseases? Can we have contagion through chemicals, reduplication and likewise conveyance to distances? If we can prove that chemicals can possess all these properties, then, indeed, have we a most formidable rival to germs, and one that would prove far more satisfactory in explaining many hitherto enigmatical happenings in disease that germs have failed to explain.

Leaving aside the radio-active substances, of which we made mention at the beginning of this article, and coming down to the most ordinary chemicals, a few moments' reflection will, I think, convince anyone of the fact that chemicals, more particularly in gaseous form, can be conveyed from one person to others, both by contact and also by mere proximity; can likewise be conveyed to distances, by means of clothing, letters, rags, etc.; can produce the same disease at distant and diverse points far removed from the original focus of distribution, thus simulating propagation, and can continue almost indefinitely, producing fresh outbreaks of the disease, until finally too attenuated to operate farther. This can be proven by any one experimenting with even the most ordinary chemicals.

To mention one crude example of the conveyance of chemicals to distances might be cited the common, every-day experience of a person present at a "smoker."

He may not participate in the smoking at all, yet it requires but a short time to be in the room where the smoking is being carried on in order to have the clothing completely saturated with the tobacco smoke. He goes home reeking with the fumes to the disgust of his wife, contaminates the air of his sleeping apartment, the air of his wardrobe, the clothing hung therein, possibly even some of his wife's, and it may be a couple of days before all traces of the chemical called tobacco smoke have disappeared. But he

is only one of several hundred that have been present at the smoker. What has happened in his home has also happened in theirs. And here, there, and everywhere throughout the city have many homes been contaminated by the odor or gas or chemical called tobacco smoke. Fellow passengers in the street cars have received some of the supply, which might be said to be almost unlimited in quantity. They have received even enough in the short space of time spent in traveling to be enabled to participate in the distribution process and convey to their homes in turn a share of the chemical.

Betaking ourselves to the various arts and trades, we find the workers therein acting incessantly as carriers of chemicals of most diverse characters and properties, either clinging to their clothing in solid particles infinitesimally small, or in gaseous form, permeating all their garments.

The trained insurance examiner, always solicitous concerning the occupation of the applicant for life insurance, depends upon his olfactories to assist him to a conclusion in this regard in many cases.

Thus, for example, the tanner has clinging to him the odor of the tan-yard, the blacksmith the odor of the blacksmith-shop, the painter the odor of the paint-shop, the coachman or stableman the overpowering odor of the stables, etc.

Notwithstanding all attempts at cleanliness among the workers in the various trades, there still cling to many of them at times the peculiar odors or gases or chemicals pertaining to their occupations. These odors are conveyed everywhere wherever the bearers of them go. They even remain for hours in a room after the visitor conveying them there has taken his departure. Frequently does the doctor open the windows and doors wide after the visit of such a patient, in order to clear the room of undesirable triple extracts.

We are all familiar with the odors of many of the lowest animals. Each of the various families and species have natural odors by which they can be recognized, even at great distances, although the animals themselves may be out of sight. These odors or gases, or, in other words, chemicals, are sometimes conveyed vast distances, and cover wide areas of ground, contaminating the air, leaving traces in footprints that serve as unerring guides to four-footed hunters who would destroy them.

So it is likewise with the human family. There are natural odors or gases or chemicals clinging to each and every individual one of us, imperceptible probably to ourselves except under certain circumstances, but easily recognizable by the lower animals, whose sense of scent is to a far greater degree than ours better developed by nature. Thus a dog will immediately recognize his master even though he may not have seen him for years—simply by the scent. The pursuit of runaway slaves for great distances with bloodhounds not only exemplifies the presence of this natural odor, but also shows how it can be conveyed for miles and miles, with a certain quantity left in every footprint, on every twig or blade of grass touched by the slave, and likewise filling the air to a very great distance around the fleeing object.

Now, if there are natural odors pertaining to us all in health capable of being conveyed distances, contaminating every thing with which we come in contact (a sort of natural contagion or normal contagion), contaminating also the air around (a natural or normal infection), as a corollary, what must we expect to find in disease?

Why, the very same thing intensified.

To any one not completely carried away by the germ theory of disease, the possibility should at once suggest itself that the emanations, or odors or scents, or, in a word, the chemicals in gaseous form, arising from the patient, are as likely to be the prime factor in causing the outbreak of the disease in others—visitors to the sick-room—as well as through them conveyed to others at distances, without in any manner whatsoever depending upon germs for the contagion or the infection or the so-called propagation of disease.

The chemical adjustment of the body is so delicate that the presence of certain chemicals in the atmosphere is just as capable of causing a long train of phe-

nomena that we call symptoms as does the mere absence of some certain chemical ingredient from the food as we find in the case of scurvy.

When we come to realize the extraordinary amount of activity contained in even the most infinitesimal quantities of certain chemicals, and also the fact that they can be conveyed everywhere from the original point of disease in quantities sufficient to set up disease in hundreds of places, until finally too attenuated to operate further, it should certainly command at least some of our attention.

There are dozens of things pertaining to epidemic diseases totally inexplicable by means of the germ theory that are as plain as daylight when read in the light of chemistry.

To cite one example: We might attempt to adjust the extraordinary spread of influenza by leaps and bounds to the germ theory of disease from now to doom's day and only get ourselves tangled up worse and worse as we progressed; whereas, the whole thing is perfectly clear and intelligible on the basis of the presence in the atmosphere of certain chemicals that cause the disease. We may not know what these are, but we do know that their presence must set up disease, and that of an epidemic character, just as the absence of chemicals causes scurvy.

The absence of also or deficiency in the normal supply of some one or other of the chemical ingredients in the atmosphere might be conjectured as a possible cause of epidemic disease in certain cases, just as the absence of certain chemicals in the food is known to cause scurvy, but the limitation of this article preclude my venturing further than merely mentioning it.

In a thousand different ways can epidemic diseases be explained on a purely chemical basis, without the intervention of germs, did we give but a tithe of the time to the subject that is now devoted to the unsatisfactory pursuit of the latter.

Just as concrete life depends upon chemicals for its bedrock foundation, so does disease, if positive, depend upon the presence of, and if negative, the absence of chemicals. It is easy enough to understand that germs never always existed. If they did they would be in possession of one of the divine attributes, viz., omnipresence.

They depend upon chemicals for their bed-rock foundation of existence; have sprung into existence in past ages from that foundation; spring into existence at the present time from the same foundation, and will probably continue doing so until the end of time.

In other words, we have had spontaneous generation at some time in the past, have it continuing throughout the present and will, no doubt, have spontaneous generation till the end of the world.

We have as much right to expect it as we have to expect spontaneous combustion.

To sum up briefly, we should expect to find:

1. As a corollary to the epidemics of scurvy, due to an absence of chemicals, epidemics of other diseases due to the presence of chemicals either in food or in the air we inhale.

2. From the peculiar properties inherent to chemicals, we should expect to find them capable of duplicating all the effects hitherto accredited to germs.

3. That particularly in gaseous form, they are capable of producing these effects to an almost unlimited extent, both by nature of the great quantities developed in this form and by the ease with which they are conveyed to distances, clinging as they do to clothing, letters, etc., in manner similar to perfumes or scents of flowers, but, unlike the latter in their usually pleasant effect, bringing with them wherever they go the baneful message of a withering destruction.

[Written for the MEDICAL BRIEF.]

Calcium Sulphide.

BY J. M. FRENCH, M. D.,
Milford, Mass.

Calcium sulphide (calx sulphurata, U. S. P.) is a mixture of true calcium sulphide, calcium sulphate, and carbon, which should contain from thirty-six to sixty per cent of absolute calcium sulphide. As a matter of fact, however, most of the

specimens found in the shops contain very much less than that, some of them as little as five or ten per cent, since the drug decomposes rapidly when exposed to the air. For this reason it is practically worthless in the form of a powder, and the ordinary unprotected tablet is little better. In order that it should possess and retain the proper strength, it is necessary that strictly fresh material should be made into an easily disintegrating pill, tablet or granule, and that this should be properly coated with a material which is as nearly as possible air-tight, and yet readily soluble. The only safe rule for the physician in the use of calcium sulphide, is to find a manufacturer whose product is reliable, and will produce results, and then always use the goods of this manufacturer.

As might be expected in view of its ready decomposition, and the great difficulty in procuring a fresh drug of proper quality, there is among practical physicians a wide difference of opinion as to the uses and value of this remedy, some claiming remarkable virtues for it, while others look upon it as inert and valueless.

In general, it may be said that the physiological and therapeutic actions of calcium sulphide are those of sulphur. This has long been known as a popular systemic and "blood remedy." Where our fathers took sulphur and molasses, we now give calcium sulphide. If this is not strictly true, it at least gives an idea of the modern uses of the drug. It will be noted that the field of calcium sulphide is very largely that of echinacea, and it is also true that in this field these two drugs have no rival.

Ringer was one of the first, if not the first, to recommend the use of this drug in small doses, frequently repeated; and in so doing brought upon himself the accusation of being "hokeopathic." He advocated its use in doses of one-tenth grain every hour, and claimed to obtain positive results from this dose.

Cushny discusses its use externally, but dismisses its internal use with the simple statement that "it is seldom used internally," a statement which is hardly justified by an examination of current medical literature.

Shoemaker says it is useful in styes, acne, and furuncles, and prevents suppuration when given early.

Ellingwood considers it specific in glandular, nodular, and pustular suppurative inflammations, especially of the skin. He adds that it is most generally relied upon to overcome the tendency to the formation of crops of boils.

Earp reports cases in which it has proved beneficial in carbuncle, orchitis, epididymitis, boils and abscesses.

Watson gives a favorable account of its use in several cases of phthisis.

Coleman claims to be able to abort whooping cough and other contagious diseases by its use, when the treatment is begun early.

Abogado affirms its efficacy in diphtheria, claiming that it cures mild cases without any further medication, and in severe cases proves a valuable adjunct to the anti-toxin method.

Castro and others have urged its value in small-pox. His rule is to begin treatment the moment the malady is suspected, and saturate the system as soon as possible.

Shaller believes that all the contagious fevers are more easily controlled and freer from sequels when the sulphide is used than otherwise.

The following are the principal indications for its use:

1. To stimulate secretion and relieve distressing symptoms, in cough and bronchial catarrhs, where the sputum is tough and scanty, the cough harsh and distressing, and the expectoration putrid.

2. To prevent or abort boils, especially when they occur in successive crops, and to check suppuration and reduce inflammation of the lymphatic glands.

3. To avert or obviate sepsis, in the treatment of all zymotic and septic diseases.

My own experience in the use of calcium sulphide has taught me its great value, and the necessity of giving it boldly and for effect. It has also taught me to be extremely careful to use only a reliable preparation of a fresh drug, put up by a manufacturer in whom I have learned to have confidence.

One use of it I believe to be of sufficient importance to be worth calling especial

attention to. I believe it is possible to produce temporary immunity to most contagious diseases by promptly saturating the system with this drug, and maintaining saturation as long as the exposure continues. An illustration of this fact occurred in my practice last winter. A lady of thirty-five years was taken down with scarlet fever, which ran a typical and moderately severe course. The house was quarantined and in it were confined the husband and little daughter of the patient; also, the husband's sister, none of whom had ever had the disease. From the first I filled them up with calcium sulphide, using four grains daily for the child, and six to eight for the adult. They were all in the same rooms and were freely exposed throughout the whole course of the disease, but none of them contracted the fever. Of course I know one swallow does not make a summer, but as a link in the experience of the profession in this line, I think the case may be worth reporting.

At our local medical society, a few years ago, a discussion arose on the merits of this drug. Dr. J., who is an enthusiast in its favor, claimed great things for it, while Dr. B., who is by nature skeptical, had no faith in it. He was at the time suffering from boils, of which he had had several crops, and had tried various remedies, but to no success. Dr. J. assured him that if he would use a reliable brand of calcium sulphide in proper doses he would change his mind as to its usefulness and activity. He agreed to do so, and was soon convinced by being cured, recanted his former opinions, and became an enthusiastic believer in and advocate of calcium sulphide. Last spring I read a paper before our district society, in which I spoke favorably of this drug. One brother jumped on his feet to say that he had used the sulphide faithfully, but had never been able to get any results from it. Dr. B. at once came to my aid, and suggested that from his experience, if you got a good brand of the real thing, it was all there, and would do its work as advertised. Then Dr. J. spoke up to say that if he should have the failures which the brother had reported with this drug, he should think it was time to try some other manufacturer. So they two are now united in their belief as to the efficacy of calcium sulphide. But Dr. B. remarked to me on the way home that he knew of but two manufacturers in the country who could be relied upon as putting in the market a first-class drug.

If My Boy Becomes a Doctor.

BY C. E. BOYNTON, M. D.,
Los Banos, Cal.

Should my son ever begin the practice of medicine I wish him to know these few things on the side:

Do not handle a nerve-straining case alone, any more than you would attempt to lift a load too heavy for one man.

Do not neglect your meals or sleep to any considerable extent because of your practice. If you do you will be the loser by it in the long run.

Never force a horse in a cruel manner to reach a case sooner. If you kill your horse to save your patient you and the horse are the sufferers. About one patient in five hundred may be generous in dealing with his physician.

If you will have to look to the county to pay you, in this case first find out whether the county Supervisors are willing to promise (the promise is best in black and white) that you shall be paid. Of course, if your pull is cut and dried or your graft is solid, you do not require this advice.

It is said that a lawyer can know too much law to be successful. If you are unable to bound all the ventricles of the brain, you may be a success as a physician in more ways than one.

It is the man that can deal with a question expeditiously that wins. He must know what to consider and what to pass over.

Farmer Brown is poor and in debt, comes to you with $2.50. August, mosquitoes, stagnant water, yellow sclerobic man, generally healthy, now feels mean. It is foolish to examine his blood, urine, feces, retina, and spend an hour inspecting lungs, sputum, heart and history. You can size up his case to the limit of his pocket-book certainly and have him pack-

ing away his medicines in twenty minutes easy. And the $2.50 can be yours and he will call again. You must learn not to put your time into a hole where it yields nothing or worse. Dispatch pays. Folks like it.

When pay is doubtful, the patient unreliable, hygienic conditions bad, and the case a mixup, avoid it and have more time to watch your office.

Do not fear to say: "Sir, your case is one that demands hard work of your physician. I have undertaken a sufficiency of work already." Understand, I study my cases This is a doctor's duty to his patients. If a doctor attempts too much work he can not study his cases. You must seek another adviser. In this you may assist him, of course.

A patient respects a doctor that does not jump to grab his case as a hungry dog jumps for a bone.

Do not suffer under the abuse of a critic and fault-finder, but promptly drop a case where you are given to understand that by being called at all to such "quality" you are being greatly honored.

A young doctor just locating in a town may get dirt like this flung at him: "We always employ Dr. Blank, but as he lives at some distance we sent for you." Really, all they are after is saving a dollar. These people will be poor pay and kickers. It may be as well to say, "Really, I do not wish the case under such circumstances. You must send for Dr. Blank." This may make your start slower, but more substantial.

In dire calamity, when anything would be sacrificed to save the patient, it is then when people are willing to turn to the physician they can not abuse for help.

When people say much about their poverty do not hesitate to say, "There are cheaper physicians. My prices are high. Why come to me when you are not able to employ me?"

Ever impress your patient that you value your time not for the money of possible practice, but for the study hours it represents.

Do not think too much of the proverb, "A still tongue means a wise head." Let people know you can talk. That you have opinions, that you are an individuality and above parsimony, policy, practice hunting and little things generally.

There are people who employ a physician in the same spirit in which they hire a day laborer. Large employers, sometimes, are shy of the self-respecting, self-reliant man. They presume that Dr. Blank knows his trade and they will hire him just as quick, or a little quicker, if he is a poor excuse of a man. You will hear them say, "Oh, he is a fine doctor if you get him when he is sober." Or, "Doc's all right when he has a drink in."

There is one very important rule of life, never degrade yourself. That is, never let liquor or dope cause your brain to halt, stumble or play the fool. Never do what you are ashamed to do.

It is a fine thing always to be kind, sympathetic, fluent, awake and companionable without getting too near, without allowing familiarity carried too far. I think of a man that has many "friends"—they borrow his money and never repay it. I think of another man, just as well liked, as well able to loan his money, but no one asks to borrow of this man. Be careful that you do not err in ways that will prompt your friends to always stand you off.

Be nobody's door mat. When pay for an office call is due say, "two dollars, please." If he says, "I will hand you the money to-morrow." Say, "you see the printed rules, 'office calls cash.'" If no more is said most likely the man gets the cash for you. Do not fall into this "all right, all right" way when they try to stand you off, but give them to understand that it is not all right, and must be set right.

It is, as a general thing, hard to make as much money at medical practice as at blacksmithing, plumbing, or saloon-keeping. If a man is not sharp and exacting, unless he is a genius, a wonder, a man of exceptional tact, he may have to face poverty in old age, if he is a doctor. So it is, if my boy practices medicine I shall see that he has a good business education, as a matter of self-preservation.

I am a great admirer of the MEDICAL BRIEF.—J. C. ANDERSON, M. D., Alexandria, La.

[Written for the MEDICAL BRIEF.]

Observations Concerning the Bottini and other Operations for Hypertrophied Prostate.

BY M. R. BARKER, M. S., M. D.,
Chicago, Ill.

Mercier first developed a method for operating upon the middle lobe of an hypertrophied prostate, by means of which a portion of this lobe could be cut or torn away. This method consisted of an instrument introduced into the bladder, through the urethra, like a metal catheter. The instrument was provided with a short cutting beak, so constructed that it could be made to grasp and cut, or tear off, pieces of the middle lobe, and thus dig a channel through the prostatic tissue and provide a way for the urine to escape. This operation did not meet with very extended, nor enthusiastic, approval by the surgical profession. The danger from hemorrhage and sepsis was great, and there was no way of controlling either. Yet this work was an advance step in the right direction, and Mercier has properly received due recognition for it.

In 1874 Bottini promulgated his operation, the inspiration for which was gained from the Mercier method, upon which it is an improvement. Bottini has since improved his instrument many times, and now it is as nearly perfect as it can be. It is hardly necessary to describe, more than briefly, the Bottini method, as it was almost universally adopted by the surgeons of the world, and used in thousands of cases and in every land. Bottini's method consists of an instrument so constructed that it could be introduced into the bladder, through the urethra, the same as the Mercier instrument. It has a short beak and a hollow shaft. A platinum blade is made to fit a slot in the beak. This blade is connected with a battery, through the shaft, and is thus heated red-hot. The blade is then drawn slowly through the diseased prostatic tissue, burning a groove as it passes. Three of these grooves are usually made, one posteriorly and one on each side of the mouth of the urethra. These grooves do not grow together, but remain open channels for the passage of urine. It is easy to understand that this operation was an improvement upon the Mercier method. The burning prevented hemorrhage, to a great extent, and the wounds were less susceptible to infection and they would not grow up. The Bottini operation was performed for every class of hypertrophied prostate. There was no differentiation made and its failures were quite numerous. In that class of cases where the enlarged prostate had so disarranged the musculature of the bladder that it could not perform its function, and in which the nerve supply was interfered with by pressure of the large prostate, this operation could not cure as it did not remove the cause of the trouble. Many of these cases which were not cured, however, were palliated, for it made a much more free egress through which the urine could run from the bladder. Hence, there was less residual urine, and what expulsive force the bladder still possessed could be used at better advantage. The operation was criticised, however, from different standpoints. It was called an unsurgical procedure because it did not remove anything, and must be done without the aid of either of the senses of sight or touch. Sometimes the grooves were burned too deeply and too long; at other times the reverse was true. Sometimes the blade was too hot, and again not hot enough. In other words, the whole procedure was uncertain. Occasionally hemorrhage followed the operation that caused anxiety on the part of the surgeon and patient, and sometimes infection followed. These things prompted renewed activities in the surgical mind to evolve some other method for the relief of these cases.

The relation between the testicles and prostate having been known for many years, and the fact that the removal of the testicles in some of the lower animals caused the prostate to atrophy, led some workers in this field to believe that castration would cause the prostate to atrophy in man. Hence, in 1885 Sinitzin performed double castration upon a man for the cure of his enlarged prostate with apparent good results. In 1894 White and Ramm, prompted by the same idea, and

working separately and unknown to each other, performed double castrations for the cure of this trouble, with encouraging results. Following the publication of these cases, the operation was performed many times, by different surgeons, with varying results. The per cent of mortality was large, as it will always be, in any major operative procedure where it is done as a dernier resort. This was naturally the case in this operation, for men would not submit to it as long as there was any other alternative. Hence, a very large per cent of patients were very feeble when the operation was done. Less than fifty per cent of those who survived were cured, while a quite large per cent were not benefited. Unpleasant psychic conditions followed in a good many cases, due to the removal of the testicles. In view of the mortality, and all the unpleasant after-conditions that followed this operation, surgeons were again compelled to seek another way.

Isnardi reasoned somewhat in this fashion: If some operation could be devised that would produce the same effect upon the prostate that double castration does, and the evil effects of castration avoided, such an operation would meet the conditions. Believing the vas deferens was the connecting link between the testicles and prostate, and that taking a piece out of each of these, in any case, would destroy the connection between the two and produce the same result as castration, this operation would be submitted to much earlier than castration; hence, would have that advantage. It could be done under local anesthesia and was in fact a minor operation. The operation was performed many times, but did not meet the hope of surgeons, yet it was probably more extensively employed than the operation of castration. Of these two last methods, we may say they were operations on one portion of the sexual system to relieve a diseased condition of another portion of the same system, and were indirect and unsurgical in this respect, and the relief sought, as it must be in all such indirect methods, was only partial and disappointing.

In passing, we may also mention the operation promulgated by Bier, which consisted in ligating the internal iliac arteries on both sides, thus cutting off the blood supply to the prostate, in the hope that such a procedure would cause the hypertrophied gland to atrophy. This work was done extra-peritoneally. Bier gained his inspiration for this operation from reported successes that had been produced by the ligation of the uterine arteries and double oöphorectomy for producing atrophy of uterine myomatous tumors. This work was too major for prostatics and did not gain surgical approval to any extent.

We have spoken of these operations in this paper for the reason that they indicate the activity of the surgical mind during the period between the decline of the Bottini operation and up to our present methods of operating upon the hypertrophied prostate, of which we have spoken in previous papers.

The question might arise in the minds of some: In view of the different methods of operating for the cure of hypertrophied prostates that have been devised, used and discarded within the last forty years, have we yet reached that high degree of proficiency which will stand the test of time? We do not know this. We only know that the work now being done is based on sound surgical principles and whatever of improvement may come must come along these lines; and that every true surgeon will work unceasingly to overcome faults that may exist, and will hail with delight any improvement in technic or method that will add one iota to the safety and comfort of his patients.

We would not convey even a suspicion of criticism upon any of the operations we have mentioned in this paper. They were all promulgated by noble men having the best interests of suffering humanity at heart. They did not arrive at their conclusions hastily, nor did they put them into operation thoughtlessly. The operations which have led up to our present and better methods in this work, characterize the caution that has ever marked the surgical profession. We have no established operative procedure today that has not been approached in this careful manner. While the results of these

methods were not as satisfactory as those which follow present and more scientific work, they were, nevertheless, good, and mankind owes to these now discarded methods a debt it can not pay.

The Bottini operation is the only one mentioned in this paper which still has a place in the surgery of the prostate. Many surgeons insist that it now has no place in this work, but I am sure they are mistaken and must join issue with them. This operation has two important places, in my judgment, in this work: First, in a certain well-defined class of cases in which it is indicated and should be the operation of choice. Second, in another class of cases where it is not the operation of choice but is justifiable. We have stated the well-known fact, in a previous paper, that prostacism may be caused by a fibrous band surrounding the neck of the bladder. This is a form of hypertrophied prostate. A portion of prostatic tissue, surrounding the neck of the bladder, hypertrophies, forming a ring about the urethra at the neck of the bladder. This ring mechanically occludes the urethra. The musculature and nerve supply of the bladder wall are not materially interfered with. The subjective symptoms are those due to dysuria and enuresis. Digital examination per rectum reveals nothing in many of these cases to the unskillful. One must be familiar with this work in order to detect this ring by digital examination in most cases. For this reason many wrong diagnoses have been made. The sound may pass with difficulty, or may not, depending upon the position and condition of the ring. If this ring is suspended, as it were, in the tissues so that when the detrusor urinæ and sphincter vesicæ muscles contract to expel the urine, it falls into the mouth of the urethra, acting as a stopper, the urine does not pass normally, if at all, while a sound passed from the opposite direction may enter the bladder easily. This has been the rule in my experience. There are cases, however, where this ring is a tense band and as time goes on, it grows tighter until the opening through it is so small that urine can not pass. In these cases a sound can not be passed at first, but usually a filiform bougie will pass, which can be followed by small sounds and thus the canal dilated. This dilatation, however, amounts to nothing, so far as treatment is concerned, as it will close up in a very short time, and the dilating can not be performed too frequently, as it will set up an inflammation in those tissues and then trouble is without end. In this class of cases the Bottini operation is admirable. It can be done under cocaine anesthesia. It burns three grooves through this fibrous ring, usually severing the ring in three places, affording ample room for the escape of the urine. The patient is up in a day or two and has no unpleasant urinary trouble following the work. In other words, it cures the case in the most satisfactory way possible.

In the second class of cases, where the operation is not the one of choice, but justifiable, is where the patient is suffering with prostacism due to an enlarged prostate, but refuses to submit to any other operation. That is, he will not submit to a cutting operation, but will submit to this. I believe it is our duty to do the best we can for these patients under all circumstances, and if this operation is the only one the patient will allow, we are justified in giving him the benefit of it, even though we know it is not the best operation for him, but are satisfied that it will ameliorate his suffering and bring to him a certain measure of relief. The Bottini method has another disadvantage. The instrument is very expensive, costing sixty dollars, besides the battery, which costs twenty more. The battery is heavy, weighing from seventy-five to one hundred pounds. Hence, it is not easily portable, and can not well be taken to the patient's home for use; and as it is indicated in a rather small per cent of cases, surgeons do not as a rule provide themselves with the outfit.

4625 Greenwood Avenue.

Enclosed find one dollar for the MEDICAL BRIEF. I have been a subscriber for many years and will continue to be as long as I continue in practice.—W. H. MCCONNELL, M. D., Brimfield, Ohio.

[Written for the MEDICAL BRIEF.]

The Secret of Health and Its Possession.

BY AXEL EMIL GIBSON, M. D.,
Los Angeles, Cal.

(Continued from page 736.)

The Basis for Good Health.—The philosophy and art of health find their practical application in a true, natural life. Nature enlists with unerring safety her noblest forces in the service of the true and useful, and while implacable and death-dealing in her action against the breakers of her laws, she becomes a protective and loving parent to those who obey her statutes and promote her aims. Fighting a disease on its own ground and with its own weapons implies the same principles as attempting to expel darkness by striking it with a club—a merely negative and futile measure—as such a fight involves an attitude of defiance of Nature in the efforts of the latter to reestablish a disturbed equilibrium, while, on the other hand, a resolute compliance with the laws of health, regardless of results and conditions, places the individual in a positive relation to life and its harmonious, constructive unfoldment. From studying the laws of death, and becoming palsied by its terrors, let the sick and suffering turn their attention and energy to the laws of life with its possibilities of health and joy. Let him eat rightly, breathe rightly, and think rightly, and his re-installment in the order of a progressive evolution will be as resistless as the revival of spring follows the breaking up of winter.

The Different Schools of Healing and Their Claims—the Fallacy of Electricity.—Comprehending existence as the expression of an ever-moving vital force, sweeping through and energizing the various forms and substances of evolution, it follows that this force—homogeneous and changeless—receives its protean appearance from the ever-shifting substances and organisms through which it acts.

This gives rise to the three primary modes of relation existing between the life-current and the forms through which it operates, viz., the normal, the supernormal and the sub-normal order of existence. To the first order we refer all modes of existence which sanely and harmoniously respond to the evolutionary impulse; in the second we include conditions which by a superinduced sensitiveness respond too vividly to this impulse; while the last-mentioned class of activity which through a lessening of natural vigor respond too slowly to the evolutionary stimuli. The first condition manifests in physiological balance—health; the second in congestion, fevers, inflammations, etc., and the third in atony, debility, paralysis and dissolution.

Now, the avowed object of any school of healing is to equalize the abnormal conditions by subduing the super-normal and stimulating the sub-normal life-processes. But while the aims of the very schools are identical, the methods and principles employed by them differ widely. The schools of drug medication base their system on the theory that the phenomenon of disease has its explanation in lack or absence of vital stimuli, and that the drug, by letting loose in the system highly charged carriers of vital dynamics, supplies this want. Even granted, however, that the relations between a deranged function and the corresponding drug could be controlled, and the special want of vitality in the function thus be adequately met, the question still remains, whether an organism losing its vital power through some structural break-down, has yet the power to assimilate and organize substances purporting to be carriers of new supplies of this power. For the great majority of diseases, so far from being caused by a lack of vital supply, are rather caused by a super-abundance of this supply.

Now, if this be so, then evidently the incongruity back of the disease is not to be traced in the presence or absence of certain vital elements, but rather in abnormal changes in the function itself. And as in our social industries, a supply, if not solicited by a preceding demand, gives rise to a congestion in the market, so a supply, forced upon a bodily function without the latter having first evinced a corresponding demand, *i. e.*, power of response, results in functional congestion with subsequent general metabolic disorders.

Hence, as a stimulating agent, medicine must be paid for in terms of depressor-effects, manifesting through devitalizing reactions. In this respect the action of medicine upon the bodily functions is very much the same as the therapeutic action of electricity, as in either case the stimulation comes from without in terms of mechanics, rather than from within in terms of dynamics. For it must ever be remembered that the establishment of true and permanent health is possible only by preparing conditions whereby life may be introduced and made to act by its own spontaneous power.

Now electricity, being unable to find the subtle tracks of nerve-connections on which the vital principle moves as organized constructive power, proceeds rudely and at random to push the side-tracked human engine across the structural and physiological obstacles which may be blocking its unguided path of action.

For electricity is a mechanic force, and can not more substitute life in the animal organism than it can substitute the intelligence by which it is charged and operated. The function of electricity as a therapeutic factor, is to serve as a vehicle for the vital messages dispatched from the psychic centers of the cerebral cortex, per *medulla oblongata*, to every physiological or functional center of the organism. Hence, simply to charge an organism with electricity is principally the same as to send off a carrier without instructing him with a message. Sweeping along or across the involved nerve-paths in currents of vitally unemployed force, the electric discharges may succeed in arousing promiscuous action in the system, but being without the power of eliciting any purposive, intelligent results, are naturally unaccompanied by any permanent, constructive, self-sustaining health.

For it must never be forgotten that the value of any therapeutic agent is limited to its power of preparing conditions for an unobstructed and tranquil flow of life from center to circumference, and from circumference back to the center. To generate life, *per se*, is impossible, hence any stimulant, introduced into the system, will be found to exhibit the same mode of action, and accompanied by the same result, as the whip applied to the back of a tired-out horse; the strain of an already decimated vitality urged to yield new efforts without a corresponding re-enforcement of the waning functional and structural powers. And this, again, will go to show that the only reliable course of therapy is found in the introduction of conditions favorable to a spontaneous assimilation and elimination. Conditions of this character are principally brought about by freeing Nature from the weights and shackles of waste products by adopting hygienic measures such as physical culture, breathing exercises, out-of-door life, and, above all, a sane diet.

Science of Diet, the Science of Life—A Moral Factor.—For the science of diet is the science of life. With the exception of an advanced structural breakdown and subsequent functional insufficiency, there is no physical ailment which is not amenable to diet when applied as a corrective. This power of a scientific diet to work miracles is due to the fact that back of most functional disorders stands the specter of an outraged stomach. And as Nature knows of no royal road to health, and furthermore, as action and reaction are equal, it becomes a mere matter of logical inference that a return to health must qualitatively proceed through a series of physiological incidents corresponding to the original points of departure, a process resembling the attempt of reëstablishing a disturbed balance, when weights must be added to or taken away from the unequal arms in exact correspondence to the extent of the original displacement. And as any violation of the laws of health means a rupture of a physiological equilibrium, with the subsequent disturbed balance of health, so the restoration of the latter means to render up a sum of dietary restrictions equal to the sum of previous over-indulgences which originally caused the disease.

Thus, at the root of every self-imposed disease is found a moral element—the inexorable sway of retributive justice with its relentless necessity of self-mastery and self-conquest. No disease can be thoroughly cured without the individual's moral nature has received a corresponding improvement. *Mens sane in corpore sane*, is a statement not less true if taken in its reversed sense. To enjoy a thor-

ough health, the mind not less than the body must be sane and balanced in its functionings. Yet there should be a motive in possessing health outside of the mere power of attainment. To subject ourselves to denials and restrictions in diet, and employ decency in our general modes of living for the mere sake of getting on the best side of mother Nature with a view of being paid off in terms of health, does not involve a betterment of our moral nature for its own sake, and is, therefore, incapable of giving birth to the harmony which is conditional to permanent health. For the motive in this case would be wholly selfish, and Nature's services can not be permanently enlisted for the furtherance of selfish aims. Health is a form of wealth, and the struggle for its possession may involve springs of motive, not less selfish and unworthy than those which may lie back of the pursuit of less valuable treasures. Health for health's sake differ in no principle way from the motive involved in wealth for wealth's sake, or art for art's sake. In either case the attainment aims only at self-enjoyment.

Usefulness, the Greatest Medicine.—What gives force and permanence to health lies in the universality of its motive. Health for life's sake; health for the increased usefulness to the world and humanity, which such attainments entails. Health culture in any form is morally legitimate only to the extent its practices aim at an increased power of usefulness and service. Desiring health for health's sake is not more rational than to build houses and edifices without connecting them with any principle of usefulness for prospective occupants.

In the successful pursuit of health, the question of usefulness enters as an indispensable factor. An hour of useful, purposive work, involving muscular exertion, such as lawn-mowing, wood-chopping, sawing, shoveling, etc., is of more vital value to the individual than several hours spent in the indoor gymnasium or athletics. Usefulness, purposiveness, helpfulness and general service furnish the keynote to the harmony and moral equipoise which forms the basis of all real health, strength and beauty, in human, no less than in universal nature.

The Practice of Medicine Based on the Principle of Vicarious Atonement.—The origin of the influence which the practice of drugs exerts over the mind can be traced to the insiduous promises it holds out of being able to confer upon the individual a power of wrenching unearned benefits from Nature. Back of it lies the old, vicious idea of sinning on grace, of shirking dues, while relying on the mystery of a vicarious atonement to help the transgressor out of his self-imposed difficulties. The hope of final triumph over disease is bound up with the realization by each individual of the fact that action and reaction are equal and uninterruptible, and that a cause can not be removed without tracing back and cancelling, step by step, link after link in the vital chain of effects, the incidents connecting the actor with his acts.

The Necessity of a Knowledge of Dietetics to Insure the Individual Against the Artifice of Modern Cookery.—Metaphysical and moral postulates so far in any way from interfering with, or substituting a practical application of individual hygiene to the elementary conditions back of health, become a positive aid in this respect. Thus, a scientific study of the laws of dietetics is indispensable with the maintenance of a physiological equilibrium. And while it is true that the robust health of the savage, who is ignorant about the physiological chemistry of foodstuffs, seems to disprove the necessity of such a study for the average man, it must, on the other hand, be borne in mind that the savage has the guidance of a natural instinct, which the civilized man has not. Hence the savage, yet in the possession of a palate vitally responsive to the unerring impulses of Nature's health-life, has a comparatively easy task in selecting a bill of fare corresponding to the vegetative needs of his nature; while the civilized man, suffering under the difficulty of having to depend for his judgment on a palate rendered utterly unreliable under the influence of a cookery which caters to sensual enjoyments rather than to functional needs, is constantly bewildered by the deceptive representations of an overwrought and almost suicidal appetite. To obtain a permanent health and vigor of the body it is necessary to know what

elements are needed, or not needed, for effecting a physiological balance in our daily existence.

A Bit of Physiological Chemistry.—As is generally known, the elements necessary for vegetative life are brought into our body economy under the three primary forms of foodstuffs: Proteids (albumin), carbohydrates (sugar-starch), hydro-carbon (fats), of which the first mentioned furnishes the muscles, the second the fats, and the third the heat, with their respective fields of usefulness; the first in the construction and repair of the body machinery, the second in the protection of its tissues from cold, contusions and friction, the third in the generating of heat and energy for general locomotion.

The extraction and assimilation of these elements from the various foodstuffs require the action of specific organs and functions in the system. Thus, the starch is extracted and digested in the mouth through the dissolving action of a ferment (ptyalin) found in the saliva, and furnished by the parotid glands. The proteids are extracted in the stomach, under the combined influence of the two ingredients of the gastric juice—pepsin and hydrochloric acid—while the fat, when reaching the small intestine, is turned into an emulsion preparatory to the final lacteal absorption.

In this connection it must be noticed that each one of these digestive ferments is specific in its kind, and can only act on a definite foodstuff. Thus, pepsin and hydrochloric acid (the gastric juice) have no power to affect either fats or starch, while ptyalin (the salivary juice) is inadequate to digest any other substance than starch, and so on. Hence it is evident that a foodstuff escaping the action of its specific ferment is largely lost to the body-economy, save through the promiscuous digestion which under the strain or expediency is carried on in the small intestines.

Why Fried Foodstuffs Are Injurious.—A careful consideration of these facts will teach us invaluable lessons in mastication and sanitary cookery. For it is evident that a substance, soluble only in saliva, can be digested only when such a solvent is secreted, the mouth; while on the other hand a certain phase of cookery—frying—by imprisoning the starch or proteid molecule in a capsule of fat, brings about a similar condition of indigestion. The distress which most people with weak stomachs experience after having eaten fried meats is due to the specific action of the various digestive ferments. For as it is first after the foodstuffs have entered the small intestine that they come under the action of the pancreatic juice, which holds the only fat-splitting solvent in the body, it follows that the encapsulated starch or proteid foodstuffs are partly lost to the assimilation, notwithstanding the tremendous expenditure of energy and secretive fluid involved in the futile efforts of the stomach to digest its impossible contents. Engineered on a basis of mechanic leverages, the gastric action continues as long as its contents resists reduction into a homogeneous and friction free pulp (pepton), conditional for absorption. For as the encapsulated foodstuffs refuse to yield to the gastric elaboration, it follows that the grinding action of the stomach continues until its available energy is exhausted, and the labor from sheer functional exhaustion is brought to a close.

(To be continued.)

[Written for the MEDICAL BRIEF.]

Intestinal Surgery.

BY DRS. PENNEBAKER AND TRIPP,
Pleasant Hill, Ky.

(Continued from page 745).

Intestinal anastomosis is done for two classes of cases, *i. e.*, acute and chronic. In the latter, patients are prepared for weeks before the operation, and hence time is not so much a matter to be considered as when emergency is the moving indication.

Distinction is made between primary and secondary resection of the enteron. The former is made for gangrene, the latter for artificial anus. In a resection, when a greater portion of bowel is removed from the mesenteric side than from the distalward part, the distension and paralysis of the tube which follows is due to interference with the vascular supply.

It is not necessary to resect a triangular piece of mesentery, and it is inadvisable to sew together the edges of the rent

in the mesentery, as it might include the vessels. Resection of the bowel is required for three classes of cases, *i. e.*, strangulated hernia, ileus, and intestinal perforation. There is considerable mortality aside from the pathology in the treatment of these conditions. Good results are attained through early diagnosis and operation when intestinal obstruction has been positively excluded.

The rupturing strength of the bowel under pressure shows that the mucous membrane offers very little support, as it became torn during the distention. It is necessary that the muscular and serous coats be united at the seat of approximation to secure proper strength of the enteron. The sub-mucous coat can be torn under considerable less pressure; hence the Lembert suture should be inserted transversely to the longitudinal axis of the enteron and should embrace the mucosa.

The differentiation of the stomach end of the divided intestine may be made as follows: Grasp the divided ends of the enteron and hold them as if the operator held a simple undivided loop of intestine, so that the divided ends of the mesentery look dextrad and sinistrad. Then place the finger in contact with the mesentery, using it as a guide to determine if the finger remains all the time upon the side on which first placed; if so, up is cephalad and down is caudad. If the finger starts in on one side and crosses to the opposite side of the abdomen and mesentery, then there is a half-twist in the loop and what is held as the end cephalward is the rectal or side distalward of the divided enteron. If the tracing finger leaves the side on which it started, passes across the meson and returns to the side where started, there is a complete volvulus, and the direction of the twist and its extent is readily determined.

In making a circular suture of the resected enteron, unless pre-sectional stitches are introduced before dividing the viscus, it is impossible to preserve a straight line in the closure. Every suture should include a bit of the sub-mucous tissue; these three or four pre-sectional stitches tend to prevent eversion of the mucous membrane. The first pre-sectional ligature is inserted at the mesenteric border of the enteron, at a point as free from adipose tissue as possible. When the segments of the resected bowel are of unequal size, one end is closed by suture and the other end is implanted in a slit made into the long axis of the intestinal tube.

Two methods of uniting the resected intestine are employed, *i. e.*, the end to end union, or lateral anastomosis, the divided enteron being closed by sutures, and the mechanical approximation of the segments, this being attained by special devices. It may be formulated, if we wish to repair the intestine we select mechanical means; the method by suture has always held its own, but requires a certain familiarity with its technique. Argument is in favor of mechanical methods, in time saved in sewing. First among mechanical devices is the Murphy button, though its position is likely to be superseded by the so-called anastomosis ring, which promises more for safety and results. The Murphy button is so made that it will accommodate itself to varying degrees of thickness of tissue and make uniform pressure. This explains why the pressure at the mesenteric junction, where there is greater thickness, is uniform. The field of the button is a limited one, and it will be mostly used in connection with operations upon the gall bladder, and in the end to end anastomosis of the intestinal canal.

It is objected that it does not secure a permanent opening in the enteron of sufficient caliber, and this is a fatal insufficiency. In one case, symptoms of obstruction supervened, the opening becoming plugged with hardened feces; here it might be conceived that enterotomy might have relieved the condition. It further may be surmised that tissue necrosis might become more extensive than desired; experience, however, does not confirm this as occurring frequently. Death has occurred from gangrene at the site of the button; in another instance the button was found in the proximal side of the anastomosis at autopsy.

In two cases of gastro-enterostomy the button was found after death in the stomach.

With the button end to end, anastomosis is fifty per centum safer than lateral anastomosis.

Prof. Ludwig reports the condition of the various coats of the intestine thirty days after the use of this device. "The line of union, almost linear in thickness, could be traced by a very small but distinct cicatrix; the various layers appeared to be in perfect juxtaposition, the longitudinal being almost restored, and with the exception of the mucosa the coats were completely united by connective tissue. The mucosa had undergone degeneration."

If the button does not pass in three or four weeks the rectum should be examined, as it may rest just inside of the sphincter. The occlusion of the button by fecal impaction can be easily avoided by cathartics immediately after the operation. Primary adhesions may be hastened in malignant cases by abrading the peritoneum with the scarifier.

As mechanical devices, the bone plates of Senn, and the vegetable plates advocated by Dawbarn, have the advantage of providing a sufficient opening and as being free from the danger of remaining in the proximal side of the anastomosis as a foreign body in the intestine.

Dr. Abbe's cat-gut rings present the advantages of a sufficiently large surface for approximation and at the same time leave an ample opening in the bowel. One case of fatal hemorrhage is reported, caused by the premature liberation of an Abbe's ring, due to its twisting upon itself; the operation was one of gastro-enterostomy.

The mortality of lateral anastomosis is comparatively small when plates or rings are used, and it has been reduced but little by the Murphy button. Patients should receive liquid nourishment as soon as possible after an operation for resection upon the enteron, and alvine evacuations should be frequently secured.

Several special forms of hernia should be discussed in connection with intestinal surgery. Among these, yet to be mentioned, congenital hernia of the umbilical cord form a class of cases that will require early operative procedure. This hernia may contain the enteron alone, the liver and enteron, or the liver only. The coils of the bowel and liver may be seen through the transparent cord. From embryology we learn that from the sixth to the twelfth week of intra-uterine life, the umbilical cord contains a portion of the tractus intestinalis. At this time the umbilical vesicle should atrophy, the bowel recede into the abdominal cavity, the navel ring close and the omphalomesenteric duct become obliterated. Just why the liver has been found here has never been explained; some museum specimens contain the heart as well.

Dr. H. Speier, of Rochester, Minn., expresses himself as follows: "The word congenital includes any morbid change that may take place in the child before it is born. In the creative, or developmental stage, which is completed at the end of the sixth week of intra-uterine life, any malformation of the child which is then present can not be remedied by nature unassisted by artificial means." If the fetus has an umbilical hernia into the cord at that time it will be born with this condition. "In other words, Nature abandons her work after the sixth week, so far as repair is concerned." The prognosis in hernia of the abdominal viscera into the umbilical cord is grave. It is advisable to operate as soon as possible and do the radical operation before adhesions form. Cases are reported as cured by wearing a truss.

Laparotomy was performed upon a female child not an hour old; there was evisceration of the bowel from the duodenum to the sigmoid flexure through a small umbilical opening; the hernia included the mesentery. This had developed in a sac formed in the cord, which would have contained about one and one-half pounds. The abdomen was so contracted from the absence of the enteron therein contained during development that it would not contain the eventrated viscera without enlarging the same. This being done, the intestine was replaced and the wound sutured; the bowels responded to castor oil and a few doses of one-third drop of tincture of opium.

Colotomy is indicated in many cases where excision of the bowel would be impracticable. It relieves the symptoms and retards the growth of neoplasms and prevents obstruction, as well as prolongs life through the relief of pain.

The operation, especially the inguinal, relieves tenesmus and constant discharges

from the rectum, and it prevents the straining and congestion of defecation. The inguinal procedure is preferable in the majority of cases to the lumbar; the incision is smaller, the depth of the wound less and it offers greater facility for abdominal exploration. Further, the position of the patient in making the operation renders anesthesia safer, and it is easier to find the colon and fix it to the skin; this operation of selection forms a better spur, and the site of the artificial anus is more cleanly and the adjustment of a pad is more practicable, and as a matter of greatest importance this operation is less dangerous. By preference the left side is selected, exceptionally the right. The direction of the colon is determined by touching the bowel with sodium chloride, thus exciting reverse peristalsis; the use of sodium carbonate for this purpose is dangerous. A great drawback to inguinal colotomy may be the inability to retain feces; this is not seen in lumbar colotomy. Stenosis or malignant growths affecting the ileo-cecal connections indicate ileo-colotomy.

Gangrenous portions of the enteron necessitate resection, and either direct restoration of the continuity of the bowel or an artificial anus.

Colectomy, made for a malignant growth, provided the meso-colon is slightly or not at all invaded, or the tumor is not too adherent to the neighboring organs, and it be possible to mobilize the tumor and to separate the diseased parts without the abdominal incision, is a possible operation. A stricture of the descending colon of a cancerous nature was excised through an incision made as for left lumbar colotomy. The patient was a lady fifty years of age, suffering from the obstruction for eight weeks. She was very feeble. The bowel was removed in the track of the incision by pulling the strictured segment through the wound; each portion of the bowel, with its two orifices after division, were then attached to the lips of the wound.

In peri-typhilitis, if the patient can withstand shock and peritonitis, the abscess will point as do others near the pelvis. There are occasional collections of matter at this anatomical site that have no relation to the intestinal canal, *i. e.*, psoas-abscess, abscess of the right ovary, the migration of pus from distant points, etc. The mortality in subacute cases is greatest prior to the third day; the generality of peri-typhlitic abscesses originate in the appendix vermiformis.

The extreme surgical practice of the present day is not founded on the invariable gravity of the disease, but on the difficulty, if not impossibility in many instances, of distinguishing when the trouble is grave, or likely to become so.

Abscess of the abdominal wall followed by a fistulous communication with the intestine, may arise from stercoral ulcers, eventuating in abscess. These cases were not uncommon, but were always fatal (Dr. C. K. Briddon). It is a prevailing opinion that such troubles are not infrequent among the colored people.

There is one other form of abdominal cavity abscess that largely owes its etiology to intestinal disease, *i. e.*, sub-phrenic abscess.

In sixty cases almost half followed appendicitis; of one hundred and twenty-nine cases, twenty-three were subsequent to appendicitis. Perforation of the diaphragm occurs in twenty-five per cent of such abscesses. The following is the clinical report of a sub-phrenic abscess that developed subsequent to appendicitis: There was great pain and tenderness in the region of the appendix and along the ascending colon. The liver was enlarged and somewhat tender and was likewise displaced downward. The patient lost flesh and concomitantly there was elevation of pulse and temperature. After an operation for appendicitis the local abdominal symptoms continued in a direction cephalad with constitutional expression. Evidence of an abscess pointing at the tip of the left twelfth rib made its appearance; this, on being incised, proved to be a large abscess, which had formed between the diaphragm and liver. The patient recovered. These abscesses may be extra- or intra-peritoneal; pus may burrow cephalad behind the colon, perforate the diaphragm and discharge through a bronchial tube. Pain is a symptom of importance, usually in the region of the liver, with depression of its lower border. Pain in the right shoulder is noted in a number of cases, and hic-

cough is rather a common symptom, due to irritation of the diaphragm. Many of these abscesses contain gas as well as pus.

The treatment is necessarily surgical, operation through the pleura being deprecated unless pus exist in the pleural cavity. Of forty-one cases operated upon through the pleural cavity in fourteen there was an exudate found therein.

The infra-costal incision is considered best, if practicable. If the abscess is located well mesad it may be necessary to drain through the thorax and sew the diaphragm to the costal pleura to avoid infection of the thoracic cavity. The incision should be below the pleura, if possible, so as to strike the abscess directly, if extra-peritoneal, or through adhesions, if time has been sufficient for their formation.

The pleura descends as low as the tenth rib, and by resecting a portion of this rib and pushing away the costal membrane, about two inches of the ninth and even eighth ribs may be resected and the abscess reached without incising the diaphragm.

The mortality of sub-phrenic abscess is forty per cent, fifteen per cent in operative cases and twenty-five per cent in the non-operative.

[Written for the MEDICAL BRIEF.]

A Case of Typhoid Fever.

BY F. MABELLE MURPHY, NURSE,
Baltimore, Maryland.

The following is a report of a case of typhoid fever that was exceptionally interesting to both the doctor and myself:

August 6. Patient a young girl, fourteen years old, tall and slender for her age; had been complaining for several days of tired feeling; was quite sick when the doctor (who was Dr. Geo. Hocking, and who attended case throughout) first saw patient; with temperature 103.5° F.; with most positive signs of typhoid. Four days later, when I went to nurse patient, temperature at noon 105° F., pulse one hundred and thirty. Patient was given cold packs, changing the large bath towels, used for the pack, every few minutes, for half hour to forty minutes, depending on nervous state of patient; followed bath by alcohol rubbing.

Orders.—Heart stimulants, strychnine and digitalin every two hours.

Nourishment.—Liquid, consisting of milk, albumen, chicken broth with well cooked rice and strained, from three ounces to four ounces, every two hours; had great difficulty in giving nourishment to make patient swallow; sometimes would hold in mouth for five or ten minutes, often taking three-fourths to hour to give three ounces. Patient vomited once or twice some of milk; that was about all vomiting during whole of the siege.

Second Week.—Controlled temperature by packs, which this time had to lessen, to great extent, owing to the poor circulation and reaction. The patient now delirious, having up until this time a clear mind; voided urine involuntarily, also stools, bowels moved every day, loose, not too excessive. Temperature, mornings, 101.4° F. to 102° F. Pulse, one hundred and twelve to one hundred and twenty. Temperature, evenings, 103.8° F. to 104.8° F. Pulse, one hundred and twenty-four to one hundred and thirty; condition running along this line, varying slightly for following seven to twelve days.

By expiration of second week, supposed to be fourteenth day, patient, evening, was very restless, with an anxious expression, temperature running high, 104.2° F.; sponged lightly arms, legs, quieted to some extent but not lowering temperature. There seemed to be nausea, great difficulty to swallow, patient being very weak; saline enema (tepid), pint every four hours, to lower temperature, which lowered about a degree. Patient in state of coma, vigil quite marked for thirty-six hours, eyes following every movement in room, then seemed to quiet and fell asleep; condition slightly improved after sleep of two hours, temperature not quite so high; tongue thickly coated.

Third Week.—About twenty-first day had quiet night, slept well, temperature, three A. M., 101° F. Pulse, one hundred and eighteen; 5:30 A. M., severe hemorrhage without any indication except sight of blood; bleeding stopped when discovered. Pulse now very good, temper-

ature 102.4° F., pulse one hundred and sixteen. Telephoning the conditions to the doctor, was ordered to give one-sixteenth grain morphia, one-six-hundredth grains atropia, hypo. for fear sudden conditions, which would be unfavorable, should arise.

Not until three hours later, nine A. M., temperature 101° F., pulse one hundred and ten, but suddenly, without apparent warning, pulse weakened until imperceptible, whole body trembled very violently, face and finger nails blue, the whole appearance of the patient was death, and that very soon, indicating further hemorrhage. Increased dose of strychnine and digitalin, and used doses of morphia one-sixteenth grain, as indicated. In addition to former orders, an intestinal astringent was given every two hours for two days.

Saline injection subcutaneous, one ounce, repeated in hour. In one and half hours after impending collapse there was violent muscular twitchings, marked cyanosis, temperature axilla 106.8° F., pulse at this time was weak and very irregular; one hour later temperature dropped to 104° F., pulse one hundred and twenty, easily counted, good volume. Could take some crushed ice four hours later, condition not so good, temperature 105.6° F., pulse one hundred and forty. Muscular twitchings, some cyanosis. Emulsions of turpentine in doses of forty-five drops was ordered by Dr. Hocking for every three to four hours. Seven P. M., three hours later, temperature now down to 104.8° F., pulse one hundred and thirty-five; circulation improved.

Five hours later, midnight, temperature 102.2° F., pulse one hundred and twenty-six. At this time patient could swallow crushed ice.

Saturday, received usual nourishment, milk and albumen. The least movement or excitement would cause pulse quickly to ascend, quieted such times with morphia. Bowels not having moved for three days, enema was given; there was some distension of abdomen now. Enema consisted:

℞ Water.....4 ounces.
Glycerine.....2 ounces.
Olive Oil.....2 ounces.

Results, very large formed stool with very little exhaustion to patient.

Following days patient sleeping great deal, only awaken for nourishment and medicine. Fourth day after hemorrhage, temperature from 102.8° to 103.4° F., with pulse one hundred and sixteen to one hundred and twenty-four.

After quiet night patient aroused, although delirious; crying, said had pain in abdomen. Temperature, 4.30 A. M., 102° F.; pulse, one hundred and twenty. Was little restless. Hypo. morphia, one-sixteenth grain, quieted for time. Again she complained of same pain. Soon following this she hiccoughed, and made several attempts to vomit. After this symptom the whole body trembled violently. There was a marked cyanosis, pulse imperceptible, thus indicating a perforation. Heart stimulants in addition to strychnine, digitalin, nitroglycerine, and hypodermics. Brandy was given. Pulse now detectible, but not countable. Noticed there was some response to stimulants.

Saline subcutaneous injections, one pint, repeated in one hour. Patient now pale and lifeless, being in this state for five hours. By three P. M., slight change for better. Orders same as before.

Three saline enemas, each one pint, at interval of four hours. At four P. M., temperature 102° F.; pulse, one hundred and thirty-two. Turpentine emulsion discontinued, and nourishment stopped for twenty-four hours. At eight P. M., bowels moved very good.

Wednesday, day following perforation, the delirium now becoming of violent character, having difficulty to keep patient in bed. In addition to orders, hyos. brom., one one-hundredth grain, was given, as needed. Temperature dropping now gradually. Pulse growing stronger. Temperature, morning, 100° F.; pulse, one hundred and sixteen, but patient is very hysterical, having crying spells. Three days after perforation, nourishment was extended to beef extracts and broths. Four days after perforation diarrhea set in. Proteine was very effectually used in this when needed. Several days temperature rose toward night, but not to go above 102° F. Still very delirious, also hysterical, then followed periods of stupor.

Fourth week, passive congestion base of both lungs. Cotton jacket was applied

with good results. No baths prior to two weeks of this had been given, owing to the very sensitive condition of skin, also a peculiar condition of skin was noticed at this time, simulating in appearance the linea albicantes. It was especially marked over the hips and knees, where the tension was great. Patient was rubbed twice daily with cocoanut oil.

Occasionally would apparently be rational, and showed all signs of convalescing, but her mental condition was pitiable. Hysterical until she sits up, especially at night, continuing until seventh and eighth week.

Hyos. and brom. mixture was used very successfully to control hysteria, and restlessness. All this time the patient had to be watched.

By ninth week, mind was clear, pulse and temperature being normal in morning for three weeks.

Tenth week, down stairs on piazza, able to walk a little. Made full recovery.

1211 East Preston Street.

[Written for the MEDICAL BRIEF.]

Semi-Revolution of the Earth—Evolution of the Brain.

BY SILAS HUBBARD, M. D.,
East Aurora, N. Y.

According to the findings in the last pre-glacial period, as indicated by the works and remains of paleolithic man and his equatorial companions, the old equator must have run through Norway and Sweden and between England and Egypt in latitude (now longitude), down through the center of Africa, lengthwise, and so continued on through Behring straits, between Alaska and Siberia to the place of beginning. All these places were pointing east and west lengthwise either under or near the old equator, or at least under the old torrid zone; but the vast accumulation at one or both of the then poles and arctic regions caused the then poles to come under the sun by the attraction of the sun on the vast accumulation of ice, constituting it the thickest and heaviest part of the earth; and that was the cause of the last glacial period.

The last pre-glacial period found Africa largely under the torrid zone and the last glacial period still left Africa there; and there it continues to be, compelling the human species there to grow black, and always continuing them black; while the other human inhabitants were also originally black, but gradually changed their complexions after many generations after being whirled from the old torrid zone into the boreal and temperate regions by the sudden semi-revolution of the earth, which caused the last glacial period and great floods by the sudden melting of the vast accumulation of ice which was suddenly brought in the now torrid zone by the sudden semi-revolution of the earth.

Some one will ask why the earth did not return to its last pre-glacial position after the ice had melted and the water had become equalized? I will answer that, with the glacial period there were great earthquakes, and the diameter of the earth became greater through the present equator than through the present poles; therefore, by the law of attraction, it is forced to remain in the present position to the sun till the ice again vastly accumulates in the arctic regions, causing the diameter of the earth through the arctic regions to be greater than through the present equator.

I will say that the former northern pole was near what is now the southwest corner of Colombia, S. A., where it joins the Pacific ocean; and the south pole was near the southern extremity of the Malay peninsula. Let geographers and geologists study the former effects of the former arctic regions as indicated by the present appearance of the land and water, which are in and near the former arctic regions, which surely would include the route of the Panama canal, in which are found many boulders of glacial deposit.

I published a short article on the subject of this paper in the MEDICAL BRIEF, Volume XXXI, page 1024, which would further illustrate the subject.

I would like to enquire of anybody who knows, whether the number of the convolutions of the brain are equal in number as to the savage, barbarous and ignorant man and the educated and enlightened man, or does the difference merely consist in the educated and enlightened man possessing greater depth and prominence of the convolutions and more gray matter?

Examination Questions of the University of the State of New York.

Answer any ten of the questions under each heading, but no more. Check the number (✓) of each one of the questions you have answered.

ANATOMY.

TUESDAY—9:15 A. M. TO 12:15 P. M., ONLY.

1. Describe the articular extremities of the humerus.
2. Give a description of the general lymphatic system.
3. Describe as to structure (*a*) a vein, (*b*) a capillary, (*c*) an artery.
4. Give the microscopic appearance of compact bone tissue.
5. Describe the hip joint.
6. State the origin, insertion, action, blood and nerve supply of *one* of the following muscles; masseter, scalenus anticus, erector spinæ, external oblique, tibialis anticus.
7. Describe the circle of Willis.
8. Mention the veins that empty into the inferior vena cava.
9. Give the structure of the spinal cord.
10. Describe the course of the pancreatic duct.
11. What is the pons Varolii, and where is it situated?
12. Give the origin and function of the abducent nerve.
13. Describe the lobes of the liver.
14. Give the anatomy of the nasal duct.
15. Describe (*a*) Poupart's ligament, (*b*) Gimbernat's ligament.

PHYSIOLOGY AND HYGIENE.

TUESDAY—1:15 TO 4:15 P. M., ONLY.

1. Mention the varieties of connective tissue and state the special function of each.
2. Describe (*a*) the animal cell, (*b*) animal cell division.
3. What are the circulating liquids of the body? Give the functions of each.
4. Describe the physiology of hearing with special reference to the functions of (*a*) tympanic membrane and auditory ossicles, (*b*) semicircular canals, (*c*) the Eustachian tube.
5. Describe the nervous and muscular mechanism of (*a*) deglutition, (*b*) vomiting, (*c*) hiccough.
6. Describe the functions of the skin and of its appendages.
7. Mention the products of intestinal digestion and state what disposition is made of these products.
8. State the function or functions of (*a*) bilirubin, (*b*) hemoglobin, (*c*) myosinogen, (*d*) fibrinogen, (*e*) caseinogen.
9. Give the successive steps in the digestion of a meal of roast beef and potatoes.
10. What is the value of alcohol as a food?
11. How long is it advisable to quarantine (*a*) a diphtheritic patient, (*b*) a small-pox patient? Why?
12. Mention the various methods of bathing and state the hygienic rules to be observed in each method.
13. Give a detailed description of a hospital ward for babies and state the hygienic regulations to be enforced in the care of the inmates.
14. What evils arise from outside privy vaults? How may such evils be averted in cases where these vaults can not be supplanted by more modern contrivances?
15. What is the most healthful material to wear next the skin? Why?

CHEMISTRY.

WEDNESDAY—9:15 A. M. TO 12:15 P. M., ONLY.

1. What are salts and how are they formed? Define neutral salt, acid salt, double salt.
2. Mention *five* elements found only in combination. Into what groups are elements divided? Illustrate.
3. Give a method of determining atomic weight by chemical means.
4. Define sublimation, distillation, static electricity, galvanic cell, organic compound.
5. Mention the halogens. Why are they so called? Give the formulas of three compounds, each of which shall contain a different halogen.
6. State the sources of ammonium compounds. Give the composition, the method of preparation and the properties of sal ammoniac.
7. Give a test for (*a*) ferric compounds, (*b*) ferrous compounds. Write the chemical names and the formulas of *three* salts of iron used in medicine.
8. Give the normal specific gravity of urine. State the pathologic and the non-pathologic causes of abnormal deviations in the urinary specific gravity.
9. What is the composition of atmospheric air? Define humidity of the atmosphere, rarity of the atmosphere.
10. What is the chemical antidote for lead acetate poisoning? Explain the chemical action of this antidote.
11. Define electrolysis, ions.
12. What are (*a*) albuminoids, (*b*) proteids? Give examples of each.
13. Give the formula of (*a*) common (ethyl) alcohol, (*b*) sulfuric ether, (*c*) acetic acid.
14. How is nitro-glycerine prepared? State the medicinal uses of nitro-glycerine.
15. Mention *four* alkaloids of opium.

SURGERY.

WEDNESDAY—1:15 TO 4:15 P. M., ONLY.

1. Give the indications for reopening wounds.
2. Describe in detail nitrous oxid anesthesia.
3. Give the various surgical methods of treating epilepsy.
4. Give the symptoms, diagnosis and treatment of fracture of the lower end of the fibula

with avulsion of the internal malleolus (Pott's fracture).

5. What is understood by spontaneous dislocation? Describe a form of spontaneous dislocation.

6. Give the indications for tracheotomy and describe the operation.

7. Give the etiology and treatment of epistaxis.

8. Give the signs and symptoms of popliteal aneurism and indicate the treatment.

9. Give the symptoms and treatment of vesical calculus.

10. What conditions of the kidney require nephrectomy?

11. Describe an operation for the cure of prolapse of the rectum.

12. Give the symptoms and treatment of rupture of the bladder.

13. Give the treatment of contusion of the eyeball and describe the sequels.

14. Give the differential diagnosis of hydrothorax and empyema. Give the treatment of one of these conditions.

15. What are the indications for curetting the uterus? Describe the operation.

OBSTETRICS.

THURSDAY—9:15 A. M. TO 12:15 P. M., ONLY.

1. What are the physiologic processes concerned in the reproduction of the species?

2. Describe the changes that take place in the uterus as the result of pregnancy.

3. Give the causes and treatment of pernicious vomiting in pregnancy.

4. What signs and symptoms, subjective and objective, should be considered in making a diagnosis of pregnancy?

5. Give some general rules for the application of asepsis and antisepsis in the obstetric chamber in private practice.

6. Mention the conditions that justify the induction of abortion (not premature labor). What appropriate means may be employed to induce abortion?

7. Define *accouchement forcé;* state indications for its employment and describe appropriate methods for performing it.

8. Give the diagnosis and management of a brow presentation.

9. Describe the technic employed in the delivery of a retained and adherent placenta.

10. How may an occipito-posterior position influence labor? Give the management of an occipito-posterior position.

11. Mention the indications for version and state methods of performing the operation.

12. What special immediate care should the newborn infant receive? State the diet of the newborn in case lactation has failed.

13. Describe the left lateral position, also known as the semi-prone or Sims' posture, and state its principal gynecologic advantages.

14. Describe the technic of bimanual palpation. State the special purposes of bimanual palpation.

15. State the uses and dangers of the uterine sound and describe the technic of its employment.

PATHOLOGY AND DIAGNOSIS.

THURSDAY—1:15 TO 4:15 P. M., ONLY.

1. What is an embolus? Mention frequent sources of emboli. State the sequels of embolism.

2. Mention the causes of cardiac hypertrophy.

3. Give the pathology of arteriosclerosis.

4. Mention the characteristic bone changes in rachitis.

5. What is the composition of the inflammatory exudates? Describe healing by granulation.

6. Define phlegmon, abscess, ulcer, fistula, furuncle, carbuncle, caries.

7. Describe gangrene and its varieties. What is the line of demarcation in gangrene?

8. What are the secondary heart changes in chronic mitral disease?

9. Mention the syphilitic lesions of the brain and of the spinal cord.

10. Describe leucemia. What pathologic changes occur in leucemia?

11. Give an outline of the structural changes that occur in phthisis pulmonalis.

12. Differentiate intermittent, remittent and continued fever.

13. Give the gross and the microscopic appearance of an epithelioma of the lip.

14. How may pleuritic friction sounds be distinguished from râles occurring in the bronchial tubes?

15. Differentiate cardiac dyspnea, nervous dyspepsia and asthma.

THERAPEUTICS, PRACTICE AND MATERIA MEDICA.

FRIDAY—9:15 A. M. TO 12:15 P. M., ONLY.

"* * * in therapeutics, practice and materia medica all the questions submitted to any candidate shall be chosen from those prepared by the board selected by that candidate, and shall be in harmony with the tenets of that school as determined by its State board of medical examiners."—Laws of 1893, chapter 661, section 146.

Questions prepared by the board of examiners representing the Eclectic Medical Society of the State of New York.

1. Describe the symptoms and treatment of sciatica.

2. Give the causes and treatment of gout.

3. From what is atropin obtained? Describe the uses of atropin in medicine.

4. How is wine of colchicum seed prepared? Give its therapeutic uses.

5. Give the causes and treatment of tetanus.

6. State from what pepsin is obtained and give its uses in medicine.

7. Describe the therapeutic uses of bismuth subnitrate.

8. Give the therapeutic uses of gelsemium.

9. Give the preparations, the doses and the therapeutic uses of scoparius.

10. Give in detail the treatment of acute capillary bronchitis.

11. Give the therapeutic uses and the physiologic action of veratrum viride.

12. Give the cause, symptoms and treatment of acute coryza.
13. Describe malarial fever and give its treatment.
14. Give the symptoms and treatment of catarrhal jaundice.
15. Describe iritis and give its treatment.

THERAPEUTICS, PRACTICE AND MATERIA MEDICA.

FRIDAY—9:15 A. M. TO 12:15 P. M., ONLY.

Questions prepared by the board of examiners representing the Medical Society of the State of New York.

1. Give the therapeutic uses of gelsemium.
2. Give the physical signs and the treatment of pericarditis.
3. On what change of castor oil in the intestinal tract does its purgative action depend?
4. Give the therapeutic uses of acetic acid.
5. Give the treatment of diabetes insipidus.
6. Give the physiologic action of podophyllum. Mention the name and state the dose of resin of podophyllum.
7. Give the therapeutic uses of prunus Virginiana.
8. Define anthrax and give its etiology and treatment.
9. What is the proportion of mercury in blue mass? State the dose of blue mass.
10. Define styptics and hemostatics. Mention (*a*) *two* styptics, (*b*) *two* hemostatics.
11. Of what pathologic condition is acute nasal catarrh a symptom? Describe the treatment of acute nasal catarrh.
12. How do tinctures differ from spirits? Give an example of each.
13. Describe the therapeutic uses of iodoform. State the dose of iodoform for internal administration.
14. Mention the sequels of influenza (grip). Give treatment.
15. State the sources and the dose of salicylic acid.

THERAPEUTICS, PRACTICE AND MATERIA MEDICA.

FRIDAY—9:15 A. M. TO 12:15 P. M., ONLY.

Questions prepared by the board of examiners representing the Homeopathic Medical Society of the State of New York.

1. Differentiate alumina and opium in constipation.
2. Give the homeopathic indications for digitalis in heart diseases.
3. Differentiate cimicifuga and rhus toxicodendron in rheumatism.
4. Differentiate carbo vegetabilis and argentum nitricum in diseases of the stomach.
5. When is viburnum opulus indicated in dysmenorrhea?
6. Give the symptoms and treatment of acute pleurisy.
7. Differentiate belladonna and glonoin in headache.
8. Differentiate esculus hippocastanum and aloe socotrina in hemorrhoids.
9. Give the characteristic respiratory symptoms of ipecac.
10. How should a case of renal colic be treated?
11. Differentiate carbo vegetabilis and muriatic acid in typhoid fever.
12. Give the general characteristics and the therapeutic uses of picric acid.
13. Describe the cough of (*a*) belladonna, (*b*) hyoscyamus, (*c*) rumex crispus.
14. Give the urinary symptoms of cantharis.
15. Describe the treatment of acute gout.

[Written for the MEDICAL BRIEF.]

Cause of Death in Drowning.

BY C. B. KING, M. D.,

Atlanta, Ga.

I want some or all of the many thousands of doctors who read the BRIEF to tell me what is the cause of death in drowning?

Does water ever enter the lungs before drowning or while drowning? Or does it enter the lungs after drowning, or does it ever enter the lungs even after drowning? Does not constriction of the larnyx in Nature's effort to shut out the water to prevent drowning cause death by asphyxiation?

I never made an autopsy after drowning and ask to know from some brother who can tell me if the lungs of a drowned person contain water after death.

512 Austell Building.

Graft.

This is the title of a reprint from the NATIONAL DRUGGIST of St. Louis, and gives in terse terms the full purpose of all "Pure Food and Drug Legislation." After the NATIONAL DRUGGIST shows up the true inwardness in the proposed legislation it proposes a remedy, if such is necessary, by which pure foods and pure drugs can be secured, but not by the lax methods that would prevail if the present prospective laws were to become a fact. It would simply result in what the writer terms a "graft" that would be far-reaching and be a disgrace to our country, and perchance by an investigation be scandalous in its nature. We enter our protest against measures that pretend to be good in their nature and at the same time smack of the elements that would make them obnoxious not only to the average person, but the professional as well.

It is good reading to all who are interested in the facts in the case, and shows up the "nigger in the woodpile."

A. Brothers B.S. M.D.

Adjunct Professor of Gynecology to the New York Post-Graduate Medical School and Hospital; Visiting Gynecologist to Beth-Israel Hospital; Fellow of Academy of Medicine; Member of the County Society, Obstetrical Society, Eastern Medical Society, County Medical Association, Harlem Medical Association, Society Alumni of Bellevue Hospital, Physicians' Mutual Aid Association. New York City.

VOL. XXXIII. ST. LOUIS, MO., NOVEMBER, 1905. No. 11

Editorial.

The Good-Natured American.

It is not queer, when you come to think of it, that the continental foreigner speaks of us as the good-natured American, the man easily imposed upon.

The Atlanta *Journal-Record of Medicine* (January, 1905) says: "The German Supreme Court forbids the use of the title 'Doctor' in Germany when granted in the United States."

Stop and think what an insult this is to the American doctor. Suppose we should do the same by the German graduates who come here to compete with us, all Germany would be wild. Let those doctors who are so fond of foreign things consider what an insult is offered to physicians who have received their diplomas in the United States and are consequently debarred legally from using their titles in Germany.

What is the matter with the American brand of science, learning and skill that it should be held in such contempt, and what is the matter with the American doctor that he will stand such treatment?

Not only do we admit German patented preparations, but allow the Continental foreigner to use the American Medical Association and its organ to run down the products of American chemists and praise up those made in Germany. In other words, the American profession is insensibly lending itself to hurt its own prestige and to lessen the esteem in which the products of American chemists are held.

There is no foundation, whatever, for this false and unnatural state of affairs. There are no more skillful doctors and no finer medical preparations anywhere in the world than right here in America when tried by the test of merit.

It is time we understood the foreigner better and made him understand us. The strongest trait in the American character is fairness. The Continental foreigner is quick to grasp at the advantage this gives him, at the same time he regards it as a weakness and has a contempt for us as a consequence. The Continental foreigner is

arrogant, very sure of himself, all virtue begins and ends with him and his.

Now, it is all very well for us to welcome the foreigner from Continental Europe to our shores and to put him on an equal basis with ourselves, but we have got to recognize his state of mind and make him keep his pretensions within bounds.

American humor, common-sense and fairness put us at a decided disadvantage in dealing with a self-important people, eager to seize and make the most of every opportunity to exploit themselves and their country.

The Germans are good people and have their own virtues. We have no prejudices against them, but we must compel them to recognize that we have some rights also, that we are their equals in every respect and insist upon being treated with the same fairness and justice that we show them.

Some of us are to blame in having shown a tendency to echo the Continental foreigner's assertion that his brand of learning and his medicines are the best. Some unthinking Americans have heard this so often they have come to take it for granted without stopping to investigate, and they are fittingly punished with the decision which the narrow provincial German Court throws into their teeth.

Do you consider yourself inferior to a man who has graduated in Germany? If not, why let anyone say so? Why tacitly accept the position of inferiority thus thrust upon us? It is one thing to give the Continental foreigner an equal chance with ourselves and quite another to let ourselves be insulted and decried on every hand.

When it comes to insulting the American doctor and the institution which graduates him, when it comes to running down the products of American chemists and using the *Journal of the American Medical Association* to push those of foreign manufacturers, it looks like it was time to draw the line. What do you think? Haven't we been easy and good-natured long enough?

The American has no superior in any department of life when you come down to facts. The trouble with the American is he does not realize the real greatness of his country. The Editor of this journal has travelled all through Germany, observing closely the people, customs and institutions. They have many good qualities, but are not cosmopolitan, lack the breadth and tolerance so conspicuous in the American's make-up. We shall be doing him a service as well as defending our own people from unjust aspersions, in refusing to be dominated by the Continental foreigner's personality.

For that is what it amounts to. When the American sets out to do a thing he has few equals and no superiors anywhere.

Opportunity.

It is in the nature of things that the selfish man misses many opportunities to get along in the world. The selfish man is so wrapped up in himself that he fails to see the golden opportunities which always come to the unselfish man.

Unselfishness quickens a man's perceptions, makes him considerate, just and fair to all. He is on the alert to do the other man a kindness, consequently he creates for himself an atmosphere of trust and regard wherever he goes, and which is a most valuable business asset. The intellectual powers of the unselfish man are free to observe closely and to engage a problem. He sees and makes the most of a chance which completely escapes the selfish man.

In other words, it is the law of compensation working out in accordance with the old French proverb that we find what we look for. This attitude of mind may be so cultivated that a man can find opportunities for himself and for his friends also. There is no question that Grant owed much of his success to the strong friends he made. It is impossible for any man to succeed without friends, not mere acquaintances, but true friends.

The man who has an optimistic mind is always on the lookout for an opportunity to assist or to benefit somebody. He is well-disposed toward all mankind, and mankind is quick to perceive and reciprocate his sentiments. There is always room and welcome for the optimistic man. He is filled with the forces of organization and progress. He expects and prepares for success. Grumbling, dis-

content, carping criticism and other forces of anarchy are absent from his composition. All his strength is given to building up his legitimate interests and lending a helping hand where he can.

Every step we take in life is governed by its own laws. In finance if we spend less than we earn we accumulate. So, also, if a man is constantly on the lookout not to do another an injustice but welcomes an opportunity to say a good word for him, it gets to be known and helps that man just as the truthful man's reputation is useful to him.

The unselfish man, whose disposition is to believe the best of his fellowmen and to do them a service when he can, often sees the truth of another old proverb exemplified, that it is always the unexpected which happens.

Do not trouble about your enemies; take care of your friends is a maxim which leads to success. Selfishness and unhappiness are inseparably connected; on the same principle unselfishness and success are one and indivisible.

The business man who habitually treats his subordinates well knows what an enormous difference it makes on the profit side of his ledger. Often, indeed, success or failure hinges on this one factor. Cheerful, prosperous, satisfied employes are bound to accomplish more than despondent, unhappy people. Selfishness does not pay as a business proposition.

Beware of the Fanatic.

Several of our best known periodicals entering the home are in the throes of what is contended to be a temperance campaign. These publications carefully study the taste of their readers, and are quick to welcome every hobby and fad that furnishes sensational matter. Spurred on by the sympathy of well-meaning white ribbon enthusiasts, they are devoting a great deal of space to a crusade against patent medicines. The flaring head-lines and melodramatic word-pictures of the effects of using alcoholic drugs have created an almost hysterical demand for immediate governmental action.

Now, we have nothing but praise for the motives which actuate the good ladies of the W. C. T. U., and those whose aid they have enlisted, but suppose we consider the ultimate results of such legislation as has been proposed to remedy the evil. Pressure is being brought on Congress to pass a law requiring every druggist selling proprietary medicines containing alcohol to take out a liquor license. Would this accomplish the desired end of killing the sale of patent nostrums? The law would make no distinctions in favor of those pharmaceuticals, dispensed on physicians' prescriptions only, in the manufacture of which alcohol is used as a necessary solvent. The druggist, therefore, would be compelled to obtain a license or lose the most lucrative part of his business—that of filling prescriptions. Whether he be high-minded enough to discourage self-drugging by refusing to sell patent medicines is evidently a question entirely foreign to the matter in hand.

Should the law become a fact, the druggist will not be blind to the opportunities offered to reimburse himself for the expense of the license, and will likely avail himself of the further privileges conferred. Wonder how the ladies will enjoy having their prescriptions filled at the same counter over which a bottle of whisky is sold the loafer too lazy to walk to the corner saloon? By the way, if the various patent medicines have really become such popular thirst quenchers, the saloon keeper will soon have to stock his shelves with them! Doubtless the over-zealous agitators have not stopped to reflect that the success of this misguided warfare against patent medicines would virtually double the number of saloons, and make it easy for topers to secure their liquor on Sunday in those localities where the saloons are closed on the Sabbath. Beware of the fanatic.

Convulsions.

BY W. T. MARRS, M. D.,
Jewett, Ill.

If everything else has been tried, even chloroform, do not forget the quick manner in which an hypodermic of apomorphine relaxes nerve tension. Dose, for adults, one-twentieth to one-tenth grain; children, one-fortieth to one-thirtieth grain.

[Written for the MEDICAL BRIEF.]

A Little True Story Illustrative of the Reversed Relation of Specialist and General Practitioner.

BY R. C. ATKINSON, M. D.,

Professor of Diseases of Children in the Marion-Sims-Beaumont Medical College.
St. Louis, Mo.

Before a man leaves the general practice of medicine for a specialty, he should be sufficiently skilled in diagnosis to enable him to recognize the exanthema so easily as not to confuse it with either the eruption of blood poisoning or any possible effect of diphtheria, yet some years ago I was called for by a father who had employed a throat and lung specialist to treat a case of diphtheria in his family, of which family I was the physician. The father asked me to go at once—that explanation would be made later, and conducted me to the door and into the carriage of this specialist, who would explain matters to me. The explanation of the specialist was this: "I found she had diphtheria, and I put her on very large doses of the tincture of the muriate of iron. Within twenty-four hours she broke out with a peculiar eruption and she grew worse rapidly; her respiration seemed to be very much affected, and I told the family when I saw the child this afternoon that we must have her family physician to see her with me, as she was in great danger."

On arriving at the house I found great alarm manifested by every member of the family; two trained nurses were present. The mother said to me: "Oh, doctor, will my child die?" I said, "I do not know, madam, I have not seen her. If she has diphtheria she is in danger." I went to the bedside with the doctor at one elbow and the mother at the other. I found a case of measles, and the following were the symptoms manifested. Catarrh of the eyes and nose, a hoarse cough, the features swollen, and a red, raspberry-colored eruption on the face, collected in crescentic groups. That was before the day of the discovery of the "Koplik spots," which will be observed in many cases as much as seventy-eight hours before the recognition of the eruption on the face. They are found in the mucous membrane of the mouth, on a line with the molars on either side of the mouth.

I have never, in a practice of thirty odd years, seen a case of diphtheria which in any respect resembled this case. There were present all of the catarrhal symptoms which are characteristic of measles, and without which I have never seen a case of measles to occur. There was a deep, hoarse cough that always accompanies measles; there was an eruption of the skin characterized by the peculiar clustering and colored as I have described. There was a temperature. All of these symptoms had been preceded by three days of malaise, during which the child appeared ill, complained of soreness of the throat and had incipient catarrh of the eyes, nose and larynx.

On examining the throat of the child I found absolutely no membrane, and I can not conceive of a case of diphtheria of the throat in which there is no membrane, and although I have read and heard of the eruptions produced upon the skin by excessive doses of iron, never having seen a case I fancy the eruption would be more of a purpuric character than of the elevated nature of the measles eruption. And I can not conceive of a case of diphtheria so well defined as to be recognized by the attending physician that could have disappeared within twenty-four hours, after the administration of large doses of muriate of iron. Suffice it to say that the conclusion of this little over-true tale is this: That at ten o'clock the next morning, the eruption having moderated, the child was infinitely better, sitting up in bed and playing with her toys. The specialist failed to meet the general practitioner, as per promise next day, having made his call an hour earlier and disappeared. The child recovered in a few days, contracted diphtheria two years afterward and died of a most malignant attack, which disease the general practitioner thinks the child never had before. During the treatment of the case of measles, there was no medicine used, except whisky as a stimulant for the purpose of thoroughly bringing out the eruption.

BY JOHN GEO. GARSON, M. D.,

Advisor on Identification to the Home Office, London; Vice-President of the Anthropological Institution of Great Britain; Honorary Corresponding Member of the Anthropological Societies of Paris, Moscow and Rome; Late Swiney Lecturer at the British Museum, and Lecturer on Comparative Anatomy at the Charing Cross Hospital. London, England.

A cursory glance at the skin of the palmar surface of the hand at once reveals the fact that there exists upon it two well defined kinds of markings.

On the palm and opposite each of the several joints of the fingers and thumb is situated a series of lines which have been conveniently termed crease lines. They mark the folding or crumpling of the skin, which is produced as a result of flexure movements of the hand, such as those of grasping. The best marked of these lines run generally more or less transversely and obliquely on the palm, longitudinally and obliquely on the ball of the thumb, and transversely on the digits. Subject to slight variation they are constant in appearance and position and are closely correlated with the movements of the joints. There are also other crease lines, less conspicuous in appearance, distributed over the palm and the palmar surface of the digits, which run in various directions, but do not appear to be directly correlated with joint-movements, or even to possess any marked degree of constancy. As old age advances and the skin of the hand becomes loose and crumpled in consequence of wasting of the subcutaneous tissues, they have a tendency to increase in number and to make their appearance in places where formerly they did not exist, particularly in persons who do but little manual labor.

The second kind of markings consist of a series of alternating ridges and furrows distributed over the whole palmar surface. They are much more numerous than the crease lines, though much less conspicuous; indeed, on certain parts of the hand they are so faintly marked as to render the use of a magnifying glass necessary to distinguish them. On the margin of the palm from the wrist to the little finger, on the eminences at the base of the digits, and on the terminal phalanges of the digits they are much better developed and impart a perceptible roughness to the skin of these parts. The height and width of the ridges and the depth and breadth of the furrows not only vary considerably on different portions of the hand, but also on the same parts of it in different persons. The number of ridges and furrows on a given area likewise varies considerably. This, together with variation in size, gives a distinctive appearance of fineness and coarseness to them in different persons. They are, as a rule, finer in women than in men, and

in children than in adults. In the latter they are best developed on the hands of persons who do a moderate amount of manual labor, and become less marked when the skin is thin and delicate, as in persons who do no manual work or protect their hands by always wearing gloves. They also become less marked by reason of pressure or wear on the hands of persons who have excessive manual labor to do and who have to handle bricks, lime and other substances, while that kind of employment is continued, but after it ceases they soon regain their natural condition, provided the skin has not been permanently injured.

The general direction in which the ridges and furrows run on the palm is sometimes transverse and sometimes oblique in long, wavy lines, but their continuity is often broken and frequently intersected by the crease lines, to which they bear no definite relationship. At the roots of the fingers these long, wavy lines are usually displaced and contorted by other systems of ridges and furrows being interposed, which run in different directions and form more or less definite patterns. On the digits the disposition of the ridges and furrows is transverse, or nearly so, except on the terminal phalanges, where the arrangement is very varied and generally more than one system of ridges occurs; here they are also grouped in such a manner as to form well marked patterns.

These ridges, which are not only to be found on the palmar surface of the hand, but also on the plantar aspect of the foot of both men and apes, are termed papillary ridges, from the relation they bear to the papillæ of the corium, which are arranged in serial rows underneath them. According to Kollmann each papilla has a body and two heads; the latter form the adjacent sides of two parallel ridges, while the intervening furrow corresponds with the cleft between the heads of the papilla. Outside each head is the duct of the sweat gland, which opens on the free surface at the apex of the ridge, while the distal side of each of the two ridges is formed by the adjacent heads of the next two papillæ. By taking the capital letter Y to represent a papilla with its body and two heads, and the letter I to indicate the sudoriferous ducts, a transverse section of the groundwork of two ridges, their sweat ducts, and the adjacent side of the next ridge on either side of them may be diagramatically represented thus, YIYIY. The completed ridges would be represented by a complex structural layer placed above and dipping down between the heads of the Y's but pierced by the I's, representing from below upwards the stratum Malpigii, stratum lucidum, and stratum corneum. The numerical distribution of the touch-bodies situated in the papillæ does not seem to be correlated directly with the degree of development or the fineness or coarseness of the ridges, because the former vary in number in localities where the latter are equally well marked. There is little doubt, however, that the ridges are intimately connected with and assist the sense of touch, though their precise relationship with it may be a matter of some speculation. The touch-bodies being situated chiefly in the heads of the papillæ which project into the structure of the ridges, are thus prominently raised on the surface of the skin. They are consequently favorably situated for receiving impressions from objects touched or handled, not only by reason of their coming into contact with them, but also by the surface-area from which the impressions are conveyed to them being materially increased by the corrugations. Furthermore, the contact pressure between the skin of the finger and the object touched being greatest on the summits of the ridges and diminishing as the bottoms of the furrows are reached, a differential sensation is thereby produced which can not but be of immense value in increasing the perceptive and discriminating powers of the fingers with respect to the character of the objects touched. While the structure of the layers of the skin superficial to the papillæ and the ready response which the outermost of these make in becoming thicker and thinner, as well as harder and softer, according to the nature of the employment of the individual, affords the degree of protection to the sensitive organs underneath that is necessary under the varying external conditions to which the fingers are subject, and is of such a character as to admirably adapt it for collecting and transmitting sensations to them and ultimately

to the more distant nerve centres. In this connection also the subcutaneous tissues, consisting of fibrous trabeculæ crossing and interlacing in a complex manner and including more or less continuous lobules of fat constituting the stratum adiposum, which in the living body is a semi-fluid condition, play an important part by equalizing in all directions pressure of contact with outside substances and so favoring the perception of the stimuli thus produced by the nerve terminations. The ridges themselves discharge an important function relative to the act of grasping from the amount of friction they cause, and in this respect the roughness of the surface due to their presence is augmented by the fact that they raise the openings of the sweat-glands to a suitable height from which moisture can be distributed evenly to the surface of the skin and to that of the object grasped. On their efficacy in this connection may depend the directions and arrangement they assume in different parts of the hand as well as in the foot, but on the terminal phalanx the development of the nail has a considerable influence in elongating the form of the soft parts and in modifying their direction, particularly at the free extremity of the digit. Whether the patterns they assumed on the centre of the terminal phalanges are related in any way to the form of the eminences which exists there, appears uncertain, and still less can it be accepted that they are produced through lateral pressure between nascent structures.

The disposition and characters of the ridges and furrows may be studied by direct examination of the fingers, but it is much more convenient to do so from impressions of them taken on some suitable material. Model impressions may be taken on wax or collodion, which are very sharp and delicate, but for practical purposes impressions made on paper from fingers previously covered lightly with a thin layer of printer's ink are by far the most convenient and useful. By this method impressions which are permanent without further treatment can be quickly and easily made. This is therefore the plan usually adopted. But to get good impressions in this way a certain modicum of care and practice is needed. From the fact that the skin has always upon its surface a certain amount of greasy excretion, the finger, when pressed upon a sheet of paper or other smooth surface, leaves behind it a portion of the excretion. If the finger be clean no mark of it will be visible to the naked eye, but a latent impression is nevertheless present, which can be readily developed by applying to it an impalpable powder, such as finely powdered plumbago or *hydrargyrum cum creta* (according as the surface bearing the latent impression is white or dark), which when moved over the impression will leave adhering to it a sufficient amount of this powder to make the ridges appear quite distinct, while the furrows are unaffected. The print will not be permanent unless subsequently fixed, but will be liable to be rubbed off or blurred by contact with other surfaces. This method has its uses, however, and does not entail any previous application of ink to the fingers to dirty them.

The apparatus required for ink impressions consists of a smooth plate of metal, glass, or porcelain, of about the size of a post-card; some printer's ink, of somewhat thinner consistency than is used by printers, which for convenience may be put in a collapsible tube, like that as artists' colors are treated; some sheets of white paper having a smooth, hard surface, and a roller such as is used by photographers and known as a squeegee, with which to distribute the ink on the plate. For the examination of the prints an ordinary reading glass, as well as a lens of about five cm. focal length, and on two needles mounted in handles, like those used in histological work, to serve as printers, are necessary. The various articles enumerated should be kept scrupulously clean and free from dust.

The following is the modus operandi of taking the impressions of the fingers: A small quantity of ink is put on the plate and thoroughly rolled with the squeegee till the whole surface is equally covered with a thin layer. The fingers, having been previously washed and partially dried, are each rolled on the inked plate and then on the paper with the least possible pressure. In applying the fingers both to the plate and to the paper care should be taken to roll it from radial side of the nail over the pulp to the ulnar

side of the nail, so that the complete impression of the ridges of the whole of the terminal phalanx from one side to the other and from the transverse crease lines of the last joint to almost the end of the digit may be obtained. No halt must be made during the process of rolling the finger and it must not be permitted to slip, otherwise an imperfect or blurred impression will be the result. If the impression be not satisfactory the whole of the ink should be washed off the finger with benzine, and the process repeated. A good impression should show the ridges as black lines and the furrows as white spaces between them, clearly and sharply defined. If the lines representing the ridges are faint in color there has been too little ink on the plate; if, on the other hand, the lines are dark enough but the interspaces are not white and clear of ink, too heavy pressure has been put on the digit whilst rolling it, or there has been too much ink on the plate. It is essential that the furrows should be free from ink and only the tops of the ridges inked to get clear impressions. Having secured the impressions of the digits of a few persons it will be found on examining them that the arrangement of the ridges on the different fingers is subject to considerable variation in form and direction. Immediately above the crease-lines the ridges run transversely across the phalanx, while at its extremity they are curved in the form of an arch. On the central portion of the phalanx it may be found in some instances that they pass gradually from the transverse to the arched form, but in by far the larger number of cases they will be seen to assume several distinctive patterns. To this central part of the impression the greatest importance attaches, and in studying it particular attention must be given to the arrangement of the ridges forming it. The first one to systematically describe and classify the various patterns which occur on this portion of the digit was Purkenje in 1823, who divided them into nine different classes. Some subsequent writers have increased the number, while others have reduced them. It is now generally recognized that there exists three main types to which the different arrangements of the ridges met with conform generally, but there are several varieties of each type, and a few patterns are constituted by a combination of two types, or are of a nondescript form. A fourfold division with certain subdivisions is therefore found to afford a sufficient classification for practical purposes. The several dispositions of the ridges are accordingly classified as Arches, Loops, Whorls and Composites.

The Arch is the simplest and most primitive arrangement of ridge met with. Fig. 1. It is formed by the ridges immediately beyond the crease-line of the last joint, which run in nearly straight lines across the phalanx, being succeeded by others which by degrees become more and more curved in the middle, till at last they assume the form of well-shaped arches, and as such the series is continued till the nail is reached. The degree of arching of the ridges and the progressive rapidity with which it occurs, varies in different fingers, but in no case do any of the ridges in their course from one side of the fingers to the other become twisted or turned. Fig. 1 is an example of an arch of ordinary form.

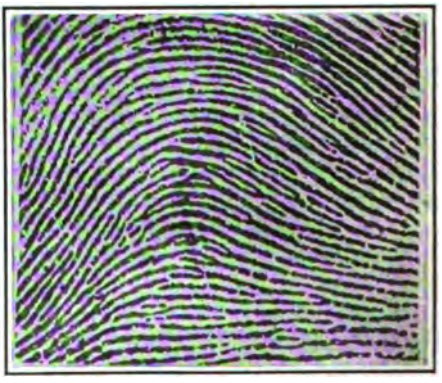

Fig. 1.

There is one variety of this type which is called the Tented-Arch. In it the more or less transverse ridges beyond the crease-lines are succeeded by one or more ridges, which suddenly become thrust upwards at an acute angle from the middle of the base of the arch, which causes the ridge immediately beyond to assume a tent-like shape. The upthrust ridges are not generally symmetrical, however, so that the arrangement has often a somewhat slanting appearance, which in some instances may make it look like a loop,

from which it is distinguished by the circumstance that none of the ridges recurve or double back again. Fig. 2 is an example of a Tented Arch.

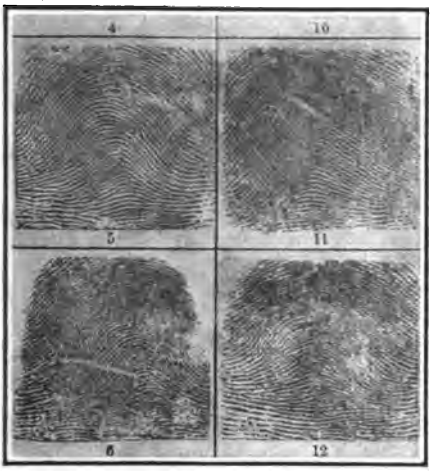

Fig. 1a.

The Loop, Fig. 3, diagramatic, is the most common form of arrangement the ridges assume. The gradual transition of the ridges near the joint from the almost straight to the arched form which was found to obtain in the Arches, fails to be carried out, and a break occurs in the regular sequence, causing an interspace between the two series in the middle of the phalanx. The manner of formation of the interspace is important. The transverse ridges immediately beyond the crease-lines are succeeded by a ridge com-

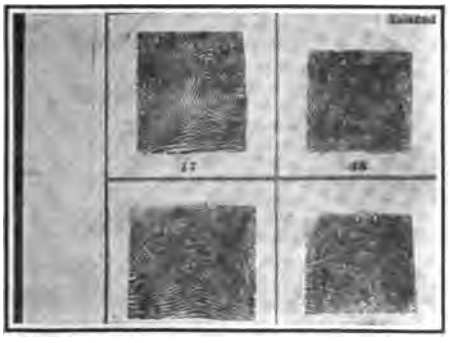

Fig. 2.

ing from one or other side of the digit, which suddenly forks at a little distance to the right or the left of the axis of the digit, Fig. 3A. The lower prong of the fork D runs transversely across the axis to the other side of the finger, while the upper prong, C, pursues an upward and arched course towards and

Fig. 3.

across the axis line, and then descends a certain distance and passes away to the opposite side of the digit to that from which it came, without meeting the lower prong again, thus a gap is left here between the two prongs C and D, and a larger or smaller interspace in the middle of the phalanx. It often happens that

Fig. 4.

instead of a ridge forking as described two ridges which have hitherto run parallel suddenly diverge on one or other side of the digit, Fig. 4, the upper of the two

ridges ascending and curving so as to form an arch, while the lower one continues its more or less horizontal course to the opposite side of the digit, thus an interspace is left between them. In either case the point of the divergence there is formed the base and one side of a delta, Fig. 3x, the other side being completed by a short new ridge forming in the interspace. The delta thus formed is a very important landmark in this pattern, and is never present in arches. The ridges beyond the upper prong or divergent ridge forming the distal boundary of the interspace, are arranged in arches till the nail is reached. Turning now to the interspace, a new series of ridges are found to enter it by the gap, Fig. 3 C. D., left between the two prongs or ridges on the side of the digit opposite to the delta. By these and by independent ridges forming in the interior, the interspace becomes filled up so that no part of it is left devoid of ridges. On tracing this new series of ridges it will be found that in the middle of the gap a ridge from that side of the digit passes into the interspace for a certain distance and then turns round, that is to say doubles round on itself without twisting, and runs again through the gap by which it entered. There may be only one ridge which thus doubles round and forms a loop. More frequently there are several ridges arranged in series round this centre or staple-like loop, some of which pass in and out on either side of it through the gap, but many of them only curve round it in the interspace. The independent ridges filling the rest of the interspace are straight or curved, are of varying length. The top of the central ridge, like the delta, is an important point, because as the outer terminus of the interspace is marked by the outer angle of the delta, so the inner terminus or the point of the core is situated at the top of the ridge farther from the delta, where it begins to bend on itself to form the top of the staple-like end of the loop. These are two fixed points in the pattern between which the number of ridges may be counted and from which the rest of the pattern may be surveyed. Certain variations of the core are not unfrequently met with which require notice. The core may appear as two central ridges which terminate abruptly, or there may be three terminal ridges round which the first of the series of ridges loops. In the former case the two central ridges are considered as the central loop, with the end defective and the point of the core is the top of the more distant of the two ridges from the delta, but in the latter case the top of the central ridge is taken as the inner terminus, the other two rod-like ridges situated one on either side of it being regarded as the legs of the central loop, the arched end of which is incomplete. In counting the number of ridges in a loop pattern the enumeration is made along a straight line from the outer terminus to the inner terminus, but the ridges on which the terminuses are situated are not included, only the ridges between them being counted. The degree of slope shown by loops varies very much in different fingers. In some it approaches the horizontal, while in others it is nearly vertical. The direction of their slope, which is determined by the position of their proximal ends, may be to the right or to the left side of a digit, but it must be remembered that the slope of similar loops will be in opposite directions on the right and left hands. When the distal and closed end or top of the loop is on the same side of the hand as the thumb and the open proximal end opens on the little finger side of the hand it is called an Ulnar loop. When the closed top of the loop is on the little finger side and its open proximal end is on the thumb side it is called a radial loop. According then as the open mouth of the loop is situated on the ulnar or the radial side of the hand so is the loop named. It is also important to remember when looking at the impression of a finger bearing the loop that the direction of the loop appears as the reverse of what it is when the finger itself is examined, and that to determine whether the impression of a single digit with a loop pattern upon it is of the ulnar or radial variety it is essential to know whether the print is that of a right or a left hand digit. Several varieties of form are met with in loops, thus some of the core loops are sometimes found to meet either an enveloping loop or the boundary ridge of the interspace at an angle, they are sometimes slightly deflected downwards at the closed end, or the central

ridge may have an oval eye-like end to it, the long axis of the oval being in line with the ridge. A loop is distinguished

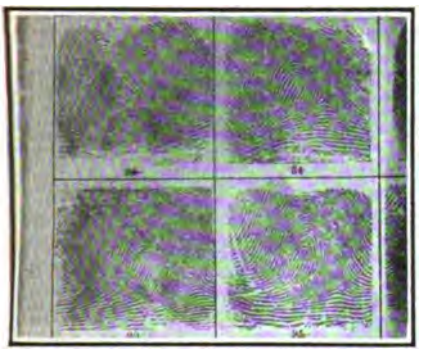

Fig. 4a. Additional Examples of Loops.

from an arch of the tented variety, which most nearly resembles it, by the presence of at least one ridge between the outer and inner terminuses of the loop.

The Whorl, Fig. 5 (diagramatic), is so named from the peculiar manner in which the ridges are coiled on the central part of the phalanx. The arrangement of the ridges forming the boundaries of the interspace between the almost horizontal ridges immediately beyond the crease-lines of last joint and the more distal arched ridges on the point of the digit, is also characteristic and will be considered first. It is a repetition on each side of the terminal phalanx of that which obtains on one side only in the formation of the delta in the loop pattern previously

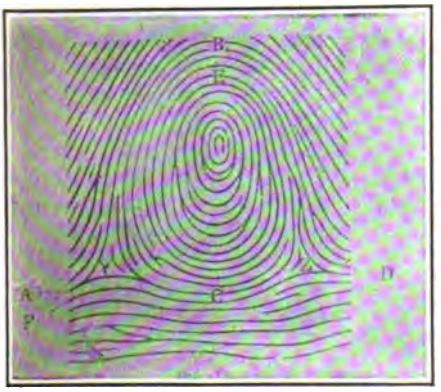

Fig. 5.

described. In other words, in the whorl there are two deltas present Z and Y, and the interspace is therefore closed on either side, so that any new systems of ridges entering into it must do so from above or below the deltas. Three arrangements are found to obtain as regards the relative positions of the ridges forming the lower prong or base of each delta. If the two prongs A C, D F pass in opposite directions across the phalanx without any other ridge intervening or are separated by not more than two ridges, they are regarded as meeting. The lower prong or ridge A, of the left delta (that is following the ridge impression from the observers left to his right, as in reading a line of print, irrespective of the hand from which the impression is taken) may pass along with three or more proximally situated ridges into the interspace *inside* the right delta, or the left prong or ridge may pass across the phalanx proximally to,

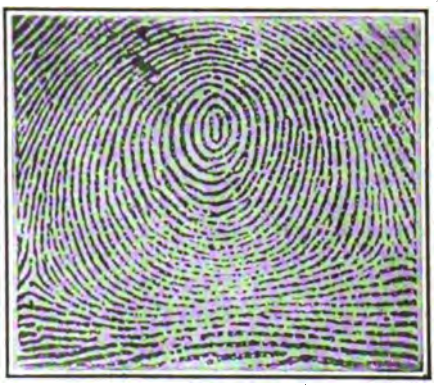

Fig. 6.

that is to say, *outside*, the right delta, while the three or more ridges intervening between the fork ridges will pass from right to left into the interspace and assist in filling it up. A corresponding arrangement may occur in respect of the upper prongs B E as they cross each other at the top of the interspace. The core of the whorl may therefore be fed from below and above only—or from above only, but sometimes it is not supplied with ridges from either of these sources to any extent, and is mainly dependent upon a series of its own arising within the interspace. From what has been stated it will be perceived that considerable variation exists in the appearance presented by the core of a whorl. It may consist of a series of concentric ridges arranged in circular

or elliptical form, or of ridges twisting round in the form of a single spiral or of a double spiral. In circular and oval shaped forms the point of the core is the center of the first ring, but when the

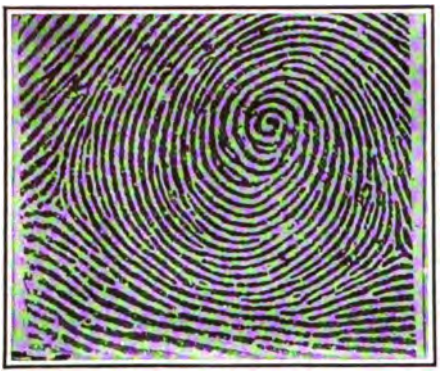

Fig. 7.

whorl is spiral the inner terminus is the point in the centre from which the spiral begins to twist. Figs. 6, 7 and 8 show different varieties of whorls.

The disposition of a whorl may or may not be symmetrical on the digit, but slope to one side or other side, and it may even assume a pear-shaped appearance, the deltas being often on different levels.

The Composites include patterns which are more or less combinations of arches,

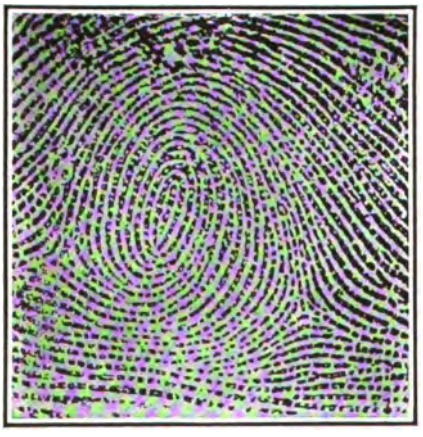

Fig. 8.

loops and whorls, especially of the two latter, and patterns too irregular in outline to be classified under any of the other groups. They always possess two deltas, though in some forms the exact position of one or other of the deltas may be rather difficult to determine, owing to its not being very distinct or obvious. The arrangement of the ridges below the core and in relation to the right delta is ex-

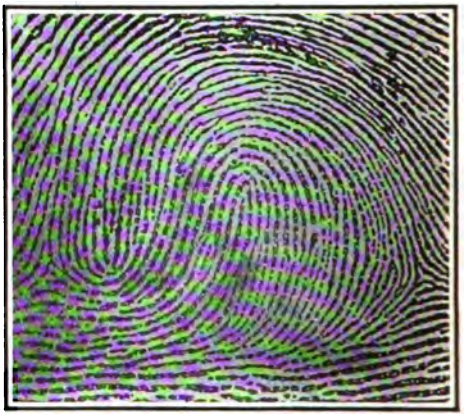

Fig. 9.

actly the same as in the whorls. The chief forms included in the composite class are (a) twin loops, (b) central pocket loops, (c) lateral pocket loops, (d) accidentals.

The twin loops, Fig. 9, consist of two well defined loops, one superincumbent on or surrounding the other, forming the core, which has therefore two inner points. The ridges on which these are situated

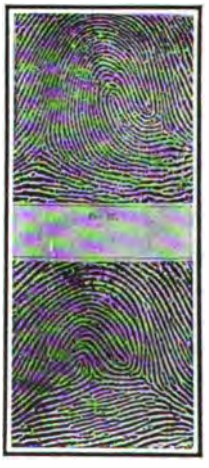

Fig. 10.

pass outward from the core on different sides of the right delta.

The lateral pocket loop, Fig. 10, is also a double loop pattern. The ridges forming the loop bend suddenly downward on one

side before turning round, thereby forming on that side a kind of pocket which is usually filled by the ridges of another loop. They are differentiated from the twin loop type by both the ridges on

Fig. 11.

which the points of the core are situated, passing outwards on the same side of the right delta.

The central pocket loops, Fig. 11, conforms to the loop type as regards the outer ridges filling the interspace, but a few ridges immediately round the core present the appearance of a whorl. Close to the latter the second delta is situated, though

Fig. 12.

not always well defined, but always on the side opposite to the other delta.

Accidentals, Fig. 12, as the name implies, include patterns which can not be classed under any of the above forms; sometimes they appear to be a combination of an arch with a whorl or core, or of a loop and whorl. To this group may be assigned the few patterns which do not

Fig. 13.

sufficiently conform to the definitions of any of the other groups to be regarded as one or other of them.

The relative frequency of these various patterns is in round numbers: Arches, five per cent; loops, sixty per cent; whorls and composites, thirty-five per cent. The greatest variety of patterns is found on the forefinger and the least variation occurs on the little finger; whorls are most frequently met with on the thumb and ring finger; loops on the little and middle finger, and arches on the forefinger. The fore-finger is also peculiar in the frequency with which the direction of the slopes of its loops differ.

Fig. 14.

It is comparatively uncommon to find the whole ten fingers presenting the same pattern of ridges. Generally there is more than one pattern present. Nevertheless, the number of cases in which loops occur

on all the fingers is considerable, and in these cases the slope, number of ridges between the outer and inner terminuses and the distinctive appearance of the loops, and finally the ridges themselves have to be taken into consideration. In cases where whorls are upon all the fingers the varieties of the cores and of the relative dispositions of the ridges with respect to the right delta serve to distinguish them.

Between the digits of the two hands there is, as might be expected, a certain amount of correlation. That is to say, the same patterns occur on the corresponding fingers of the left hand as exists on those of the right, with greater frequency than any other pattern in about the proportion of three to two. The actual degree of correlation between the different digits of the same name varies somewhat, but that between the middle fingers is greater than between any of the others.

A matter of much importance respecting these ridges and the patterns they form is whether they are persistent during life or are they liable to vary from any circumstances. Upon this depends their value for purposes of identification. The data at hand for determining the question are not extensive, and several years may have to elapse before it can be conclusively settled. The material available at present for the solution of the problem is mainly that which has been collected by the energies of Mr. Francis Galton, assisted by Sir William J. Herschel and a few other friends. It consists of fifteen cases; in some of these the impressions of only one finger, in others of two fingers, and in a few all the fingers of one hand were available. In all between twenty and thirty digits have been exhaustively studied by Mr. Galton, the impressions of which had been taken at intervals of from nine to thirty-one years. The ages of the persons at the time of taking the first prints ranged from two to sixty-two years, while the second impressions were taken at ages varying from fifteen to seventy-nine. The result of the research was that in every instance there was entire agreement between the various details in each set of prints with one exception. Comparisons made between numerous other double sets of impressions retaken at shorter intervals show the same persistence of pattern to prevail. The evidence, therefore, is very strongly in favor of there being no material change or variation in the ridges and furrows of the digits during the life of the individual. Figs. 12 and 13 show impressions taken at long intervals, arranged in pairs, for comparison.

In comparing impressions for the purpose of determining the persistence of patterns or whether two sets of impressions are those of the same or of different individuals, the characteristics of the ridges in each print have to be examined with great exactitude. The average number of characteristic points of comparison in an impression of a single finger amount to between thirty and forty. They consist of points of forking and of fusion of ridges, the presence of short, independent ridges at certain given points and of spurs projecting from a ridge, the abrupt termination of a ridge, the appearance of new ridges, and the occurrence of small oval or circular enclosures formed in the course of a ridge by forking and the prongs again immediately reuniting and so walling around depressions that are variously termed craters, lake-basins or islands. Each of these peculiarities has to be exactly localized by counting the ridges from definite points, such as the outer or inner terminus, and by triangulation from these or other fixed prints. In the case of whorls the ridges below the deltas should be traced and their relation to the right delta noted, also the course of the ridges forming the spirals. Allowance must be made, however, for imperfections of printing, thus, for example, a distinct forking of a ridge in one print may appear in another print of the same digit as an imperfect fork, a break in continuity of one or other of the prongs being shown—though generally it is easy to trace some indication of juncture, the important fact to observe being the appearance of a new ridge at the given point, rather than the exact correspondence of detail of minutiæ; again an enclosure or lake basin in one print may appear as a partial enclosure in the other. The scars of incised wounds show a white line, and are attended by dislocation of the continuity of the ridges, whereas crease-lines (which should not be considered, owing

to their liability to vary) show break in continuity, but no dislocation of ridges; other scars, such as those of burns, which have injured the true dermis, show actual destruction of the ridges over a larger or smaller area, according to the severity of the injury. Scars from needle pricks, common on the digits of tailors and women, appear as small, irregular white marks in the impressions. In prints of the same person's fingers taken at different intervals discrepancies arising from injuries are likely to be met with, but owing to the many other points of comparison available on parts not affected by the scars do not materially interfere with the work of tracing their similarity, particularly if there are the impressions of several digits available for comparison.

The results of careful comparisons made on many thousands of finger prints have shown up to the present time no two sets of prints of even a single digit have been found to be identically alike, except they were those of the same digit of one and the same individual. It is the case, however, that single digits of different persons have been found to show not only close correspondence in pattern, but also similitude in three or four points of detail in the pattern; the other points have invariably been sufficiently unlike to differentiate their individuality clearly and with certainty. Finger impressions have, therefore, come to be recognized as a most reliable and easy means of effecting personal identification, and are adopted for this purpose by several police forces for the recognition of old offenders and sometimes for the identification of the perpetrators of crime. Their use might well be extended for the purpose of preventing pensions being drawn by others than the pensioner himself, and indeed for all purposes of identification. When well taken prints of the ten digits of the hands are available for comparison with another set of impressions equally clear, the utmost reliance may be placed upon the evidence they give of the identity or non-identity of the person or persons from whom they were taken.

The impression of one or more fingers may be accidentally made on other substances than paper; it may be on the surface of some object at a place where a crime has been committed on charge of which some person has been arrested. The question of the identity or non-identity of the print found with the pattern on any of the digits of the prisoner becomes a matter of great importance. The casual print has been made under very different circumstances to those with which it is compared; generally it is the result of a digit somewhat moist with the normal excretions of the skin, plus some dirt superadded, coming in contact with a surface not specially suitable by want of smoothness or otherwise to receive the impression, unless the surface happens to be glass, porcelain, or polished metal. The moist condition of the digest may be due to blood upon it, in which case the furrows, as well as the ridges, have probably been covered more or less equally by it. The conditions are, therefore, not as a rule favorable to obtaining good impressions, and it may not be possible to improve them to any extent by dusting powder over them or otherwise. In those cases the greatest caution must be exercised in coming to a conclusion as to the identity of the prints. The affirmative should only be asserted after stringent examination has shown many points in the prints compared to be thoroughly in agreement, and likewise the absence of any obvious disagreement between them. The latter condition is as essential as the former, while the presence of any disagreement should be regarded as distinct evidence that the prints were made by different fingers. A question of some importance is whether any discrepancy will be produced in two prints of the same finger by reason of their being made under different degrees of pressure. Minor variations, such as those which depend on differences in height of the ridges, do occur in the prints as a result of the finger being lightly or heavily pressed in printing; in the latter case a ridge may appear continuous, which in the former case shows interruption in continuity, but irregularity in inking the finger will produce the same effect. Heavy pressure flattens the ridges somewhat, and therefore makes them appear broader in the print, but again this condition is to some extent at least inseparable from the manner of inking the fingers, for if only the summits of the ridges

have been inked, the lines they show in the impression will be narrower than when the ink has extended further down the sides of the ridges. It is only by taking into consideration the general and special aspects presented by the two prints and studying them in connection with the structure of the skin that the factors can be determined. The main features of the ridges and furrows are not distorted or altered in their directions by varying pressure, because in consequence of the difference in consistency which exists between the surface layers of the skin and the subcutaneous tissues the pressure is distributed and equalized in all directions. The expert who is called upon to determine the question of identity or non-identity from casual prints has frequently a difficult problem to solve, upon which he must bring to bear his knowledge of the anatomy and physiology of the finger as well as the information derived from his observations of the prints in order to enable him to arrive at his conclusion. Should he embody photographic enlargements of the impressions in his study he will find it desirable to use positives made on glass in his investigation.

The classification of finger impressions is chiefly of interest to those who have to arrange large collections. It has been elaborated with much care by Mr. Francis Galton and the staff of the Bengal police into a very complete system, of which only the outlines can be given in this monograph. For this purpose the arches are classed with the loops and the composites with the whorls, so that only two divisions of patterns have to be dealt with. The different combinations possible of these two classes on each pair of digits, beginning with the right thumb and forefinger, are then taken into consideration. Under this scheme there are four possible combinations on each pair of digits, which may be represented thus

LL	WL
LW	WW

using the initial L and W for loops and whorls, respectively. The five pairs of digits give individually and collectively with one another one thousand and twenty-four possible combinations, which form the primary divisions of the classification. The size of the groups will be most irregular as regards the number of sets of prints in each, but as the various forms bearing the impressions of different persons' fingers are kept in portfolios a larger or smaller number of groups can be placed together, much after the plan of a dictionary or encyclopedia, covering several volumes, where the size of the volume is the regulating factor. The actual formula of each pair of digits is written in the form of a fraction, of which the upper letter denotes the pattern of the first digit of the pair and the lower letter that of the second digit, thus the right thumb and forefinger bearing respectively a loop and a whorl is indicated as $\frac{l}{w}$, and a complete formula might be written as follows:

$$\frac{l}{w}\,\frac{l}{l}\,\frac{w}{l}\,\frac{l}{l}\,\frac{w}{w}$$

As the number one thousand and twenty-four is the square of thirty-two, all the combinations of the upper letters would be represented in a horizontal row of thirty-two small squares, and those of the lower letters in a vertical row of thirty-two squares, placed at a right angle to the former row. Constructing a large square with one thousand and twenty-four compartments of chess-board-like appearance from these and other rows, each compartment would be accurately defined by the intersection of any of the horizontal lines with any of the vertical lines, and it is possible to assign to each of the one thousand and twenty four combinations represented by the compartments definite numbers corresponding to their places in the horizontal and vertical rows. This is done by considering the whorl division only, and assigning a serial number to each whorl according to the position it occupies in the finger formula. A whorl on either digit of the fifth pair bears the value one, a whorl on the fourth pair is two, on the third pair is four, on the second pair is eight, and on the first pair is sixteen. Taking the formula already given for the ten digits of the hands, it might be written according to the values of the letters composing it thus.

$$\frac{0}{16},\ \frac{0}{0},\ \frac{4}{0},\ \frac{0}{0},\ \frac{1}{1} = \frac{5}{17}$$

Totaling up the values of the rows, the upper row equals five, while the lower row is seventeen, the fraction five-seventeenths would indicate the compartment at the place of intersection of the fifth horizontal row with the seventeenth vertical row, as the definite position in the classification of a form bearing the above value, supposing the respective rows were numbered from 0—31. A finger formula composed entirely of loops would occupy the first place or upper left corner compartment of the chess board and would be designated 0, both horizontally and vertically. By writing out the formula and summing it up for the finger impressions of each person, the exact place he occupies in the primary classification is obtained. Secondary classifications are obtained from the particulars displayed by individual digits, such as the presence of an arch on the fore-finger; the slope of a loop, and the number of the ridges between the outer and inner terminuses; the deposition of the ridges below the deltas in a whorl, the special form of a composite, and the like.

Sterility in American Women.

BY A. BROTHERS, B. S., M. D.,

Adjunct Professor of Gynecology to the New York Post-Graduate Medical School and Hospital; Visiting Gynecologist to Beth-Israel Hospital; Fellow of Academy of Medicine; Member of the County Society, Obstetrical Society, Eastern Medical Society, County Medical Association, Harlem Medical Association, Society Alumni of Bellevue Hospital, Physicians' Mutual Aid Association. New York City.

Owing to the institutions of this country, with the opportunities for education and freedom of movement, the American woman is recognized to be intellectually the superior of many of her sisters across the ocean. This advanced position is not without faulty consequences, and these faulty consequences include, among others, a tendency, or rather disinclination, toward having large familes. As we descend in the scale of education among women, we find that this lack of desire to bear children becomes less and less marked, but even among the ignorant classes there is a distinct difference in this regard between the women of various nationalities and religious beliefs.

The modern woman of today, like her educated sisters abroad, aims at having a small family. Perhaps placing the average of three children to a family would approximately express the truth in regard to our wealthy and cultured women of today. Besides the native women our country includes among its inhabitants a large population which has migrated to our shores principally from the older European nations, and which represents the ignorant or peasant classes. Among these women it is safe to say that a family of six children will represent a low general average to a family; in other words, roughly speaking, the number of children in a purely American family is one-half that which we find in the families of our immigrants. . What are the principal reasons for this vast difference in procreation among women with the same anatomical and physiological qualities?

1. The majority of our foreign women are poor, intensely so, and from this circumstance are restricted rigidly to home life, which in itself is conducive to the rearing of families.

2. We find religion more scrupulously observed and believed in the lower we descend in the scale of humanity. Among certain religions, particularly the Roman Catholic and the Jewish, feticide is recognized as a crime in the eyes of the church, therefore, criminal abortions do not receive the complaisant sanction that they do among ladies and classes with lesser religious scruples. Among Jewish women particularly the prevention of conception is rarely practiced, even among the poorest, by the woman herself. The male, on the other hand, frequently may make use of such procedures within certain limits. The orthodox Jewish woman recognizes that she must at all hazards bear children. The Mosaic law has practically marked the Jewish woman as unwomanly if she persists in remaining unfructified. One distinct provision of the Mosaic law allows the husband (with the sanction of the wife) the privilege of divorcing her and taking unto himself another wife, if after a lapse of ten years she has borne him no progeny. Strange as it may seem in this land of advanced

civilization, we have thousands and tens of thousands of these classes of women in our very midst today, so that in large cities like New York it is not an unusual occurrence for a woman to consult a physician in regard to her sterility, and acknowledge that her only reason therefor is based on a threat of the husband to take advantage of this ancient provision of Jewish law, and so deeply fixed is the religious belief of most of these women that they are ready to disregard the protection of the laws of the land in which they live and submit to the law laid down many thousands of years ago.

Nor is this true alone regarding the Jewish race. We find that in ancient Rome similar laws prevailed, so that in the time of the Roman emperor, Justinian, we find divorce allowed because of childless marriage. In this case, however, divorce is allowed the woman because of impotency on the part of the male.

3. The greatest portion of our imported population comes from the absolutely illiterate and ignorant classes, hence the artificial methods of preventing conception which have been so thoroughly mastered by the native daughters of our American soil, remains a closed book to them.

Such methods as include a diaphragm in one form or another cheat Nature of her original intentions. The use of chemicals to destroy or neutralize the natural secretions so carefully and wonderfully prepared for male and female, the use of metal stems introduced within the womb itself by obliging members of the medical profession, are things absolutely unknown and not within convenient reach of the large mass of immigrant women who swarm to our shores. These poor, ignorant and illiterate women are ready to follow in the same grooves laid down by their mothers for centuries. As a result of this ignorance they give birth to their children in regular cycles, covering eighteen months to two years, until ten, fifteen or sometimes twenty children have been born, and frequently they are not embarrassed when their next accouchement happens to coincide with that of one of their daughters.

The American woman has a horror of large families. She has, however, not yet reached the stage attributed to French women by Emile Zola, of being ready to sacrifice her reproductive organs in the desire to avoid conception at any cost. But she does, alas, make use too often for her own welfare of every method of prevention of conception and interruption of pregnancy.

In spite of the disastrous results which follow this mode of procedure, it is only fair to state that very few of our women have any serious intention of remaining absolutely sterile. In their efforts, however, to curtail the number of their offspring, they only too frequently do so at the risk of becoming invalids themselves and of inducing absolute sterility.

In seeking to establish the cause of childless marriages, I find that the male is responsible once out of every four or five times. In some races, particularly among the highly civilized, cultured and wealthy, we find that venereal disease is strictly accountable for this. Among the poor, however, particularly of the Jewish faith, evil personal habits are frequently responsible.

In general dispensary practice, where all nationalities are represented, Engleman, of Boston, found the percentage of sterile women to range between eight and eleven per cent. My experience is that in private practice a much larger proportion of women apply for the relief of sterility, and three times as many Jewish women who wish to overcome this condition than women of other religious faiths. In sterility in all classes of women following an effort to interrupt Nature's course during the first period of pregnancy, I have found that thirty-eight per cent of child-bearing women, who subsequently became sterile, could be directly traced to miscarriage occurring early in married life. Abortions occurring before the end of three months accounted for a large number of these cases. One-third of such relatively sterile women unfortunately had suffered from a difficult childbirth, which had left lesions in the organs of reproduction. One-fourth of such women had suffered from various kinds of pelvic inflammation after childbirth.

The modern woman presents one cause for sterility which her more ignorant sisters from foreign lands seldom show. It is infection with venereal disease of

the genital tract acquired from husbands of a higher civilization and intelligence, but of a lower grade of morals. In a small series of several hundred women applying for relief of sterility, not less than twenty-one innocent wives suffered from the results of gonococcus infection. Allowing that there is no error in the male, and that the woman has no congenital condition to be a bar to fecundity, my experience has been that after a period of from two to five years such women have one chance in ten to become pregnant. After five to ten years the chances are reduced to one in fifty; after ten years the chances are still further reduced to one in one hundred.

These figures are slightly better than for women who have never conceived at all. Still, even in cases of primary sterility there is one chance in ten in overcoming the sterility, and the more seriously the woman looks at the matter from the earliest period after marriage, the better the chances for overcoming the condition. The advice given by some authors to wait until three or four years after marriage until Nature has been given a fair trial is wrong. I should advise no woman to wait longer than one or two years before placing herself under proper medical supervision, and better to place herself in the hands of a thorough student of gynecology, for in no class of cases are greater care and better judgment required.

112 East Sixty-First Street.

[Written for the MEDICAL BRIEF.]

Some of the Difficulties in the Diagnosis of Recurrent Attacks of Appendicitis, with Case Report.

BY RUFUS B. HALL, A. M., M. D.,

Professor of Gynecology and Clinical Gynecology Miami Medical College; Former President of the American Association of Obstetricians and Gynecologists and the Ohio State Medical Society; Member of the British Gynecological Association; Gynecologist to the Presbyterian Hospital; Member of the American Medical Association; Member of the Academy of Medicine. Cincinnati, Ohio.

The question of diagnosis in an obscure intra-abdominal disease is a very important matter, both to the patient and the physician. Ordinarily it is not difficult to make a correct diagnosis in recurrent appendicitis. But, occasionally, one sees a case in which the diagnosis of appendicitis is suspected, but very difficult to prove. There are two conditions which may be confounded with and mistaken for recurrent appendicitis. These are a stone in the right kidney, and gall stones. On the first impulse one would say that it did not make very much difference whether a positive diagnosis of appendicitis was made until after the operation was undertaken. But after due deliberation, it must be granted that it would be very much better for all concerned if it were possible to make a positive diagnosis before the operation is begun.

When we duly appreciate these complications we see how necessary it is to be certain of the diagnosis before proceeding with the operation, because if it is a urinary calculi it would be much better for the patient to make the incision in the loin and extirpate the stone in that manner.

In a given case where a positive diagnosis can not be made before the operation is commenced, one could make a three-inch incision at the outer edge of the right rectus muscle, the lower end of the incision just over McBurney's point. This would permit exploration of the appendix, the gall bladder and the kidney. If the condition proved to be chronic appendicitis, the incision could be extended, if necessary, an inch lower down, giving ample room for all necessary manipulation. If the condition calling for the operation was found to be a diseased gall-bladder, the incision could be extended upwards. This necessitates a very long incision, however, and is far from an ideal operation for gall stones, and unnecessarily weakens the abdominal wall. For this reason I prefer to make a second short incision just over the gall-bladder for removal of gall stones or for drainage of the gall-bladder. If our exploration demonstrates the presence of a urinary calculi, the stone could be removed by the combined operation of Thornton.

It is most desirable if one can always make a positive and correct diagnosis, and say that this is appendicitis, that is gall-stones, the other one a urinary calculi; and I will grant that in a large

majority of cases, this can readily be accomplished by the careful physician, yet this does not always hold true, as the following case very forcibly illustrates.

Mr. J. L., farmer, aged forty-nine, residence, Camargo, Ill. The case was referred to me on February 13, 1905, by his physician, with an uncertain diagnosis of appendicitis, gall stones, or urinary calculi. The case gave such a varied and complicated clinical history that one could well call it either one of the three, and have a good clinical history to substantiate the diagnosis. The man was of spare build, always temperate and correct in his habits, a hard worker, and enjoyed most excellent health until early in June, 1904, at which time he was taken suddenly ill with an obscure pain in his abdomen, which continued for about one week. The man was compelled to keep his bed for three or four days, and at this attack he had a slight rise of temperature the first day. The second day his temperature was about 101° F., and the pain was localized in the region of the head of the colon. On the third day after his attack, his doctor was uncertain whether or not there was a slight enlargement in the region of the appendix.

The abdominal muscles over the whole abdomen were rigid. On the fourth day he was better, and on the fifth day he left his bed. He was much needed on the farm and from this on he superintended the labor, but made no attempt to do any manual work for more than a week later. The doctor at that time made a diagnosis of appendicitis, and so stated to his patient and his family. From this until the time he came under my observation the patient said that he was never perfectly well. He was always conscious of something wrong in the right half of his abdomen. The location of the pain varied from the kidney down the course of the ureter, with an irritable bladder, with frequent desire to urinate. The pain also shifted to the region of the gall-bladder, and he was always tender over the gall-bladder upon palpation. The skin became slightly colored, like jaundice, but the conjunctivæ were not discolored. He was able to superintend his work until about the first of October, at which time he had a second attack. The pain was very acute for the first few hours, requiring a hypodermic injection of morphine for relief. The following day his temperature was 101°. All the pain was referred to the region of the kidney, radiating down the ureter, with frequent desire to urinate, with occasional vomiting. The acute symptoms passed off in thirty hours, but he remained in bed, upon the advice of his physician, for five days.

The entire abdominal muscles became rigid and tender upon palpation, and the abdomen became distended with gas. There was no pus or blood in the urine, but with the pain located in the kidney, and the pain paroxysmal in character, the uncertainty of any enlargement of the appendix, the diagnosis was changed to urinary calculi. After a week or ten days he resumed his occupation as before, but always as that of a semi-invalid. His family physician urged him to consult a surgeon, telling him he would have to be operated on before he recovered. The doctor wrote to me in reference to the case at that time. But the patient concluded he would defer the operation with the hope that Nature would cure him, and I heard nothing more from him or his doctor until December, 1904. The doctor wrote me about the 20th that the patient had been ill since the 15th of December with a very sharp attack of pain, and he was inclined to believe now that the patient was suffering from gall-stones. He said the attacks of pain were intermittent, just as gall-stone colic is, that he had extreme tenderness in the region of the gall bladder, that he required morphine in large doses to relieve him; that he was more discolored than heretofore, and there was a slight jaundice of the conjunctiva, and he vomited frequently. He had a temperature for several days during this attack, ranging from 100° to 101° F., and one day the temperature was 102° F. The entire abdomen became rigid, with marked tenderness in the region of the gall bladder and over the kidney, extending along the course of the ureter and especially over the head of the colon. There was never at any time a distinct lump which could be localized in the region of the appendix, and over that region there was always an area of resonance

upon percussion. After this attack, which continued for four weeks before the man was able to leave his room, he consented to have the operation made, but he wished to wait until he regained his health somewhat. He lost fifteen or twenty pounds in flesh, and weighed when he came to see me on February 13 about one hundred and twenty pounds. He looked much older than forty-nine years. He was anxious now to have the operation made if it was thought best to do so. When he entered the hospital his pulse was eighty, and his temperature was 99.6° F. at 7:30 P. M.

Upon examination of the abdomen the muscles were rigid over the entire abdomen. When he was asked to locate the seat of pain, he said he could not do so, that the whole right side pained him some place inside. He described it as a deep soreness. He could walk readily, but said that it hurt him to do so. On palpation the abdominal muscles were so rigid that it was impossible to palpate with any degree of satisfaction. By percussion there was no dullness to be detected over the head of the colon.

The kidney was not enlarged, and there was no enlargement in the region of the gall bladder. The conjunctiva were very slightly tinged, if at all. The skin was somewhat bronzed, appetite was poor and bowels constipated. He had a frequent desire to urinate. Repeated microscopic and chemical examinations of the urine were negative. The man was kept under observation for six days. A careful clinical history was taken and written out for reference. For four days daily his history was carefully gone over and recorded again in writing to see if we could elicit anything new, and especially to compare the answers. The same questions were asked in each examination, varying the phraseology somewhat, using a history blank to record the answers for the purpose of being minute. The symptoms were so like stone in the kidney that at the end of the fourth day I decided to have an X-ray picture made (as that will usually show the presence of an urinary calculi, if one exists), to see if that would throw any light upon the subject, as he referred to the pain more to his kidney than he did to the gall bladder. There was also more tenderness upon deep pressure over the lower margin of the kidney than over the gall bladder or appendix. The X-ray picture, which was a good one, was negative.

In dealing with recurrent attacks of appendicitis, I am convinced that in almost every case examined in the interval, one can find a tender point over the appendix, but this symptom was of no value in this case because there was tenderness over the entire right side of the abdomen, and especially so over the region of the gall bladder and the kidney. The muscles likewise were also rigid at this time. When he came to the hospital I was convinced that he must be operated on before he would get relief, and this fact had some bearing upon the delay in confirming the diagnosis. You will observe that I have omitted one very important point, in fact, the most important one, in settling definitely the diagnosis in all obscure conditions inside the abdomen; and that is placing the patient thoroughly under an anesthetic for the examination. I have always insisted upon this and have practiced it for years. I spoke repeatedly of this to the patient, but told him it was one of the three conditions mentioned, and that we would make the one anesthetic do, that we would be prepared when we gave him the anesthetic to make whatever operation was found necessary after he was anesthetized. It was decided on the evening of the 19th that on the morning of the 20th we should operate. It was agreed that after he was under the anesthetic, if we could not make a positive diagnosis from palpation, that is, if we could not locate an obscure lump or enlargement, we would make an exploration of the abdomen in the region where we could make an appendectomy and explore the kidney and the gall bladder. If we found a kidney stone we would make an additional counter opening in the loin for the removal of the stone. If we found gall stones we would make a second short incision over the gall bladder to remove them. When he was placed on the table and the abdomen perfectly relaxed, by very gentle palpation over the region of the appendix, a distinct hard lump could be felt, apparently

about the size of a hulled black walnut, deep down in the region of the appendix, which was not adherent to the abdominal wall. I at once changed my plan of making the incision in the line of the right rectus muscle to that of the usual McBurney incision for the removal of the appendix. In other words, my heretofore uncertain diagnosis was now made positive as that of appendicitis, and the operation proceeded.

Upon opening the abdomen we found the intestines glued together over the head of the colon, covered over with a glutenated omentum. These were separated and we opened an abscess holding about a drachm or two of very thick, offensive pus. The appendix was perforated near its attachment to the colon, and this was the nidus of the infection. The pus was carefully cleaned away, the appendix removed, and over the soiled area a narrow strip of gauze was packed, and a counter opening was made three-fourths of an inch in length, near the anterior superior spine of the ilium, the gauze being carried out through this opening as a convenient place for its removal, which was done on the fourth day. By this procedure you eliminate the danger of contamination of the catgut used in closing the wound, and thus prevent a hernia. The abdominal incision was closed without drainage. The patient made a rapid and uninterrupted recovery, and regained his health perfectly. The case is an interesting one as illustrating "some of the difficulties that may be encountered in the positive diagnosis of recurrent attacks of appendicitis." It also illustrates in a very forcible manner the desirability in doubtful cases of administering an anesthetic to aid in making a correct diagnosis.

I have been a recipient of the BRIEF for a long time by regular subscription, and assure you that the BRIEF fills a place second to none in my daily reading.—L. P. ARMSTRONG, M. D., Newtown, Ind.

[Written for the MEDICAL BRIEF.]

A Few Points on Circumcision.

BY O. L. SUGGETT, M. D.,

Professor Syphilology; Associate Professor Genito-Urinary Diseases, Barnes University; Surgeon in Department of Genito-Urinary Surgery in Centenary Hospital and Barnes University Dispensary; Consultant in Venereal Diseases, City and Female Hospitals; Member A. M. A. St. Louis, Mo.

It is a little strange that an operation, the necessity for which was recognized so many ages ago, should not enjoy in this day the fullest understanding. As to the antiquity of the operation, its origin probably antedates its performance by Zipporah, wife of Moses, upon her son, which is recorded in the twenty-fifth verse of the fourth chapter of Exodus (about 1491 B. C.), for it is unlikely that she should have ventured upon so radical a procedure without having had a precedent, even though actuated as she was by a resentful spirit.

In substantiation of the fact that the presence of a prepuce (foreskin) was an indication and a mark of uncleanliness and impurity, from a spiritual as well as an hygienic standpoint, the ceremony, or procedure of removing it (circumcision) among those religious sects who practice it ritually, is performed in lieu of the baptismal ceremony of other denominations, showing its possessor to be unclean in the sight of the Creator (as well as man), it is one of the residual evidences of man's origin according to the doctrine of Darwin. It is, indeed, the sheath commonly called sheth of the reproductive organ, found in horses, dogs and the lower orders. All male children at birth have a prepuce of greater or less redundance, and of variable retractability. The prepuce, which is a reduplicature of the skin covering the body of the penis, assumes in its inner layer (that which comes in immediate contact with the glans penis) a quasi-mucous membrane character, the secretions from its odoriferous glands and sebaceous follicles furnishing the disagreeable and highly offensive smegma, with which its possessor and the genito-urinary specialist has continually to contend.

As the boy approaches and passes beyond the age of puberty, the growth of the penis

being disproportionate with that of the foreskin, the glans-penis is gradually, almost imperceptibly, pushed through and beyond the preputial orifice, the latter turning inside out, as it were, until at the proper age in the normal individual the glans is completely uncovered, and that portion of the foreskin which closely covered the glans-penis and kept it continually bathed and saturated in a secretion far more offensive than pus, has gradually lost its muciferous character, and becomes quite nearly like the external skin of the penis, of which it is a virtual continuation, without the former reduplication, except, perhaps, a few redundant folds just back of the sulcus, to allow for its elongation with the occurrence of an erection. Such is its natural evolution and that which occurs in the majority of individuals. Those in whom this natural uncovering of the glans does not take place will engage our attention. It was for their relief and benefit that the various operative procedures for removal of the foreskin (circumcision) were created. There are numerous reasons for its removal, while there is no rational excuse for its existence.

At least two conditions may account for the existence after the period of adolescence of a long foreskin in some individuals; the first, and probably the most frequent, being phimosis. The contraction of the preputial orifice and its lack of elasticity, or, in some instances, its intimate adherence to the glans, are sufficient to prevent the glans from insinuating itself into, and ultimately beyond it, thereby uncovering or freeing itself, as it were; hence, in its growth or in its temporary engorgement (erection), it carries the foreskin forward with it. The other and less tenable reason is in the case of those children in whom the preputial orifice is sufficiently patulous, non-adherent and retractable, but who, as babies, are continually pulling at their prepuce, stretching it forward, which develops into a habit, persisted in far into their boyhood. I have seen gonorrheics and others, after placing a piece of cotton over the meatus, stretch the foreskin forcibly forward, a procedure which, if persisted in, undoubtedly tends to lengthen it. Though the word phimosis is derived from the Greek word which means to constrict, it is applied to any abnormal redundancy of the foreskin, constricted or not. It is this constriction of the preputial orifice when retracted which is responsible for that condition ofttimes serious, if not even dangerous, paraphimosis, an emergency which, failing of reduction and relief by manual manipulation, urgently demands a dorsal slit to relieve the tension and strangulation and release the engorged glans; or later, if not at the time, a complete circumcision to prevent a recurrence of the accident. Foreskins which are long, but not necessarily phimotic (constricted), are a source of uncleanliness (germ harboring), and though not a source of danger from paraphimosis, require removal for hygienic reasons. I might say here, and I believe that it is the experience of other genito-urinary specialists, that fewer than ten per cent of our patients are Jews, and that more than eighty-five per cent of our venereal cases have long foreskins. The reason for this is obvious. The numerous folds, cracks and crevices in a long foreskin are most excellent places for the lodgement and retention of bacteria, and the secretion from such a prepuce furnishes a rich, nutrient culture medium for their growth and propagation; the many little recesses not being reached by the ordinary ablutions practiced at the time of exposure (not forgetting the intoxicated ones who wash carelessly or not at all), whilst the washings and cleanings required once or twice daily in the absence of any exposure are an annoyance and a nuisance. The sensitive, delicate and tender condition of the epithelial covering of the glans and inner surface of the foreskin, when restricted, render it especially liable to injury (abrasions, strong antiseptic solutions commonly and ignorantly used), and such an abrasion becomes an ideal location for the entrance and confinement of pathogenic secretions, whilst this very delicacy of the mucous membrane and the close contact of its opposing surfaces permits and promotes a maceration of the epithelium and absorption of the virus, even where no abrasion exists. This is especially true of chancroidal, though less of syphilitic virus. Sores, venereal and otherwise, when once formed beneath

such a foreskin are protracted and rebellious to good treatment on account of the irritation incident to the friction of the opposing surfaces, combined with their being continually bathed in a fetid secretion.

Various conditions and emergencies render the operation not alone a necessity but imperative. First may be mentioned paraphimosis of a non-inflammatory type, when the condition can not be relieved, or reduction and replacement be effected by manipulation, or taxis, as it were. This condition often occurring in children, and occasionally in adults, is merely a vascular engorgement of the glans following a retraction of the foreskin, either accidentally or purposely, preventing by its constriction a return of the blood through the veins and producing a strangulation of the parts beyond. Operative interference in this instance is most often limited to a mere snipping with scissors or scalpel of the constricting band. A circumcision at this time would not be out of place, and aside from its requiring but a little more time and preparation and pain to the patient, he or his friends would be easily impressed and convinced of its value and needfulness upon this occasion. Needless to say that this simple non-inflammatory condition may become one of a highly inflammatory and serious type if permitted to continue for many hours.

Next may be mentioned the inflammatory and edematous type of phimosis and paraphimosis of varying severity, which was primarily so (the result and not the outcome of inflammation), such condition occurring in an otherwise easily retracted and loose foreskin. This variety is frequently found in a lymphangitis accompanying gonorrhea.

Many accidents could not occur in the absence of a foreskin. A few of the injuries I have seen in my clinic are: burns from the use of strong solutions of carbolic acid or corrosive sublimate, put up in convenient tablets, sold by the pharmacist and so commonly used by persons having promiscuous sexual relations; extensive or deep cauterization, uncontrolled or unlimited, practiced indiscriminately by the patient or the druggist upon an oftentimes innocent lesion or abrasion; bites or other injuries inflicted through pervert acts; tears through trying to force the glans through a constricted preputial orifice, tears resulting from the bursting of a condom, or French ticklers, ingenious devices invented to increase (or decrease) the pleasure of the sexual union, "haircuts" and other injuries produced while effecting intromission, besides numerous instances of self-inflicted injuries and mutilations by the sexual hypochondriac or the insane. Any of the above wounds may, of course, become infected and most often do.

Other morbid conditions affecting the situation which this state of phimosis may complicate are the initial lesion of syphilis (chancres) chancroids, epitheliforma, acute or chronic eczema, simple ulcers, lymphangitis, erysipelas or venereal phlegmonous erysipelas, various syphilides and lupus erythematosus. A number of these conditions remain unrecognized until they have assumed formidable proportions, when concealed by such a prepuce. Especially true is this of chancroids, which become very troublesome and difficult to treat successfully when so situated. Under such circumstances, should a circumcision become absolutely necessary to expose them, there is little hope of avoiding infecting the entire surgical wound, thereby creating an ugly state of affairs indeed. A number of recent experiences have forced me to the conclusion that a circumcision and not a dorsal slit should be made, as the latter only imperfectly exposes the sores, and the edema accompanying the almost inevitable infection prevents a complete retraction of the foreskin, so that should the sores be in the sulcus, behind the corona, upon the sides and under portions of the glans, you have bettered conditions but little, if any, and ultimately have a "dog-eared" condition, which must be corrected, any way.

(In a subsequent paper I will give the technic of my operation.)

The Sympathetic System and Pelvic Lesions.

BY M. H. AXLINE, B. L., M. D.,

Professor of Gynecology and Abdominal Surgery in the Cincinnati Polyclinic and Post-Graduate Medical School. Cincinnati, Ohio.

The sympathetic nervous system plays an important part in the symptomatology of diseases of the viscera. Extending from the skull to the coccyx it provides a means of communication between the viscera, which it supplies en route. This intimate connection often gives rise to unexpected phenomena in the presence of disease. Two rows of ganglia, one on either side of the corpora vertebræ, form the main trunk of this system. These ganglia are connected with each other and with the spinal nerves by nerve trunks. These two chains are united in the cranium by Ribés' ganglion, and in front of the coccyx by the ganglion impar. The nerve bundles leaving the ganglia pass forward through plexuses and ganglia, eventually reaching the organs which they supply. The histology of this system shows it to contain very fine, nerve fibres, whose cells are located in the spinal cord, together with fibres whose cells are located in the sympathetic ganglia. The fibres of the Rami communicantes between the ganglia and spinal cord are mostly efferent and vaso-motor. The sympathetic nervous system, if we disregard this admixture of spinal nerve fibres, appears to be distinct from the great central system. The axons of these cells do not intermingle with the dendrites of the spinal cells, nor do those of the spinal cells appear to carry impulses to the sympathetic cells. The function of those cells and fibres, distinctly sympathetic in origin, is a limited control over and co-ordination of the actions of the body viscera. This is borne out by a study of reflexes or sympathetic manifestations which can not be reasonably explained by investigation of the cerebro-spinal system. The sympathetic system is not sensory, and in the following studies it is noteworthy that all pain is caused by the secondary condition, and is not a reflex pain from the organ in which the lesion exists. Furthermore, it is of importance that it is not acute conditions but conditions of a graver or chronic character that most frequently cause reflex phenomena.

The uterus and ovaries being plentifully supplied with ganglia, and fibres originating in the hypogastric plexus and its divisions, are often the starting point of such reflexes, which manifest themselves in far distant organs.

The eye receives sympathetic fibres from the third, fourth, ophthalmic division of the fifth, and sixth cranial nerves, besides a branch accompanying the central artery into the eyeball. Pelvic disorders may cause such symptoms as asthenopia, epiphora, dilatation of the eyeball, ptosis of the lid, and even recession of the eyeball, resulting in headaches and other secondary symptoms. At times the ocular trouble assumes primary importance to the patient, who visits the oculist, only to find that glasses, however well adjusted, do not afford permanent relief. (At times glasses properly adapted to the condition afford relief for a day or two.)

The following illustrates very typically several features of this sympathetic reflex originating in the pelvis. An eminent oculist of this city received a young woman in his office who complained of trouble with her eyes. His examination revealed some astigmatism, which he corrected, with but temporary relief to the patient. After repeated examinations he at last elicited the information that her menses occurred tri-weekly. He then referred her to me. She gave a history of defective vision of several months' duration, which, as stated, was not permanently relieved by glasses. Furthermore, she stated that she had been a sufferer with periodic attacks of sick headache with severe vomiting and nausea. These attacks were increasing in frequency, and at this time occurred two or three times a week. She often thought that certain foods brought on these attacks, but she was not sure. Constipation present but not marked. Heart slightly erratic, both in force and frequency. Stomach showed hyperchlorhydria but no dilatation. All symptoms were marked by their irregularity in force and time of occurrence. Vaginal examination re-

vealed a cystic ovary the size of a goose egg. Removal caused a cessation of all symptoms, and as she said, "I am a well girl for the first time since I can remember."

The salivary glands, thyroid and breasts, are known to be in intimate relation with the generative organs, and disorders of these glands which appear to be idiopathic usually indicate some disease in the pelvis. The pelvic symptoms, however, are usually of such a character as to attract the attention of the examiner. These glands receive fibres through the cervical and superficial cardiac plexuses of the sympathetic.

The esophagus often presents the so-called globus hystericus in pelvic lesions, but this is rarely, if ever, the most prominent symptom and usually accompanies some gastric disorder.

The heart is unusually well supplied with sympathetic fibres and ganglia, and is more or less disturbed in all affections of the uterus and appendages. This deviation from the normal consists in changes in rate and force, but rarely anything more serious. The condition might be called cardiasthenia. The beat gradually becomes slower and weaker, although quite regular for several moments, when it very suddenly becomes stronger and faster, probably when the condition of the blood becomes such as to cause inhibition of the vagus. The signs might be overlooked except by continued or repeated examinations. The results of this condition are anemia, slight pallor, which alternates with more or less flushing, shortness of breath, lassitude and deficient nutrition of the entire body. This condition is often mistaken for anemia, and is common in girls at puberty, whose sympathetic system is not fully adjusted to the changes in the generative organs. It is also noted at the menopause, when conditions are reversed. When occurring between these periods it is suspicious of pelvic disorder and indicates a careful examination of this region.

The stomach is often a Waterloo for the general practitioner. We may have cases so severe that it is not thought necessary to look further for the lesion; indeed, if such a thing were attempted, the patient might accuse the physician of being mediesome. The symptoms are about the same as in the morning sickness of pregnancy. A case typical of this condition occurred recently at the Cincinnati Polyclinic. A patient, of about forty years of age, presented herself at the clinic, complaining of stomach trouble. There was pain but no marked tenderness over the stomach. This pain extended upward beneath the sternum with occasionally the sensation of a lump in the throat. There was belching, some nausea and occasional vomiting, usually aggravated by eating but not entirely dependent upon the ingestion of food. The variation of symptoms and failure to reveal any definite lesion, together with the futility of treatment, indicated a nervous dyspepsia. The professor, noting that all her symptoms were aggravated monthly, referred her to the gynecological clinic. Examination here disclosed a general congestion of the pelvic viscera. A few days of treatment directed to the pelvic organs relieved the gastric symptoms entirely. An interesting and instructive feature was the cause of this congestion. Although she had a child over twenty years old, and still lived with her husband, she stated that she had never had an orgasm. This in spite of the fact that sexual desires were easily stimulated. The repeated congestion of the genital organs, without the natural relaxation accompanying orgasm, had gradually set up a chronic congestion, with its attendant symptoms.

The bowels very frequently respond to pelvic troubles, with constipation, sometimes alternating with diarrhea. This condition may become very severe and treatment appears to give only temporary relief. It is customary to attribute this to pressure on the rectum, which is true in some instances, but probably such cases are less frequent than sympathetic constipation.

The urinary system manifests its sympathy by polyuria, frequent urination and occasionally cystitis, dysuria and other symptoms. This, too, has been erroneously attributed to pressure.

Diagnosis in the above conditions may be difficult, but usually yields to painstaking examination. The greatest difficulty is woman's natural modesty, which, of course, must be respected, yet when a

possibility of such sympathetic involvement exists, a most thorough examination is the only justifiable course.

In individual cases the strongest proof of the nervous origin of the above conditions is their variability and nonconformity. Symptoms most pronounced at one examination will, under exactly similar conditions, be hardly noticeable. Thus, nausea may occur at the sight of food, while later in the day even eating will arouse no such symptoms. Then, too, the symptom complex usually lacks some important symptom. Thus, dilatation of the stomach may be absent when according to all other symptoms one would expect to find it present. The absent symptom may appear later on, only to mark the disappearance of another equally important. An anatomical lesion is never present as a result of the secondary condition. There may occur a coincident condition. For example, the eye is usually myopic or astigmatic, but then oculists tell us that emmetropia is extremely rare.

Treatment of the secondary condition usually gives temporary relief, but on account of the variance of symptoms beneficial treatment of today may aggravate the condition tomorrow. Sedative and tonic treatment is always grateful to the patient, and she is an easy convert to the many nostrums embodying these features. Rational treatment is, of course, directed toward the primary cause.

Further study along these lines will undoubtedly remove many of the clouds that obscure our knowledge of hysteria and neurasthenia, their effect and cause.

Buttermilk as an Infant Food.

BY S. M. BLOOMSTEIN, PH. G., M. D.,

Clinical Professor Pediatrics, Medical Department University of Nashville.
Nashville, Tenn.

Buttermilk as a food for infants suffering from dyspepsia and diarrhea has been used in the hospitals of Rotterdam, Holland, for some years, and during the last three years has been employed with great success by Prof. Baginski in the Kaiser and Kaiserin Hospital at Berlin. It may be difficult to see how children could thrive upon this method of feeding, since the proteid contained in the buttermilk averaged about four per cent, but the fact remains that babies suffering from the various forms of dyspepsia recovered under this feeding more rapidly than by any other system of feeding. Of course, there were some cases not adapted to this method of feeding, but these cases were in the minority, and the rule was a steady improvement in the health of the infant, following this diet.

Baginski insisted that the buttermilk be fresh daily, and this one fact that fresh buttermilk only must be used makes this system of feeding rather difficult, but where such buttermilk can be procured daily, there is little doubt in my mind as to the value of its use in the conditions before mentioned.

The method of preparation, as practiced by Baginski, is as follows: To one litre of fresh buttermilk were added thirty-five grams of sugar and thirty grams of wheat flour. This was placed over a fire and heated under continuous stirring, until it reached the boiling point, when it was removed and allowed to cool a few minutes, when it was again replaced and again heated to the boiling point. This process was continued for three successive times, then strained through gauze or a fine sieve and immediately placed in bottles and kept on ice.

The little patients were first given a cathartic and the bowels thoroughly cleansed. During the first twenty-four hours nothing was given except a little barley water. At the expiration of this time, or in bad cases, on the second or third day they were started on the buttermilk feeding. In most cases the character of the stools immediately changed, vomiting ceased, diarrhea stopped, and the children improved rapidly.

As the patients were removed from the hospital upon recovery, I had no means of following these cases. Most of the children were put upon a sweet milk diet after being removed to their homes, or some "infant food," and not infrequently the dyspepsia returned and the babies were again brought to the hospital for treatment.

Finally, it became the custom in the hospital, owing to the difficulty of carry-

ing out this method of feeding in the patients' homes, to accustom the babies to the sweet milk diet for a few days prior to their removal from the hospital.

One interesting point is the fact that the very young infants received the same kind of food as the older ones, the only difference being in the quantity given. Where this food is continued for any length of time after the infant is in good health, a very small quantity of butter should be added to the mixture daily to supply the fat deficiency in the buttermilk.

The Relation of Clinical Pathology to Practice.

BY E. E. SMITH, M. D., PH. D.,

Professor of Pathology in the New York School of Clinical Medicine; Pathologist to the Trinity Hospital; Pathologist to St. John's Riverside Hospital, Yonkers; Pathologist to the West Side German Dispensary; Pathologist to St. Bartholomew's Clinic: Consulting Pathologist to the Somerset Hospital, Somerville, N. J.; Fellow and Secretary of the Section on Medicine of the New York Academy of Medicine; Member of the County Society, Pathological Society, Medical Association of Greater New York, etc., etc. New York City.

There was a time, and not long ago, when clinical pathology consisted of a few crude examinations made by the practitioner in his back office while the patient waited. At the present time, among the practitioners who are able to work to best advantage, such examinations are given to the specialist and are conducted in a laboratory properly equipped for this purpose. The value of these improved and extended laboratory examinations depends upon a number of factors.

The practitioner himself is responsible to some extent for the value of the results obtained. This is in part because he controls the material and upon him rests the decision as to what shall go to the laboratory and what shall not. If a case is referred to the laboratory for one or more examinations, simply because other means of diagnosis have failed, the results may be of value, but it is not to be expected that they will so frequently be helpful as when the laboratory examination is directly indicated. The character of the specimens must be such that the efforts of the clinical pathologist will be made to advantage. It is not an unusual experience for an unrecognized case of pulmonary tuberculosis to visit the laboratory office for a blood examination because of suspected malaria. Of course, in such an instance the clinical pathologist usually does not suggest an examination of the sputum without a previous consultation with the practitioner.

Many practitioners, desiring that the laboratory report shall be unbiased by clinical symptoms, neglect to give any history of the case, at the same time requiring from the clinical pathologist an opinion as to the interpretation of his findings. This is unfortunate; such an opinion must necessarily be guarded and in most instances is equivocal. This uncertainty would in a measure be removed by a personal consultation with the pathologist after receiving the report. In most instances it remains for the practitioner to reach the final opinion in the case. This suggests the limitation in the usefulness of the laboratory report that arises from a failure of the practitioner to give the results due consideration. It happens with some physicians that they have already decided on the diagnosis, and only give weight to the laboratory findings when they are confirmatory of their preformed ideas. In some instances this is unquestionably justified by the preponderance of the clinical symptoms, but the independent value of the revelations of the laboratory in other instances is equally unquestionable.

Another responsibility taken by the practitioner in the examinations of the clinical pathologist is in the taking of specimens. Much material sent to the laboratory is unfit or insufficient for the examination desired. Dried blood smears are thickly spread; discharges that need to be stained are sent dried between the slide and cover glass; the specimen of urine is not collected at a favorable hour, and perhaps has already undergone decomposition; blood to be examined for malaria has been taken after the administration of quinine. Some of these deficiencies can be overcome by the resource-

fulness of the pathologist, but others can not.

The success of the laboratory worker depends in the first instance upon his ability to obtain suitable specimens, and finally, to conduct properly the examinations themselves. As to this latter, the personal equation is quite as great a factor as in other departments of medicine. The person making or having a responsible charge of laboratory work in the field of clinical pathology needs to be familiar with the fundamental facts of biology, including bacteriology and histology, of pathology, and of chemistry. The fact that he is familiar with certain tests and even that he can conduct them intelligently and well does not warrant his being recognized as capable of assuming the entire responsibility of the laboratory examinations under consideration. There is as much difference in laboratory men as in men of any other vocation, and it is incumbent upon the physician to see that his work is undertaken by those properly qualified as to their ability, their training and their experience. Nor is it safe to depend upon the reputation of a laboratory, as the management, and with it the policy of any institutional laboratory, is subject to change. The growth of clinical pathology has been naturally attended by the springing up of many laboratories; some under the control of manufacturing firms and drug houses; the laboratories of health departments and colleges and private laboratories. A personal acquaintance with those having professional responsibility of the work is advisable.

If the material for laboratory examination has been properly taken, and if the work of the clinical pathologist has been properly done, there is yet another factor to be considered in estimating the value of the results, viz., the interpretation and use of the findings. Here, as everywhere, extremes are to be avoided. Where errors of diagnosis are not dependent upon errors in technique, they can usually be attributed to the lack of conservatism in interpretation. As in other departments, the use of the facts revealed by clinical pathology demands firmness in the interpretation of unequivocal indications and conservatism where the laboratory finding is less conclusive.

The Essential Incontinence of Urine.

BY CHARLES SETH EVANS, B. S., M. D.,
Professor of Genito-Urinary Diseases in Cincinnati University.
Cincinnati, Ohio.

This variety of incontinence is observed almost entirely among infants and young adolescents, and is characterized by the involuntary emission of urine without any apparent lesion of the urinary apparatus. I wish particularly to call attention to this form, as it is not only the most frequent form of incontinence but the form which is most frequently misunderstood. It has been well studied only among authors who have formulated certain theories, of which one may say they are all right and all wrong, because of the fact that they have limited themselves to the one symptom common to all the types, that is, involuntary passage of urine at night. However, if one would take the trouble to study these little patients during the daytime he would be immediately struck with the fact that they belong to many and different types.

The first of which, and the type which represents the great majority of the cases, is one in which the child wets the bed at night, while during the daytime he has perfect control of the act of urination. Yes, more than perfect control; is able to retain the urine beyond the average time. In school this boy rarely troubles his teachers with a request to go out, and for that reason this type is not known by school teachers. Whereas, in another—the second type—the child is also afflicted by copious involuntary voiding of urine at night, he has frequent and imperious desires to urinate during the day. His request of the teacher that he may go out is more in the nature of a demand, and he hastens out and reaches the urinal barely in time.

The third type may have the same nocturnal symptom, differing in the diurnal symptom in that when he "goes out" in school he reaches the urinal too late. In other words, he has a diurnal as well as nocturnal incontinence.

To these three types, which are really the three types of essential incontinence

of urine, may be added two others for completeness. One, in which there is a continuous incontinence of urine both day and night, and the other in which the incontinence is associated with epilepsy and epileptic seizures.

To consider these forms in detail let us say that in the first form, the essential incontinence of urine is of the psychopathic order, which corresponds to the theory of Petit. Petit describes this form exactly and definitely, and perfectly understood its cause. It is purely of psychopathic origin. A child may have this form of incontinence from infancy, or, in other words, may never have obtained complete control in what we call the second infancy. It shows itself along the fifth, sixth or seventh year, or perhaps sooner, and is characterized by the fact that it is associated with nocturnal dreams, which dreams are augmented as to their occurrence by the punishment administered to the child. It is a well-known fact that the dreams which we remember in the morning are those that occur in the last moments of our sleep; so these children, if they are caught in the act, awakened and questioned, will tell a story of having had a dream, not necessarily of urinating, but of the fall of rain, or of running water, of a babbling brook, or possibly of seeing some animal urinate, and responding to this dream the bladder contracts and there is involuntary copious emission of urine. This form, then, is due to no trouble with the urinary apparatus; it is simply and purely psychopathic, and must be treated as such. Needless to say that punishment administered to the child, or threats of subsequent punishment, but increase the condition, because the child's last thoughts before going to sleep are along this line.

The second class due to vesical irritability, according to the theory of Trousseau, is characterized not only by the nightly emissions, but by the frequent and imperious diurnal micturitions. This class, which has been called by the English writers the "irritable bladder," is frequently found associated with some sort of external irritation, such as phimosis, atresia of the meatus, or hypersensitive spinal irritation.

In the third form, which is the form of essential incontinence of urine due to faulty contraction of the sphincters or a urethral anesthesia, according to the theory of Guyon. This form differs from the others in the fact that the patient is unable to have complete control of the bladder during the day as well as during the night. This is the form in which the child soils its linen before reaching the urinal, and is most frequently due to a faulty development of the genital apparatus, of the sphincters, or to a previous operation dealing with the dilatation of the sphincter, or, occurring in later years, is due to hysterical anesthesia of the posterior urethra. These patients are still able to empty their bladders completely when in the erect position by means of the abdominal press. They have no real paralysis of the bladder, but simply an inability to promptly contract the sphincter on the one hand, and on the other hand a lack of the normal sensation of the urine in the posterior urethra. The incontinence naturally occurs when the bladder is full, and from the contraction of the muscles the urine is forced into the posterior urethra.

In the fourth condition, due to paralysis of the bladder and of the sphincters, the urine escapes in small jets, or drop by drop. This is a most infrequent variety in children, and is caused either by the prolonged retention of the urine or of the forcing of the sphincters to relieve the same, or what is rare in infants, of hysteria.

As to the form which occurs with epilepsy, the fifth variety, it has been very well studied by Trousseau and others, and interests us but merely to mention it, an evacuation of the bladder which occurs at the end of an epileptic seizure.

As to prognosis, it must be said in general that the prognosis is good in all the forms, even the paralytic, and all respond early to treatment.

As to the treatment, many remedies have been mentioned, among them belladonna, strychnine, electricity, and even chloral. We must consider the different forms with which we have to deal. The treatment of the first form, the psychopathic form, must be of a thoroughly psychopathic nature. It must be sugges-

tion, and to the parents of the child the assurance may be extended that at puberty the child will certainly recover. Puberty works its changes in the child by changing his line of thought. From a micturial preoccupation the child is apt to have a sexual preoccupation, and at that time the sleep becomes less profound, the child awakening very easily to the contraction of the bladder. The sleep can be made less profound by keeping the child from sleeping upon his back by means of some simple appliance, and by the administration before sleeping of a little black coffee.

In the second form, vesical irritability, we find that the belladonna works extremely well.

In the third, electricity and strychnine serve a very valuable purpose, as also in the fourth form, whereas the fifth form rarely comes under the notice of the genito-urinary specialist, more likely in the hands of the neurologist.

There has been a method of treatment by spinal puncture proposed, but I have had no personal experience with it, and I would hesitate to employ it because of the danger, though minimum, which is associated with it.

Chloasma (Liver Spot Disease).

BY S. A. PEAKE, M. D.,

Professor of Dermatology and Skin Diseases in the College of Physicians and Surgeons; Dermatologist to Jefferson, St. Louis Baptist and St. Louis City Hospitals.
St. Louis, Mo.

This peculiar affection of the skin, which is macular in form and diffused over the back, chest and trunk, is one quite frequently met by the general practitioner, and causes much concern as to its identity, because of its low organism and tendency to recur, the patient's own idea, *i. e.* (liver troubles), where such discolorations of deep yellow or yellowish brown, or chocolate brown is found; their differentiation is often the cause of much study, especially if the patient has been using arsenic, silver nitrate, etc. The well defined form of chloasma uterinum is so named on account of its frequent association with pathological conditions of the uterus, both in the married and unmarried. In hysteria, pregnancy, anemias, ovarian disorders, there will be noted certain changes in the skin's coloration, usually over the region of the forehead, of a yellowish brown type; but in the class of patients whose skin has been the subject of tuberculosis, cancer, malaria, syphilis, the hue of coloration is more of a yellow or deep chocolate.

Chloasma advances with great persistency, not only selecting the trunk and chest, but frequently occurs over the back and neck. Often after the patient has followed instructions for treatment, the discoloration may return after a few days and disappear again after a return to medication, only to again appear more progressive than ever.

Persistency in treatment is one of the cardinal points in this peculiar trouble. The various discolorations due to eczema, lepra scleroderma, are of an entirely different hue, and are not in any way liable to be mistaken for chloasma. The above discolorations are due entirely to an excess of the coloring matter normally deposited in the skin. In furfuraceous desquamation, the existence of a vegetable parasite is readily demonstrated under the microscope; this low organism has a tendency to roam over the skin, taking in new fields and rapidly producing discoloration.

Many methods have been advised for the early destruction of the trouble. For this purpose sulphur has received much attention. Mercury, iodine, benzine and carbolic solutions have been used. Many cases of dermatitis have been traced to a desire on the part of the patient for a too severe treatment with mercury for the removal of the discoloration. Ptyalism is not uncommon. A case of dermatitis recently under my care was due to a too severe inunction of mercury for the removal of chloasma.

A treatment which has met with universal satisfaction in recent years is that of thoroughly applying to the affected area sapoviridis and rubbing same into the skin well, allowing it to remain thirty minutes, then washing well with hot water, and applying a solution of hypo-

sulphate of sodii twenty-five per cent; daily applications of this treatment usually suffice to destroy the parasite and cause bleaching of the skin. Benzine, a cheap product, and usually found in every home, accomplishes in a remarkably short time the total destruction of the lesion. I have observed that under this form of treatment, where the ordinary lye product of home manufacture has been used, similar to the method employed in the first treatment and then followed by a liberal application of benzine, that the process yielded rapidly and did not recur. With the foregoing methods of treatment this annoying condition of the skin will rapidly disappear.

Lubrication in X-Ray Exposures.

BY GEO. H. EVERHART, M. D.,

Professor of Physiology and Electro-Therapeutics in the Baltimore University School of Medicine; Visiting Physician to Same School; Visiting Physician to the Aged Women's Hospital, etc. Baltimore, Md.

In the long tirade of abuse which has been vouchsafed in the case of light therapy against the X-ray, in regard to a condition known as "X-ray burn," I feel somewhat as does the surgeon of the present day in regard to pus, that, in some way, somehow, the surgeon or his technique are responsible for all infection, and while the many and various antiseptics are of value in assisting nature in a cause most injurious to good surgery, yet with the knowledge possessed by the present-day surgeon, the blame can in no way be reflected upon the chief actor, his assistants and paraphernalia. That asepsis is the only road to success in surgery has long been established. With this knowledge the profession and the world at large is given a great degree of confidence and surety in all the stages of surgery under careful, watchful technique. With the surgeon, an established, well-worked out law of technique has been formulated. All experimental stages have given place to proved conclusions. If error is apparent, the blame rests where it belongs. While with light therapy, this new avenue of medication, whose field is of equal importance to the medical world, these laws of technique vary so widely that it is next to impossible to form any fair working conclusion. That much has been done for the advancement of this work by able-minded men and women, with the result that there has been a gradual narrowing down process of the overgenerous technique. Yet there have been so many points of discussion to be solved that in the limited time that the work has gone on, opportunity has not been afforded for the regulation of all conditions. This state of affairs, its cause, its treatment, the danger to patient, have been widely discussed, but very little useful information has been gleaned as to its prophylaxis, what the surgeon would consider, asepsis.

Early in my use of this agent I reasoned that if this medium was of value as a destroyer of a pathological condition, that it must also, to a certain extent affect the normal tissue; that if the pathological condition of lupus, rodent ulcer, carcinoma, etc., were being attacked and made inocuous by the ray of this light, that, to a greater or less extent the normal tissue must be influenced, so that in my judgment all the epithelium that surrounded these tissues was needed in the restoration of the condition to its normal state. I endeavored to keep as nearly as possible the epithelium from degeneration by the use of the light, and have found the most efficient means to be a thorough soaking or steaming of the surrounding tissues, as contrary as this would seem to an ordinary sunburn, where the burn increases by contact with water.

After each treatment I have an assistant to well massage the surrounding tissue. So positive am I that this treatment is effectual in lessening and preventing burn, that I never allow a radiograph to be taken without first being prepared in this way. I have seen from eight thousand to ten thousand exposures during the last four years, with remarkably little degeneration, and positively not a single burn.

[Written for the MEDICAL BRIEF.]

On Some Conditions in Which the Presence of Albumin and Casts in the Urine Does Not Necessarily Indicate Serious Renal Disease.

BY E. G. WOOD, M. D., C. M.,

Professor of Practice of Medicine and Clinical Medicine in the University of Nashville. Nashville, Tenn.

The desire to find some sign pathognomonic of disease too often leads many of us to unduly exalt the diagnostic value of individual symptoms and signs. By attaching too much importance to these signs our diagnostic perspective soon becomes narrow, precipitate conclusions are formed and unfortunate errors arise.

Probably no clinical signs have been accorded a greater value than the presence of albumin and casts in the urine. For a long time many practitioners believed that albuminuria indicated serious, structural disease of the kidney and a diagnosis of Bright's disease was at once recorded. It was soon discovered, however, that renal albuminuria occurred in many other conditions than Bright's disease, such as the acute specific fevers, toxic irritation of the kidneys, changes in the blood pressure in the renal vessels, the congestion of serious cardiac disease, various nervous manifestations, etc. Then it was thought that the association of casts with albumin was sufficient to stamp the case as one of serious organic disease. But traces of albumin and sometimes casts were occasionally discovered in the urine of perfectly healthy individuals who presented absolutely no other sign of disease. It was observed that healthy individuals might present a slight albuminuria after excessive ingestion of nitrogenous food, severe muscular exercise, cold baths, etc. By some writers these cases have been classed as physiological albuminuria. It is, however, highly improbable that appreciable quantities of albumin can pass through the renal epithelium under strict physiological conditions; it is more than likely that the albuminuria always indicates disturbed function in the epithelium of the glomeruli and tubules that may be transient and of trifling importance or permanent and due to grave structural disorder. Though some cases in which traces of albumin are found in the urine of apparently healthy individuals subsequently develop other signs of Bright's disease, many either recover or live in perfect health for years and never die of renal disease, though they are the subjects of persistent or intermittent albuminuria. In many of these cases the pathological condition responsible for the albuminuria is not clear. Every physician whose practice has extended over a period of years must be impressed with the number of cases in which he has discovered albumin and possibly casts in their urine and yet they never developed any other signs of renal disease. Observation over an extended period must convince us that both albumin and casts may be present in urine quite apart from any form of Bright's disease. In drawing attention to two interesting conditions in which the albuminuria is in itself of minor importance, I do not wish to be understood as minimizing the value of examinations of the urine, but rather as emphasizing the importance of drawing our conclusions more from the general condition of the patient than from the state of the urine.

Orthostatic Albuminuria.—The great majority of cases of orthostatic albuminuria occur in childhood and early adult life, and in children many have been preceded by the infectious diseases. It has been observed more frequently in females than males and different observers have recorded two or more cases in the same family. All writers on the subject refer to the neurotic condition of these patients and Mix is of the opinion that adults affected with this albuminuria are almost invariably neurasthenic. He proposes the term "neurasthenic albuminuria of adults," and attributes the excretion of the albumin to the vaso-motor paresis so common in neurasthenics. As a rule, in orthostatic albuminuria there are no subjective symptoms, and these individuals generally consider themselves quite healthy. In adults various neurotic symptoms are common, and particularly throbbing of the abdominal aorta. But in the adult cases the condition is usually discovered

accidentally, often during an examination for life insurance.

The urine is normal in quantity and its specific gravity is usually 1020 or over. Albumin is uniformly absent in the urine secreted during the night, but appears shortly after rising and continues until the patient retires at night. It is usually present in traces only, but sometimes in considerable quantity. Casts, as a rule, are absent, there being no hypertrophy of the left venticle, no accentuation of the aortic second sound, increase in arterial tension or other signs of renal disease. Many cases entirely recover after a definite period, improvement seeming to follow free exercise in the open air. In other cases the albuminuria persists for years without any apparent failure in health, and many such cases have been recorded.

The recognition of a case of orthostatic albuminuria should not be very difficult, but in some instances a definite conclusion may not be reached until the individual has been kept under observation for a considerable period. The intermittent character of the albuminuria, occurring through the day, but being completely absent during the night in an individual who presents no cardio-vascular changes or other signs of renal disease should at once suggest this condition.

A condition much more common in this country than that just described is the slight albuminuria often met with in men past middle life. The discovery of a trace of albumin and a few tube casts in the urine is a bar against a man's acceptance by any life insurance company, and in the minds of many physicians is sufficient evidence to warrant the diagnosis of Bright's disease. Physicians of some years' experience, who have made a practice of examining urine of their patients, must have been struck with the frequency with which a trace of albumin and a few hyaline and perhaps granular casts are met with in certain men who have crossed the meridian of life. Active business and professional men who have lived a strenuous life, working at high pressure, eating freely and perhaps drinking a few glasses of wine daily, often show at a comparatively early age some evidences of vascular degeneration. Among these evidences I am impressed with the fact that a slight albuminuria and a few tube casts are not uncommon. In addition one may find that the radials are palpable, the temporals prominent, the arterial tension high and the aortic second sound accentuated. The urine contains a trace of albumin, often persistent, and a few casts usually hyaline, but sometimes granular. It is but little in excess of the normal, ranging from fifty to sixty-five ounces, and its specific gravity is not very low, usually between 1015 and 1022. Yet these men consider themselves healthy, and are astounded when they are informed that they are rejected for life insurance on account of their urine. If told that this condition means Bright's disease, they are immediately thrown into a state of alarm, which may be the means of inducing them to modify their habits and to begin anew, living as near as possible to the physiological line. If such a man will eat moderately, abandon his alcohol and be content to slow up, he may enjoy many years of active life in good health, and never develop any further signs of kidney disease.

It may be said that a patient who presents the symptoms enumerated, viz., albuminuria with casts, arterial changes and high tension must be the subject of chronic interstitial nephritis, and if not, how can the two conditions be differentiated? I admit that in many of these cases it may be very difficult, if not impossible, to exclude chronic Bright's disease until the patient has been under observation for some time, yet I am convinced that these men are not suffering from the chronic interstitial change which we recognize as cirrhotic kidney. I believe in these changes the renal condition is a secondary degeneration, senile in type, occurring in the subjects of arteriosclerosis. The albuminuria, in my experience, is always slight, and may be transitory, entirely disappearing, if the patient changes his habits, gives up whisky and eats moderately.

Two years ago an active, energetic and successful business man of thirty-eight consulted me in a state of alarm because albumin had been discovered in his urine by a life insurance examiner. He had suffered for some years from a mild

neurasthenia, but otherwise considered himself quite well. He worked hard under constant high pressure, lived very well, drank from three to six glasses of whisky, and smoked ten to twelve cigars daily. On physical examination the apex beat of the heart was in the fifth space in the nipple line, the aortic sound was accentuated, the radial arteries were palpable, and the blood pressure registered 200. He averaged sixty ounces of urine in twenty-four hours; it was clear, with a specific gravity of from 1016 to 1021. There was a distinct trace of albumin, and a few tube casts both of the hyaline and granular varieties. There were no eye changes and no edema, and he looked well. This man at once corrected his habits, ate sparingly, gave up his whisky, and cut his cigars down to three per day. In four weeks his urine was entirely free from both albumin and casts, and though it has been frequently examined since, no trace of albumin has been found, and he is now apparently in perfect health.

I have followed other cases in older men for a much longer period, and while in some of these tube casts and a trace of albumin are constantly found in their urine, they have developed no other symptoms, and continue to live active and healthy lives. Two of these men were said (ten and six years ago respectively) to have chronic Bright's disease, yet today both are active men and consider themselves in good health.

From the foregoing it may be gathered that while albuminuria always suggests grave organic disease, both albumin and tube casts may be present in the urine in the absence of any recognized renal lesion. Both albuminuria and casts must be regarded as symptoms which must be considered in connection with all the other features of a case before their significance can be properly estimated, and before the presence or absence of serious organic disease can be decided.

[Written for the MEDICAL BRIEF.]

Principles and Practice of X-Ray Therapy.

BY OTTO JUETTNER, M. D., PH. D.,

Professor of Practice at the "Cincinnati Post-Graduate School of Physiological Therapeutics," and Director of Roentgen Laboratory of the School; Fellow of the "American Electro-Therapeutic Association;" Author of "Physio-Therapy, a Text Book of Physiological Therapeutics," etc. Cincinnati, Ohio.

The average physician looks upon the therapeutic use of the Röntgen rays as an interesting experiment which at one time promised a great deal, but has accomplished comparatively little. That this "experiment" possesses positive therapeutic value with well-defined clinical indications is denied by the bulk of the profession, while even radio-therapeutists of experience hesitate to make an unconditional statement of this kind on behalf of the mysterious X-ray. And yet, the Röntgen rays, as a therapeutic agent, do occupy an established position. The disappointments which have followed in the wake of X-ray therapeutic work are all attributable to one factor: misuse of a valuable therapeutic agent in the hands of misinformed or unskilled operators. The popularization of the static machine has placed the Röntgen rays in the hands of every physician who cares to invest in a machine. His equipment includes an X-ray tube. He is told how to attach the tube properly and then proceeds to bungle along, treating one case after another without diagnostic consideration for his case, and utterly disregarding the physical conditions of his tube. Thus he adds to the bulk of X-ray work which is done throughout the country. After his first optimistic ardor has cooled off, he neglects the work and joins the vast army of the skeptics who smile at the claims which are made on behalf of radio-therapeutic work. Adding to the skepticism of the bulk of the profession the untold injury which yellow journalism has inflicted on this modern branch of therapeutic work, we can readily understand the unjust position of X-ray therapy and the reasons therefor. Yet it is an undeniable and an easily demonstrated fact that the X-ray

is an established therapeutic agent with a clearly defined sphere of usefulness. It is not a panacea nor is it a specific. Like all other therapeutic agents in medicine and surgery, it meets certain conditions within certain limitations. The personal equation of the patient's physical makeup is always a factor which cannot be defined with accurate precision. It is always the unknown quantity in any therapeutic problem, and makes the concrete application of any therapeutic agent an art, however scientific the abstract physiological activity of the given therapeutic agent may be. In this sense X-ray therapy is on precisely the same level with the bulk of therapeutic agents at our command. The success of X-ray therapeutic work depends on an accurate knowledge of the physical phenomena which are included in the radio-activity of an excited X-ray tube. Without some knowledge of the physics of the X-ray tube, the therapeutic use of the Röntgen rays is nothing but haphazard guesswork.

THE PHYSICS OF AN EXCITED X-RAY TUBE.

What happens when the converging beam of cathodal light is concentrated in the anodal focus and unites with the electro-positive element? The appearance of the illuminated X-ray tube is familiar. One hemisphere is aglow with a greenish light, while the hemisphere behind the anodal (anticathodal) disc remains dark. These phenomena were known long before the time of Röntgen (Crookes, Geissler). Röntgen's discovery concerns a force-modality of some sort originating on the external surface of the excited tube. Röntgen could not account for the evidences of this mysterious radiating energy, and designated them, therefore, as the unknown-quantity-rays, or X-rays. They are the product of an induction process of some sort or other, or, to speak with more accuracy, it seems that the phenomena which take place in the excited tube induce a series of correlative force manifestations outside of the tube. I say "correlative," because the X-ray phenomenon depends in all its characteristics on the ever varying physical conditions which prevail in the interior of the tube. The term "X-ray" then is rather a generic term covering an almost endless variety of manifestations and degrees of intensity of this mysterious induced force.

The most important physical element of the tube is the degree of exhaustion. Upon it depends the relative intensity of the phenomena induced on the outside of the tube. From the lowest degree of exhaustion to the highest vacuity compatible with the safety of the glass tube there is a constantly changing activity on the outside of the tube. As the degree of exhaustion becomes higher, the X-ray waves seem to travel with greater velocity and penetrating power. The wave lengths diminish in inverse ratio to the internal resistance of the tube, while the number of undulations, measured in units of space dimension as well as of time increases. As the internal resistance of the tube decreases, the wave length of the force manifestation on the outside of the tube increases, while the number of undulations per inch or per second is gradually diminished. In making these statements we are reasoning from premises which are furnished by the vibratory theory of force manifestations, now generally accepted by physicists and by the experimental evidence adduced by careful observers.

The computation of the length and velocity of vibrations of the different parts of the solar spectrum is not altogether a theoretical calculation. Wave speed and wave length, while they are the results of abstraction and deduction, furnish the only plausible explanation of the various phenomena of light, light transmission, and, in fact, of all manifestation of force by which matter proclaims its existence in nature. The X-rays being one mode of energy, must have their undulations and their wave lengths analogous to those of other force manifestations. When the vacuum of the tube is too low for X-ray production, there is, nevertheless, an abundance of chemical light-energy. These radiations are located in the spectral field beyond the violet end, and, therefore, classified as ultra-violet radiations. This is a distinctly generic designation, because it refers to perhaps thousands of different forms of radiation whose wave speed is greater and wave length less than those of the

rays in the violet field. The length of a wave from the violet field is approximately given as the 0.0000167 of an inch, while the number of undulations per second is about 727,000,000,000,000 (Eisenlohr, Silliman). The radiations from the ultra-violet field diminish in wave length as they get further away from the (visible) violet field, while the vibrations increase in number. All these vibrations belong to the invisible chemical field of the spectrum.*

That the force-modalities which are manifest on the outside of an excited X-ray tube generically include an indefinite variety of force-modalities representing different speed and length of oscillation and undulation of ethereal molecules, is plain. That some of these modalities are characterized by relatively slow oscillation and comparatively long waves is proven by the presence of heat rays, while, strangely enough, spectroscopic analysis of cathodal rays shows a scarceness of luminous rays but an abundance of chemical rays. It seems justifiable, therefore, to consider the Röntgen rays a generic aggregation of force-modalities rather than one specific kind of radiation.

The question of refrangibility is of some importance in solving the problem of the character of the X-rays. The least refrangible rays are the red. The refrangibility increases toward the violet end of the spectrum. It has been stated that a certain quantity of ultra-violet radiation comes from the inside of the X-ray tube and penetrates the glass. Considering their extreme refrangibility, it would not be difficult to imagine these radiations to have been refracted by the curved surface of the tube, which in this case acts like a prism. This seems to offer a plausible explanation for the tangential waves which Walter has described under the name of "Secondary radiations." They are unquestionably refracted ultra-violet radiations from within the tube.

That the X-rays belong under the generic head of ultra-violet radiations is further shown by their action on sensitive photographic plates. They affect photographic plates like actinic rays. The greater penetrating power of the Röntgen rays is due to the speed and intensity of transmission. The ordinary chemical, solar or electric arc light does not affect the silver throughout the entire thickness of the film, but only the superficial layers of the film. The X-rays penetrate the film down to the glass. In this way the different manner in which a sensitive plate acts after an X-ray exposure or after exposure to sunlight is easily explained. It is almost impossible to overdevelop an exposed X-ray plate, because the whole film down to the glass has been acted upon.

The intercepting power of glass is another feature which suggests the similarity of the two forms of radiation. Finsen discarded glass because of its absorptive action. He used rock crystal in its place. It is peculiar that glass will cast a decidedly deeper shadow on the fluoroscopic screen than rock crystal. The latter, if a good, pure quality, seems to offer absolutely no obstacle to the Röntgen rays.

The therapeutic effects seem to furnish the best evidence. The destructive action of the X-rays results in necrosis due to impairment of the trophic nerves and a resulting obliterative endarteritis. The so-called X-ray burn is distinctly a necrotic process. The same effect on a smaller scale and more superficially is noticed after forced application of concentrated actinic rays. Beginning with the primary erythema, the subsequent dermatitis and the resulting deposit of pigment, the effects of the two forms of radiation are certainly only different in degree of intensity and the depths of penetration. I have seen a typical dermatitis and superficial necrosis follow prolonged actinic exposures, the gross features and microscopic appearances not differing in the least from analogous effects produced by the X-rays. The relative degree of germicidal action of the two forms of radiation is unquestionably an argument in support of the views expressed. The ultra-violet rays are distinctly germicidal; so are the radiations from a low tube. The higher the internal tension of the tube, the slighter is the effect on germ life. This fact has estab-

*Quoted from author's "Contribution to the knowledge of the radio-activity of the X-Ray tube," *Journal of Advanced Therapeutics*, May 1905, and *Journal of the Rœntgen Society*, London, England.

lished the therapeutic value of the soft tube, and, at the same time, explains the futility of the therapeutic efforts made with the higher tension tubes. No one thinks nowadays of X-ray therapy in connection with deep-seated lesions. The harder the tube, the more meager the amount of energy generated, the more rapid the penetration and diffusion. The softer the tube, the greater the output of energy, the more concentrated and powerful the effect. The softer the tube the more striking is the resemblance between the action of the X-rays and the effect produced by concentrated chemical rays.

My object in dilating upon these physical characteristics of the X-rays is plain. I desire to demonstrate that they are true ultra-violet radiations, and thus to find a solid scientific basis for the therapeutic indications of X-ray work. We are fairly well acquainted with the physical character and the physiological activity of actinic rays. Finsen's researches have given us much information concerning this subject. If the X-rays generically are ultra-violet radiations, we are no longer at sea in regard to their therapeutic possibilities. One additional point indicates the strong generic relationship between the two force modalities. Finsen has shown that the deposit of pigment in the skin is Nature's way of protecting the organism against the destructive action of the actinic rays. Pigment absorbs these rays. Experience has taught me that the skin of the negro offers more resistance to the X-rays than non-pigmented cuticle. It is harder to get a good skiagraph of a negro's spine than that of a white man. The large surface exposed (abdomen and back) contains so much pigment that a good deal of X-ray energy is lost, being absorbed by the pigment. The pigment in the red blood cells absorbs X-rays. Thus, we can explain why it is comparatively easy to skiagraph a bloodless part (hand after an Esmarch bandage has been applied to the arm). Radiographers know that an anemic person is an excellent subject for radiographic work.

The practical conclusions from these theoretical premises may be summarized as follows:

1. The X-rays and the actinic and ultra-violet rays of the solar spectrum belong under the same generic head.

2. The difference between the two force modalities is the greater speed of oscillation and the shorter wave length of the Röntgen ray.

3. The penetrating power of the X-rays is in direct proportion to the pressure of the vacuum in the tube.

4. Penetrating power and quantity of energy are in inverse ratio to each other.

5. Like all induced forms of energy the X-rays lose their volume in proportion to the distance from the source of induction.

6. The X-rays, like all actinic rays, are slightly intercepted by pigment in the skin and in the blood (hemoglobin).

7. The destruction wrought by the X-rays is due to the disintegration of the pigment carriers (skin and red corpuscles).

8. The therapeutic action of X-rays is confined to the place of greatest interception, *i. e.*, the skin.

These eight points contain the principles of X-ray therapy. Translating the language of the theoretical physicist into the therapeutic directions which the X-ray operator needs in his practical therapeutic work, the eight points enumerated above could be formulated as follows:

1. Generically speaking, the active principle of X-ray therapy and of Finsen light and sunlight is the same *i. e.*, the germicidal, stimulating and destructive ultra-violet force modality.

2. The ultra-violet ray of Finsen is closer to the violet field of the solar spectrum than the X-ray.

3. The harder the tube, the more penetrating the rays; the softer the tube the more superficial the effect.

4. The harder the tube the less X-ray energy; the softer the tube the greater the amount of X-ray energy, making the soft tube the ideal therapeutic tube.

5. The closer the tube is to the skin of the patient the more intense the effect.

6. The X-rays are partly taken up by the pigment of the skin and in the blood. The greater the amount of X-ray energy the greater the amount absorbed.

7. The X-rays, after being partly absorbed by the skin pigment and the hemo-

globin, first produce a stimulating effect. Through the sympathetic (vaso-motor) nerves, the stimulating effect is reflected and thus a stimulating and pain relieving action is obtained in distant or deep structures. If the application is continued, over-stimulation takes place, resulting in irritation of the pigment carriers (skin and blood corpuscles). The skin reacts by a distinctly inflammatory process. The red corpuscles are disintegrated and the small arteries are occluded, causing local necrosis by lack of nutrition. If the part is composed of morbid tissue, the latter dies, leaving a comparatively healthy ulcer behind. The absorption of the X-rays by the red corpuscles explains the phosphorescence of the tissues which frequently interferes with the skiagraphic result. It also explains the appearance of an X-ray burn in parts that have not been directly exposed. If an X-ray treatment is not pushed to the extent of overstimulation, it may enhance local metabolism. This explains the absorption of growths after X-ray treatments.

8. X-ray therapy should be confined to superficial lesions. The cure is accomplished by disintegration and subsequent local destruction of the pigment in the red blood corpuscles. Keeping in mind the physics of the X-rays and the physiology of their action on organic tissue, we can readily see that deep-seated lesions are inaccessible to the therapeutic action of the Röntgen rays. In addition to this, we know that the therapeutic effect is in proportion to the amount of X-ray energy. Since the latter is in inverse ratio to the penetrating power of the rays, and since the deeper the lesion the greater the penetration required, it stands to reason that energy is lost according as we increase the depth of penetration.

THE TECHNIQUE OF X-RAY THERAPY.

The fundamental law of therapeutic X-ray work is suggested by the necessarily superficial character of the therapeutic effect produced by the Röntgen rays. The soft or low vacuum tube produces an abundance of X-ray energy with but scant penetrative power. The soft tube is, therefore, the therapeutic tube par excellence. Gauged by Walter's skiameter, it should light up three or four of the test holes of the instrument. The standard for an exposure is ten inches distance between the tube and the surface to be treated. The duration of the standard treatment is three minutes, a treatment to be given every other day. This kind of a treatment (soft tube, distance ten inches, duration of treatment three minutes) would under ordinary circumstances produce a stimulating effect, and result in more active granulation and absorption. It would be indicated in indolent ulcers, in various forms of skin disease due to malnutrition, in fact, in all conditions which demand an increase in local metabolism. In most non-bacterial skin diseases the results are not usually permanent, because these diseases are but local expressions of systemic conditions. By lessening the distance between tube and skin, or by continuing the exposure for a longer time, or by repeating the treatment every day, the effect would be intensified. It would be like increasing the dose of a remedy. When the action of the rays get beyond the stimulating point, the germicidal effect is best marked. Whether the latter is produced by the action of the ray on organisms of but little resisting power, or whether the germicidal effect is coincident with the accumulation of oxygen in the part treated, is not quite clear. It has been demonstrated, however, both by laboratory experiments and on the living subject, that pus germs and the tubercle bacillus soon are rendered inert and finally die if they are exposed to oxygen. We know that currents of high voltage and high frequency have an effect on the composition of the atmospheric air by their affinity for oxygen. How far this affinity will affect the oxygen in the body we are as yet not prepared to say. There is, however, no doubt about the germicidal action which follows applications of the X-rays. If the X-ray dose is increased still more, we arrive at the point at which destructive effects are to be expected. A destructive treatment would be administered by a soft tube used every day for five to ten minutes at a distance of ten inches. This is the typical X-ray treatment for superficial cancer. It is understood, of course, that the stimulating, germicidal or destructive

effects do not follow one treatment, but represent the accumulative effect of a series of treatments.

It would be folly to recognize iron-clad rules, which must prevail in any and all circumstances in every case. The personal equation of the patient as apparent to the individualizing judgment and to the experienced eye of the operator, is the unknown quantity which can not be forced into the tight-fitting limitations and indications of a stereotyped law. As long as every patient presents a personal equation of his own to be solved by the personal equation of the physician, every kind of therapy must necessarily contain an uncertain element which makes therapeutic practice an art rather than a science. The suggestions given are hypothetical. In applying them the experience of the operator must adapt them to concrete conditions. This may mean shortening or lengthening the exposures, changing the distance of the tube from the skin, etc. It is understood, however, that the tube must at all times receive its full capacity of current. There should be no sparking. The current should not overheat the anode before the time of exposure is over.

The surface to be treated and the anodal disc should be placed approximately parallel to each other. An imaginary line drawn through the center of either should be at right angles to the plane of the anode and to the plane of the surface to be treated. Thus, if a patient suffering from epithelioma of the lower lip is lying on his back on a suitable table, the tube should be placed directly over the affected area. The anode should be parallel to the surface and should be directly over it. The glass of the tube should be ten inches from the area to be treated. This is the ideal position. Variations from this position are frequently necessary, owing to the peculiar location of the trouble.

The tube-stand should have a lead shield attached which has adjustable diaphragms in its center, and is interposed between the tube and the patient. This tube-stand is not an absolute necessity, but a most desirable convenience. The perforation in the center of the diaphragm is placed directly over the area to be treated. Pieces of sheet lead are put around the perforation so that only the area to be exposed remains uncovered. When no shield is used, the patient has to be covered carefully with sheet lead (not lead foil), so that the X-rays can not impinge upon any part except the area which is to be treated. If the hand or arm of the patient is to be treated, the patient can sit on a chair and place his hand or arm on the table. Otherwise it is by all odds best to place the patient on a properly constructed table. The recumbent position is the most convenient and the most comfortable for both patient and operator. Always be careful to cover every bit of skin that is not to be exposed to the X-rays. The lead dressing is the most important part of the whole procedure, because it limits the action of the rays and in this way prevents X-ray "burns." The latter are not really burns. They are evidences of reaction, and if they occur in the right place have the highest therapeutic significance. Inasmuch as reaction is necessary, the cure in cases of morbid growths depend upon it. X-ray burns over large areas of healthy tissue are in the majority of instances due to faulty technique on the part of the operator. Exposures should be made in a darkened room, so that the operator can watch the phosphorescence of the tube, should be noiseless in order not to frighten the patient, and should be painless. The tube should be properly attached to prevent sparking. The operator should not expose himself unnecessarily, especially his hands and eyes. The deleterious effect of the X-rays on the procreative faculty of operators have been emphasized by many observers. A tube which has become hard from constant use should be allowed to rest a week or longer and then be softened. The employment of the regulating (softening or hardening) device on overworked tubes is not conducive to preserving the tubes.

Clinical Indications.

The triple action of the X-rays (stimulating, germicidal, destructive) should be remembered in adapting means to the end. The operator should have a clear pathological conception of his case before

he can attempt to make X-ray exposures intelligently. The X-rays are at their best in conditions where morbid tissue is to be destroyed and where the lesion is extensive and involves the subcutaneous tissues. The following list of diseased conditions probably represents the present status of the question, as suggested by the study of over five hundred cases which have been under observation during the past four years at the Cincinnati Post-Graduate School of Physiological Therapeutics. The directions given should be modified to suit the individual case.

Acne.—In the common form of acne the results are very good. Exposures every day or two for five minutes. Distance of moderately soft tube ten inches. Protect the eyes. In acne rosacea the results are not so uniformly good; the condition is likely to return.

Carcinoma.—Cancer of the breast does very well in the early stages. Treatment every other day with moderately soft tube for ten minutes, distance ten inches. Whenever the lesion is at some distance below the skin in this or any other kind of a case, the tube should be correspondingly harder to insure penetration. The results, of course, are correspondingly less certain. After the first stages of breast cancer, amputation is the proper remedy. It should be followed by X-ray treatment. In cancer of the stomach, bowels, rectum, or for that matter, any of the deep abdominal viscera, the X-rays, like all high potential force modalities, relieve pain and produce an alterant effect, thus prolonging life. I have never seen a case cured and doubt whether the reported cured cases of kind could stand critical analysis. I have known of pain to be relieved by the X-ray that resisted opiates of all kinds. Exposure should be at long range (fifteen to twenty inches) with a comparatively hard tube. Ten minutes every day or two.

Eczema.—In many cases of chronic eczema, especially the vesicular variety, the X-rays produce a cure. In nearly all cases they relieve itching and lessen or stop the discharge. Treatments with moderately soft tube for three to five minutes every other day. Distance five to ten inches. Constitutional treatment is imperative in all these cases. Locally, the high frequency current seems to be better adapted than the X-rays.

Epithelioma (common skin cancer).—It is nearly always curable by the X-rays, usually located in the face (lip, nose, angle of eye). Patient should be treated every day for from five to ten minutes. Distance of soft tube five to ten inches. If there is much induration of surrounding or subcutaneous tissue, vacuum of the tube should be somewhat higher. As soon as the induration disappears and conditions assume a healthy aspect, the addition of Finsen's actinic rays seems to accelerate the process of repair. Exposures should last from thirty minutes to an hour. In reality this is equivalent to using a force modality of less rapid oscillation and greater wave length in order to supplement the work done by more rapid vibration and shorter undulation. The Finsen treatment can be advantageously added to X-ray exposures as soon as the process of repair has begun.

Favus.—Two cases treated and both cured. Technique same as in treatment of eczema.

Hypertrichosis.—I have not been able to produce more than a temporary effect in these cases. Recurrence seems to be the rule.

Keloid.—Results were negative in three cases. Patients were colored.

Keratosis Senilis.—Results are good, especially if the excrescences are removed and the remaining denuded surfaces treated. Technique same as in the treatment of eczema.

Leukemia.—Results seem favorable, as shown by general improvement, and in a few cases by blood count.

Exposure over region of spleen with comparatively hard tube for ten to fifteen minutes every two or three days.

Lichen Planus.—Out of six cases two were cured, two relieved and two passed from notice. Technique similar to that of eczema.

Lupus Vulgaris.—In the hypertrophic form characterized by nodular enlargement and much contiguous involvement, the X-rays are superior to the actinic rays of Finsen, while the latter are preferable in the ulcerated form. Comparatively hard tube for five to ten minutes every day or two. In suitable cases the

X-rays are almost a specific. In the erythematous form of lupus (seborrhea congestiva) results have not been satisfactory. In two cases aggravation seem to follow X-ray treatment. The high frequency current seems to be the proper agent.

Mycosis Fungoides.—Results fair. Technique similar to that in the treatment of eczema.

Pruritus.—The neurotic form seems to respond very well. Three cases, two cured, one relieved. Frequent but very short exposures by means of a soft tube. The itching of many skin diseases is relieved by the X-rays.

Sarcoma.—Results uncertain and seem to vary in even apparently identical cases. Radio-therapeutic treatment should supplement surgical interference. One case of postnasal sarcoma which was operated upon and referred to me by a local laryngologist was cured.

Sycosis.—Results are good. Technique as in acne.

Tinea Tonsurans.—Results usually good. Technique as in acne.

Tuberculosis.—In the glandular form the results are good if the infected glands are not too deep. See technique under "cancer of the breast." In peritoneal tuberculosis I have seen temporary improvement general and local. Technique as in deep-seated cancer. Tuberculosis of joints responds favorably in many cases. If suitable, general and local treatment is added. Technique same as in cancer of the breast. Use a comparatively hard tube. Skin tuberculosis responds to frequent exposures with the soft tube. Technique as in lupus. In tuberculosis of the lungs, X-ray seems to be of doubtful value. The proper agent locally seems to be the high frequency current applied by means of the double resonator.

The best results in X-ray treatment are obtained in epithelioma of the face, in the hypertrophic form of lupus and in acne. In these conditions the X-rays surpass any and all other agents because they are painless, are almost specific in their action and serve an admirable cosmetic purpcse, especially in the common skin cancer of the face. The first and essential condition of success in the use of the Röntgen rays is knowledge of their physical properties and of the effects which they are capable of producing on organic tissue. Without any knowledge of this most important part of the subject, the art of skiagraphy becomes amateurish guesswork, the science of X-ray therapy a conglomerate of empirical notions. There can be no progress without logical elaboration of the principles that underly the work we attempt to do and the technique we adopt. *Sit modus in rebus!*

[Written for the MEDICAL BRIEF.]

Vaginal Puncture and Drainage for Pelvic Abscess.

BY D. M. GIBSON, M. D.,

Professor of Obstetrics and Gynecology in the Homeopathic Medical College of Missouri, St. Louis, Mo.

Although the term "pelvic abscess" may not be a very definite one, it denotes a collection of pus within the pelvic cavity, more or less localized, and will serve to define this condition. As a rule, it is the result of septic infection, either gonorrheal, or from debris left within the uterus. The onset is oftentimes so gradual, and the local symptoms so obscure, that for a time the physician may be in doubt as to the exact nature of the disease. When once, however, localization of the swelling has taken place, and more particularly when fluctuation can be made out (fluctuation, however, is not always easily demonstrated), the case may be dealt with in a very satisfactory manner and by a very simple procedure, for it is a well-known fact that formation of pus, *i. e.*, the localization of the inflammatory products, is one of the happy, if not the most happy, terminations of pelvic inflammation.

The presence of pus is, of course, a prime indication for its removal, and although the patient may not be within range of hospital facilities, and although the practitioner may not have had great experience, operative, he can, nevertheless, handle this class of cases very satisfactorily and with but little danger.

The procedure is as follows: After the patient is anesthetized the neck of the uterus is caught with a volsellum forceps

and the uterine cavity explored. If there be any septic focus within which has not been previously removed, or if there is a purulent discharge therefrom, the uterus should be well cleaned either with the rinsing curette, or mopped out with iodoform gauze, and a small, loose iodoform gauze is left in the uterine cavity in order to provide for drainage, if it be needed. The next step is the most important one. The vaginal cavity is dilated widely enough to get a view of the posterior cul de sac, through which an incision is made with a pair of scissors close to the uterine body. If the abscess has gravitated low into the pelvis, the incision will be followed by a gush of purulent matter. If, however, it is located higher up the first incision may be followed by a dilatation with any suitable instrument, after which the finger is introduced and further dissection made by this means. If it be done carefully, there need be no danger of injuring the rectum, nor need there be any danger of injuring the important structures of the pelvis, if we bear in mind to keep close to the uterus while making this dissection.

If the pus be located on either side it will be readily found by the sense of touch of the finger within the cavity. The quantity of purulent matter liberated varies from a teaspoonful to a pint, and the smaller the quantity the more difficult it will be to find. In cases where there is no well-defined accumulation of pus, this opening-up process tends to shorten the duration of the disease.

After sufficient drainage has been secured, the track made by the instruments and the fingers, or the abscess cavity, if one be found, should be packed with iodoform gauze, five to ten per cent. This gauze packing of the cavity should be followed by another packing of the vagina. As a rule, there is but little shock and there is but little systemic disturbance, reaction from the operation is prompt and satisfactory. The gauze thus placed should be removed from the vaginal outlet within forty-eight hours, but that which is within the abscess cavity or drainage tract should be allowed to remain at least seventy-two hours, and no trouble will be experienced if it be left for twice that time.

It may be argued that this is not the most scientific operation, but it has the following points in its favor:

1. It is safe, efficient, and, if necessary, can be followed by a second operation, at much less risk to the patient.

2. It is easy of performance and does not require elaborate care afterward, and is within easy range of the general practitioner.

3. The results in the majority of cases are prompt and satisfactory, and most patients make a good and thorough recovery.

We are indebted to Dr. Pryor for advocating this most valuable operation, and while he may not have been the originator of the idea, he brought it prominently before the profession, and for this reason deserves due credit.

241 South Jefferson Avenue.

[Written for the MEDICAL BRIEF.]

The Non-Obstetric Uses of Ergot.

BY RALPH ST. J. PERRY, M. D., LL. D.,

Surgeon to Doctor Perry's Sanitarium; Formerly Professor of Dermatology and Genito-Urinary Surgery, University of Minnesota; Ex-President American Association of Orificial Surgeons; Post Surgeon-General Sons of Veterans, U. S. A.; Formerly Surgeon to the African Medical Missions of the Protestant Episcopal Church; Physician to H. R. H., Bara Kapaidy, Sultan of Vey Land; Honorable Surgeon-Major Liberian Army, etc., etc. Farmington, Minn.

Ergot, like many other drugs, has suffered from the circumscribed enthusiasm of its friends, who rejoiced in the discovery of its usefulness in obstetrical work and lauded its use in such practice only, totally ignoring whatever value it may have in other fields. It has suffered because of the timidity of weak-spined practitioners, who, knowing of its capabilities as an abortifacient, have feared to use it in any except labor cases lest druggists, nurses or the blathering laity suspect them of illegitimate practices. It has suffered because of its abortifacient properties being generally known to druggists, nurses and the laity when its other uses were to them unknown. Under the circumstances, the demand for the promulgation of the indications of ergot, aside from its obstetrical uses, is timely. During over twenty years spent in active

general and special practice, ergot has been used by me for the following purposes:

1. To check hemorrhage.
2. To relieve acute local congestions.
3. To induce local anemia in chronic congestions.
4. To excite uterine contractions (non-obstetrical).
5. To check secretions.
6. To tone up and effect contractions in relaxation of muscles.
7. To reduce blood pressure.
8. As an astringent.
9. To excite inflammation with plastic exudation.
10. According to its "*methodus medendi.*"

My first uses of ergot were extra-genital. Before serving a week in the Indianapolis (Ind.) City Dispensary, to which I had been elected an interne, a man staggered into the office suffering from profuse pulmonary hemorrhage. While arranging him comfortably pending the anticipated call for the dead-wagon, the superintendent stepped into the office and directed me to administer hypodermically one drachm of fluid extract ergot. The hemorrhage stopped suddenly, and the trip to the morgue was exchanged for one to the hospital. My dispensary duties were such that no obstetrical work fell to my lot, yet many opportunities came to hand for testing the efficacy of ergot and its preparations along other lines, a desire which had been stimulated by my initial experience in its use.

Later on I was transferred to the Indianapolis City Hospital, and placed in charge of the obstetric and gynecological wards. One of the first cases coming under my care was a negro woman suffering from an uterine fibroid with hemorrhage. The consulting gynecologist was called in, and his eyes glistened as he palpated her abdomen. Said he:

"Doctor, take good care of her; feed her well, treat her the best you can, and when college opens up in the fall we'll have a clinic such as the boys seldom get a chance to see."

She was taken good care of, fed well and treated the best I knew how; and in that treatment came the temptation to try the effect of ergot. The professor's clinic was hopelessly ruined. When brought prominently into view by bimanual manipulation and carefully measured with large calipers this tumorus uterus was found to be five inches in width and extended six and one-half inches above the pubic crest. In administering the ergot, ergotin was used, one grain being given in the abdominal region daily. After two months of this treatment measurements conducted similarly to the previous ones showed a width of two and one-half inches and an extension of three inches above the pubic crest. No satisfactory intra-uterine measurements were taken at any time. This patient showed her gratitude in after life by sending me several cases of uterine growths for treatment without operation. One of these was a uterine polypus with very profuse hemorrhages, threatening the patient's life. For two or three years she had been treated for chronic anemia, phthisis and other wasting diseases, by several physicians, to none of whom had she mentioned the uterine hemorrhages because of fear of an operation. Lured by hopes of a cure without operation she told me her entire case history and was given the following treatment:

℞ Ergotin.....1 scruple.
Acid Gallic.....4 drachms.
M. Ft. Capsules, xx. Sig.: One capsule every four hours.

The effect was to stop all hemorrhage within a few days and to materially decrease the size of the polypus, which originally was as large as a clenched fist. The general health was re-established by suitable tonics and good food. Later the polypus was removed by the ecraseur. The causes of uterine hemorrhage are various, and amongst those of common occurrence are:

1. Simple menorrhagia, as a climacteric symptom.
2. Carcinoma.
3. Intra-uterine polypus.
4. Sessile fibroids.
5. Hyperplastic endometritis.
6. Fungous endometritis.
7. Laceration of cervix with endometritis.
8. Procidentia with laceration of cervex.
9. Procidentia with intra-uterine tumor.

10. Uterine fistulæ.
11. Atheromatous degeneration of uterine arteries and capillaries.
12. General muscular atonicity or flabbiness.
13. Traumatism.
14. Incomplete abortion.
15. Ectopic gestation.

The physician occasionally encounters cases in women over forty years of age presenting small uterine hemorrhages at irregular intervals after the cessation of the normal menstrual flow; small "spurty" hemorrhages, which are not dangerous, yet annoying, and which give rise to many fears in the minds of the patients. A thorough examination fails to reveal anything abnormal whatever, and the phenomenon must be looked upon as purely a climacteric symptom—the spasmodic effort of the uterus to relieve itself of a transitory congestion. In these cases ergot can do no good, unless the hemorrhage be prolonged for some hours or unless the flow be very heavy and depleting from the start, in which cases give one grain of ergotin hypodermically every hour or oftener, as the case requires.

In carcinoma the hemorrhage becomes a constantly present symptom after degeneration changes have brought about a breaking down of the organ. Here ergotin may be of use in preventing undue waste and in conserving the vitality of the patient, being given in capsule or tablet form with strychnia arseniate. The hemorrhage from intra-uterine polypi and sessile fibroids can readily be controlled by ergot, especially if combined with gallic acid, as mentioned in the case history just given, or with strychnia, hydrastine, or cinnamon oil. The hypodermic use is particularly efficient in sessile fibroids.

In hyperplastic and fungous endometritis, the two commonest forms of hemorrhagic endometritis, the internal use of the ergot preparations combined with local application of ergotin in the form of uterine bougies presents a fairly acceptable substitute for operative treatment. Many girls and young women suffering from hemorrhagic endometritis refuse to submit to any operative form of treatment; many of them go to physicians who do not resort to surgical methods, and here the physician needs depend upon purely medical treatments. A bougie which has proven valuable in my hands is:

℞ Ergotin .....2 grains.
Pulv. Dessic. Suprarenal Gland ....5 grains.
Gelatin Bougie Mass.....q. s.
M. ft. uterine bougie 1. Sig.: One bougie to be inserted daily.

These bougies should be inserted after having given such electrical or other treatments locally, as the case may call for. The gelatin mass used in preparing these bougies is made as follows:

℞ Gelatin .....10 parts
Aquæ Dist.....20 parts
Glycerin.....30 parts
M. Sig.: Over sand or water bath.

The remedial agents are incorporated while the mass is just thin enough to pour, and before "set." Internally there was given ergotin or fluid extract ergot in combination with such nutrient general tonics and uterine tonics or sedatives as seemed indicated by the individual conditions of the patient. What has been said of these anti-operative cases of hemorrhagic endometritis is also true of lacerations of the cervex complicated with endometritis, in procidentia with polypoid or sessile tumors. Where patients refuse an operation, do the best you can by way of palliation. Frequently when an operation is to be made, a short preliminary treatment of ergotin and its adjuvants will materially benefit the case and help insure a satisfactory termination. Occasionally one sees cases of metrorrhagia due to excessive flabbiness of the uterine muscular tissues, associated with a general muscular atonic condition. No other pathological condition is discoverable. These patients need ergot with adjuvants, and a course of general treatment calculated to tone up the entire bodily muscular system.

Hemorrhages due to trauma of the uterus are rare. Some years ago I attended a young woman who had fallen upon a fence post and a projecting spike had penetrated the vagina, wounding the cervix. Probably a dozen cases have been seen where hemorrhage was due to the misdirected efforts of ignorant persons to induce abortion by "opening the womb" with lead pencils, hat pins, catheters and other pointed objects. One case was seen where a diffident maiden had slightly

lacerated the cervex while masturbating with a Haarlem oil bottle. In only a few of these cases was it necessary to resort to ergot, and in those the effect was all that could be desired. In hemorrhages due to athermatous degeneration, the use of ergot may be combined with that of Trunecek's serum, the latter dissolving the lime deposits in the arterial coats. The hemorrhages of incomplete abortion and ectopic gestation come within the field of obstetric work and are passed over. In the long continued administration of ergot or its preparations in menstruating women the most acceptable plan is to give small, frequently repeated doses during the inter-menstrual period, and omit the dosage during the menstrual flow. The effects of the remedy upon the uterus are enhanced by strychnia, hydrastia, hydrastinine, gallic acid and cinnamon preparations. Should toxic symptoms develop (ergotism) they can be antidoted by tincture of *solanum nigra*, the common nightshade.

In uterine hydatids ergotin internally and locally has proved efficacious in checking their growth and starving them to the disappearing stage. Menstrual disturbances due to acute or chronic congestions of the uterine body or plethora are often amenable to ergot. Congestive dysmenorrhea has frequently been relieved during the acute pains by ergotin in one grain doses; the amenorrhea of plethoric women has been remedied by the same treatment. Hemorrhages from various extra-genital sources and causes have been and can be controlled by ergot. Pulmonary hemorrhages in tuberculosis and pneumonia are readily controlled except when the larger vessels are involved in the tubercular cases. Intestinal hemorrhages in typhoid fever, dysentery, ulcerations during the course of a chronic colitis, enteritis, proctitis or sigmoiditis, or from traumatism, can be checked usually by small doses of ergotin. In cases of gastric bleeding from ulcer, carcinoma or traumatism, whether followed by hematemesis or not, ergot is beneficial and is best administered hypodermically, thus relieving the stomach of any additional trouble through exciting digestive efforts.

In hematuria, whether due to cystic, ureteral or nephritic hemorrhages, a few doses of ergot will often correct the condition. When traced to the use of quinine, ergotin should be administered with the quinine if the latter can not be discontinued. In epistaxis, either acute or chronic; in those occasional hemorrhages associated with hypertrophic rhinitis in catarrhal affections; in tubercular and syphilitic pharyngitis and laryngitis, and in bleeding gums, ergotin and the other ergot preparations have proved efficacious.

In a few cases of cerebral apoplexy, where the hemorrhage was slow and apparently from small vessels, I thought the progress of the flow was checked by hypodermics of ergotin. While my experience in these cases has been limited, I believe it a measure worthy of trial whenever possible, one which can do no harm and may do much good. In future cases I would combine ergotin and the active principle of the supra-renal gland. Occasionally one meets a case of bleeding piles where the hemorrhage persists far beyond reason—more than the mere emptying of a pile tumor, and here the local use of an ergotin suppository and the hypodermic injection of ergotin will do much good. Quite often in surgical and dental work we encounter cases of hemophilia, or "bleeders," and ergotin has proved a satisfactory adjunct to local means in arresting and preventing undue loss of blood. Where a patient is known to be hemophiliac the operation can be preceded by a prophylactic course of ergotin with adjuvants. In the minute subcutaneous hemorrhages, purpurea hemorrhagica, I have found ergot to be of value, often completely checking the trouble. To relieve acute local congestion ergot has been tried with more or less success in acute pharyngitis. Some years ago a case of this kind was rapidly subdued by giving ergotin one-tenth grain every hour and spraying the pharyngeal mucous membrane every half hour with:

℞ Ergotin.....1 drachm.
Glycerin.....6 drachms.
Aqua Dist.....q. s.....1 ounce.

After four hours' treatment, the patient, a lecturer, went upon the platform and talked with comfort for two hours. In the amenorrheas of plethoric women and

girls and in congestive dysmenorrhea, ergot has many times done good by restoring the equilibrium and permitting the functions to take place in a normal way. The discomforts and dangers of cerebral hyperemia—headaches, mania, flushed face and congested eyes, threatened apoplexy, etc., can be abated and removed by small doses of ergot frequently repeated as needed. Conjunctivitis, blepharitis, ophthalmitis and facial erysipelas have all been subdued and ameliorated by ergot internally and locally. In whooping cough and hypostatic congestion of the lungs this remedy is of good repute, though one seldom used. Combined with strychnia, ergot and ergotin have been employed as remedies in several spinal affections, especially spinal myelitis and cerebro-spinal meningitis.

In the induction of local anemia where chronic congestion has existed, ergot has been successfully tested in nasal hypertrophies, rectal prolapsus, hemorrhoids, enlarged prostate, varicocele and varicose veins by the application of an ergotin ointment and the injection of ergotin or aseptic fluid extract ergot directly into or around the involved parts. The ergotin ointment used is:

℞ Ergotin.....1 drachm.
Lanoline.....4 drachms.
Benzoated Lard.....4 drachms.
M. Ft. Ungent.

The treatment of piles by the injection method has long been in vogue, and one of the popular and most successful injecting fluids is the following:

℞ Acid Carbolic, 95%.....1 drachm.
Glycerin.....2 drachms.
Fld. Ext. Ergot.....1 drachm.
Aqua Dist.....1½ drachms.
M. Ft. injection fluid.

In enlarged prostate the injection of a few drops of aseptic ergotin solution (equalling one grain of ergotin) was made directly into the substance of the gland and into the surrounding tissues, care being taken not to puncture the bladder or urethra. In varicocele an injection of aseptic fluid extract ergot is made into the connective tissues surrounding the mass of veins, without puncturing any veins, and in varicose veins similar injections were made alongside the involved veins; the object being to excite a contracting plastic inflammation as well as to secure the depleting effects of the ergot. In prurigo, erythema, urticaria, acne rosacea, eczema, herpes genitalis and herpes of the nipple, erysipelas, and many other forms of dermal congestion, the ergotin ointment has admirably aided in overcoming the disease. This ergotin ointment has proved especially good in my work as an application to frozen fingers and toes to prevent gangrene, and in cases where the local use of carbolic acid dressings had threatened a gangrenous destruction of the parts. In diabetes and exophthalmic goitre ergotin has proved beneficial. While practicing in West Central Africa, a favorite remedy for the splenic enlargements found in missionaries and traders suffering from chronic malarial poisoning was ergotin combined with arseniate of quinine. In metritis, endometritis and in uterine polypi and fibroid tumors, ergotin locally assists the anti-hemorrhagic action of its hypodermic or oral administration by inducing a local anemia.

In the treatment of uterine hydatids, polypi and sessile fibroids, the drug actions already mentioned are further aided by the proneness of the ergot to excite utrine contractions, thus tending to compress and expel the intruding neoplasm. This same excitement of muscular contractions has effected cures in many cases of small aneurysms.

The use of ergot to control secretions is one of its commonest outside of its obstetric uses. In controlling and decreasing the exhausting night sweats of consumption and other debilitating diseases, or occurring during convalescence from protracted acute fevers, ergot has long been a favorite. In galactorrhea and in drying up the normal secretion of milk after the death or removal of the baby, ergot has been successfully used for years. The secretions of the alimentary canal, from a too free flow of saliva to the pathologic secretions of diarrhea and dysentery, are amenable to ergot. In gonorrhea, ergot has had its chance along with the rest of the *materia medica*, and with some slight degree of success, though not sufficient to supplant other drugs; in gleet it has proved fairly efficacious in the bougie form combined with other remedies. In leucorrhea of the purely vaginal form, local applications of

ergot, either by tampon, suppository or painted directly upon the mucous membrane, have been of value.

In spermatorrhea the beneficial effect of ergot and ergotin is due not so much to their power to control the secretion as to the fact that ergot acts as a sedative to the irritated parts and also tones up the relaxed muscular conditions present. In other forms of muscular relaxation ergot has demonstrated its value. Its use in flabby uterus has already been commented upon. In prolapsus of the rectum, where there is relaxation of the sphincters, ergot is of utility; also in cardiac dilatation without valvular lesion. That ergot is of value in the atonic paralyses of the bladder and of the vesical sphincters every physician of experience can give personal testimony, especially as to cases of enuresis. Another valuable use of ergot in cases of muscular relaxation recently brought to notice, and which I have tested, is its hypodermic administration to victims of dipsomania, morphine, cocaine, chloral and similar drug habits, who suffer from a general systemic flaccidity. The ergot excites to contraction the muscles of the debilitated blood vessels in the affected organs, restores their vitality and is a most decidedly beneficial adjunct to the strychnia treatment usually employed in such cases.

In reducing the blood pressure ergot is beneficial in large aneurysms and in all forms of hemorrhage.

Ergot possesses an astringent action, and its alcoholic preparations a power to excite a plastic exudative inflammation. These two actions combined in the fluid extract ergot are utilized in varicocele and varicose veins, as just detailed; in the injection treatment of hernia, and in deficient penile erections, due to enlargement of the vena dorsalis penis. In hernia the injection is made directly into the evacuated inguinal canal, and in cases of deficient erectile power they are made alongside of the enlarged vein.

Like many other drugs ergot possesses a *methodus medendi*, as Roberts Bartholow used to put it, and upon close scrutiny of the therapeutic and physiological actions of the drug, it does seem remarkable that many of the symptoms produced by toxic doses are also cured by therapeutic doses. For instance, I have frequently with ergotin cleared up post-epileptic stupor in an hour or two in cases where it previously lasted for many hours and even days. Patients suffering from transitory, ill-defined dizziness, drowziness and stupid feelings, without any apparent cause, have been readily and rapidly relieved by one one-hundredth grain of ergotin every hour or two.

The photophobia and flashing, fiery dots that float before the eyes of the "lost manhood" victim, and those interaural noises known as buzzing, humming and singing, whether due to the too free use of quinine or to other causes, are easily eliminated from the patient's repertoire of troubles by minute doses (one one-hundredth to one one-thousandth grain) of ergotin frequently repeated.

Epistaxis, bleeding from the gums, enuresis and hematemesis are conspicuous evidences of the *methodus medendi* of ergot. That form of diarrhea in which the discharges are watery, slimy or bloody and accompanied by exhaustion—a condition bordering upon Asiatic cholera, has many times been corrected by ergot in minute doses. The curing of laryngitis and pharyngitis, the prevention of gangrene in frozen, scalded and burnt fingers and toes, and the amelioration of the painful itching, swelling and tingling in frost-bitten parts are all proofs of the dual action of this drug. So, too, with the various skin symptoms already detailed; the profuse, cold, clammy sweats; the purpura and congestions; all have been found in the manifestations of ergot poisoning—all have been cured by the proper use of ergot. This dual action of ergot, its *methodus medendi*, is a vast field for therapeutic investigation, one opening great possibilities to the student of today and one scarcely touched upon in the past.

In my general and special practice the exhibition of ergot was originally limited to the ordinary fluid extract and to ergotin. With later advances in pharmaceutical science came the physiologically standardized fluid extracts, alcoholic and ethereal, and the aseptic preparations designed especially for hypodermic use. Ergotinine has rarely been used, being practically unobtainable.

[Written for the MEDICAL BRIEF.]

A Plan for the Treatment of Eczema in the Hands of a General Practitioner.

BY A. RAVOGLI, A. M., M. D.,

Professor of Dermatology and Syphilology in the Cincinnati University; Dermatologist to the Cincinnati Hospital; Member of the American Dermatological Association; Member of the Dermatological Associations of Paris, France, and Naples, Italy; Member of the American Urological Association, etc., etc. Cincinnati, Ohio.

In a brief article it is impossible to enter into the debated question of the etiology of eczema. It is sufficient to consider it as a catarrhal inflammation of the skin, usually chronic, in many cases of an acute course.

In choosing a plan of treatment for eczema, it has to be taken into consideration the periods of its evolution. It is clear that a remedy which will be useful in an old chronic form of eczema will be irritant and injurious in an early acute stage of the disease. In consequence, the distinction of the eczema in acute and chronic is of great interest for the practitioner. In the same way it has not to be neglected the distinction of eczema in its erythematous, papular, vesicular, squamous forms, because it gives the key for the selection of the external applications.

In an acute form of eczema, when redness and swelling of the skin is associated with burning and itching sensation, usually a simple application of an absorbent powder, as talcum, rice, amylum with some oxide of zinc, or one per cent of boric or salicycic acid often repeated will answer the purpose. If there should be also some oozing, the powder will form a kind of paste and protect the excoriated epidermis, prevent the breaking of the vesicles, and the acute inflammatory process will gradually subside. In cases of eczema intertrigo, the natural folds of the skin must be separated with strips of lint or absorbent cotton.

In some cases the simple application of powder does not relieve the inflammation, and bathing with solution of two per cent of subacetate of lead or of aluminum are found useful to diminish the inflammation. But as soon as the purpose has been obtained it has to be stopped and dry applications resumed. In a general way moist applications macerate the epidermis, and for this reason are not so beneficial in eczema.

In these cases, as a sedative lotion, it will be found a mixture of calamine in the following proportions:

℞ Pulv. Calamin Prep. .....2 drachms.
Zinc. Oxid .....2 drachms.
Glycerin .....1½ ounces.
Aq. Rosæ .....1½ ounces.
M. Sig.: Shake the bottle before using.

This is applied on the surface with a camel's hair brush, or with strips of lint dipped in the lotion.

In cases of an acute eczema with deep excoriations, accompanied by abundant serous discharge and unbearable itching sensation, the use of the ichthyol in liniment form will be found beneficial in many cases.

℞ Ichthyol .....2 drachms.
Olei Amygd. Dulc. .....4 drachms.
Aq. Calcis .....4 drachms.
Aq. Rosæ .....1 ounce.
Glycerin .....1 ounce.
M.

This is applied on strips of lint saturated in the liniment, and the dressing is changed twice a day. Ichthyol cornifies the young epidermic cells of the corpus mucosum and forms a temporary protection to the papillary layer. It diminishes the exudation and relieves the itching sensation. The surface is washed with a mild solution of one per cent of carbolic acid or of borate of sodium before the liniment is applied again. Cleanliness is necessary for eczema, and it has to be greatly reproached by some kind of superstition spread by general practitioners amongst the people, that eczematous surfaces have not to be washed. On the contrary, eczema has to be cleansed as stated, and if the water should be irritant for awhile could be resorted to the olive oil.

When the excoriations begin to heal up and the irritation has ceased, it is necessary to apply some mixture, which may protect the young epidermic cells, giving them time to be reproduced; may prevent the exuded serum to form crusts, and, at the same time, may possess certain antiparasitic properties. For this purpose pastes are applied as continua-

tion of the treatment. Lassar's paste is very useful and a good composition:

℞ Acid. Salicyl. .....10 grains.
Zinc. Oxid ..... 2 drachms.
Amyl ..... 2 drachms.
Vaseline..... 1 ounce.

To this mixture we often add one drachm of sulphur, which has good antiparasitary action. It is spread on the affected parts, and is easily removed, wiping it off with a little olive oil.

In cases of pustular eczema of the scalp or of the beard, a salve with white precipitate has given us good results.

When the inflammation has subsided, the excoriations and the fissures have healed up, the infiltration has diminished, then the application of tar becomes useful:

℞ Unguent. Picis Liquid .....3 drachms.
Zinc. Oxid.....1½ drachms.
Unguent. Aq. Ros.....4 drachms.

In a great many cases the old Wilson salve will be found greatly beneficial. Sometimes it seems that every application increases the trouble, and a few applications of this innocent salve have given very satisfactory results.

When the eczema has healed up, but the skin remains tender, itchy, easily cracks, the application of a solution of carbolic acid is very beneficial.

℞ Acid Carbolic.....1 drachm.
Glycerin.....1 drachm.
Aq. Rosæ.....3 ounces.
Alcohol.....3 ounces.

With a moist cotton tampon the skin is gently rubbed, then dried and dusted with rice or amylum powder.

It is necessary that the local treatment of eczema be associated with an hygienic and internal treatment. For this purpose the physician must study the condition of the general system of his patient and also his habits of living. In so doing he will detect troubles of the digestive organs, of the excretory functions, or of the general nutrition, or of defective metabolism, or of dietetic errors, which often are the true causes maintaining the eczema.

In chronic forms of eczema, when the skin is thickly infiltrated, hard, inelastic, covered with hard epidermic scales, which conceal deep rhagades, the treatment must be rather of an irritant nature, so as to be able of producing the reabsorption of the exuded elements. The soap of potash, green soap, finds good application to dissolve and remove the epidermic masses, and as an irritant to produce the reabsorption. It is rubbed on the surface, left for ten minutes or more, and then is washed off. As permanent application the old Hebra diachylon in some cases, mixed with ichthyol one drachm to one ounce has given gratifying results.

In cases of this kind, if the green soap does not produce the desired effect, we can resort to a strong solution of caustic potash soda to remove the thickened epidermis. The rhagades must be touched up with a solution of nitrate of silver from three to six per cent to obtain their healing.

Tuberculosis From a Hygienic Standpoint.

BY E. L. MCGEHEE, SR., M. D.,

Professor of Hygiene in New Orleans College of Dentistry; Member of the Louisiana State Board of Medical Examiners.
New Orleans, La.

The prevention of tuberculosis is a medical and social problem which all humanitarians should consider. Since Koch discovered the tubercle bacillus in 1882, we know that this bacillus must enter the body to produce the disease, hence, it is communicated and not inherited. It is to our company and not our antecedents that we are indebted for this disease. The tubercle is an effort on the part of Nature to segregate and destroy the germs; in many cases the surrounding tissue breaks down and is replaced by scar tissue in cases that recover. Tuberculosis, which is responsible for one hundred and fifty thousand deaths annually in this country alone, may affect any part of the human organism—bone, brain, lungs, bowels, etc., etc. It is probable that under ordinary conditions of city life that tubercle bacilli gain entrance from time to time into the body of almost every individual. In most cases the human organism is able to overcome and destroy the invading microorganisms, but under special conditions, hereditary predisposition, unhygienic surroundings, disease, dissipation, overwork, worry, any condition, in fact, which

lowers the vitality, permits the disease to gain a hold. The nature of "predisposition" is not well understood. Simply "the soil is favorable."

Tuberculosis prevails especially during early adult life. The micro-organism is breathed, swallowed or absorbed by the skin as through an open wound. It is safe to say that in most cases the bacilli enter the economy through the nose and mouth during respiration. The bacilli are spread chiefly by the sputum expectorated, or sprayed in coughing and speaking.

It is possible through the combined efforts of a wise government, well-trained physicians, nurses, and intelligent people, to not only prevent the spread of this disease but eradicate it.

The results are so terrible and far-reaching that no effort should be omitted to bring about a lowering of this appalling death rate. The economic effects of tuberculosis must be taken into consideration. The earning capacity of the patient is at an end, and statistics show that fifty per cent of those afflicted are upon charitable aid. About twenty-five per cent die in charitable institutions. Nor does it end here. The father dies, his support is cut off, the children's education must be stopped, they must work to support the family.

How can this disease be prevented?

Statistics show that in those States where suitable sanatoria have been erected, and where an active campaign is carried on against the scourge, a noticeable decrease in the death rate has followed. In New York in two years the death rate has decreased from twenty-five to twenty-one per cent; in Boston, in the same period, the decrease has been two per cent, while in Baltimore, where there has been no such activity in stamping out the disease, the increase has been three per cent in two years.

There should be a special ward for tuberculous patients, in every hospital, or better still, a building completely isolated. As an instance, the North Texas Hospital for the Insane, located at Terrell, showed a percentage of thirty-three per cent of deaths from tuberculosis. After adopting the isolation method for one year, the percentage was twenty-four per cent, the following year 23.3 per cent.

A proper enforcement of the spitting ordinance, combined with instruction of the general public as to the mode of propagation and sanitary measures to prevent spread, are essential.

Compulsory notification to health authorities of the existence of every case of tuberculosis.

Disinfection of premises vacated by consumptives.

These, with the isolation method in hospitals, and proper sanatoria, are the best measures we can hope for until our State legislatures and municipal authorities awake to the importance of combating this disease.

Hurst and Webster Streets.

Who Is Competent to Administer Anesthetics?

BY L. S. COLTER, B. S., M. D.,

Professor of Physiology and Anesthesia in the Cincinnati College of Dental Surgery.
Cincinnati, Ohio.

The condition of complete general anesthesia is one of the most grave of human life. So closely does it approach the boundary line between life and death that it is truly astonishing how near we approach that border, and yet so rarely cross it. This being so, it should not be necessary to state that only those skilled in the use of these deadly agents which abolish completely all sensibility, should be entrusted with their administration.

While it is our belief from observations of recent years that the profession in general are beginning to realize the importance of intrusting the administration of an anesthetic only to one who is an expert in the handling of these agents, yet we know that in many instances the necessity is not appreciated, and that too often the medical man with the least experience is the one entrusted with this great responsibility. As an instance, I quote the case of a medical student who started to read medicine in the office of a prominent practitioner, whose office was located in a part of the city where almost every house for several squares had a physician's sign attached to it. Very early the services of this student were in demand by

many of the physicians in the neighborhood, to assist in surgical operations in the capacity of anesthetist, as it was not presumed he was sufficiently fitted by skill and experience to sterilize and handle the instruments. Many an abdominal section, amputation, bone resection and other operations, both of major and minor character, were done under this same anesthetist. Infants a few weeks old, and patients long past the Osler chloroform age, those weakened by long periods of suffering, suppuration, sepsis, hemorrhages, etc., alike came under his care. The good Lord must certainly have been kind to these patients, for not one of them died from the anesthetic, and this seems the more remarkable when in every case chloroform was the agent used. The early experience of the writer in administration of anesthetics has proved very valuable to him in later years. The knowledge thus gained and still further added to during experience in a large hospital finally led him to be regarded as one specially adept in the handling of these agents. In the past fifteen years the writer has administered the anesthetic in over four thousand cases. Familiarity in the use of these agents, however, has not bred a contempt for the dangers involved, and it is with far greater fear that he undertakes the task began as a medical student.

From his long experience the writer believes that the all too common practice of intrusting the administration of chloroform and ether to the most recent graduate, to say nothing of turning the task over to a student or nurse, is to be strongly condemned. There are danger signals to be recognized that nothing short of considerable experience will detect. Of course, this experience can not be gained without at some time assuming the risk of administering his first anesthetic, but the point we wish to emphasize is that one should be very carefully instructed in the administration of these drugs before being intrusted with the lives of patients who must subject themselves to some operative or other procedure requiring an anesthetic.

For some years the writer, in his college work, has been attempting to instruct students in the handling of anesthetic agents, and he has found it exceedingly difficult to impart the requisite knowledge by didactic teaching. The only satisfactory method is for the teacher to stand beside the administrator of the anesthetic and to point out the danger signals as they arise, to indicate what symptoms call for an additional amount to be used, and which indicate the withdrawal of whole or part of the agent. There are many symptoms which must be taken in their entirety in order to know the proper course to pursue.

The laity at the present day are beginning to recognize the importance of having a skilled assistant to administer the anesthetic; the fact is being brought home to them that the surgical operation of itself is not likely to kill the patient, but that the anesthetist, on the other hand, has the patient's life under his thumb, and that he may, by giving too much, or failing to recognize danger signals, send the patient into an eternal sleep. The public has a right to demand protection in this respect, a right which in the past has not always been accorded. Today the usefulness of the anesthetist is gradually being recognized, and a skilled and experienced man is always in demand. Lastly, he should be paid a fee commensurate with the grave responsibility that he assumes, for the task which he undertakes is without doubt in many cases far more serious than that of the operator.

[Written for the MEDICAL BRIEF.]

Concerning the Surgical Treatment of Gall-Stone Disease.

BY RICHARD WARD WESTBROOK, M. D.,

Professor of Orthopedic Surgery in the Long Island College Hospital; Consulting Orthopedic Surgeon to Jamaica Hospital; Member of the Medical Association of Greater New York; Member of the Kings County Society, Surgical Society, Brooklyn Medical, Long Island Medical and Pathological Society, etc., Brooklyn, N. Y.

Considerable difference of opinion prevails at the present time regarding the proper treatment of gall bladder disease. Surgeons will advise early operation, while the medical practitioner will often be equally positive in recommending treatment, which in the end can only be preventive or palliative.

The gall bladder is not an indispensable part of the economy. But it is the breeding place of gall stones, and it gives rise to almost as much chronic disease and disability in adult life as the appendix. We may extirpate the appendix, as it is a functionless part and better out than in, but not so the gall bladder, which is a functional and continuous part of a system of bile ducts of wide extent. To the surgeon the gall bladder is a natural drainage tube. In the surgical treatment of gall-stone disease, the *drainage* of an infected biliary tract is what we aim at; the removal of the gall stones is of secondary importance, and is done to insure a radical cure.

Nowadays a great deal is said about drainage of the hepatic duct with removal of the gall bladder—a formidable procedure. The same object may be accomplished far more simply and safely by drainage, by leaving the gall bladder, opening its fundus, inserting into it a rubber tube held by a purse string suture, and thus guiding the infected bile outside the body. If done in this manner the fistula will close in two or three weeks and the stones will not reform. When the gall bladder may no longer serve this purpose as a drainage tube in the hands of the surgeon, that is, when for any reason bile will no longer flow through its cystic duct to the outer world, it were better extirpated.

The cystic duct at times may be closed by stones which cannot be readily removed, or by stricture, or by the kinking of adhesions. A gall bladder shut off only remains to make constant trouble. If, then, in a word, we find bile present in the gall bladder, retain it; if we find no bile present, remove it.

The so-called "ideal" operation of opening the gall bladder, removing the stones and closing it up by suture, is no longer considered good surgery. Whenever gall stones produce symptoms, such a gall bladder is infected. The gall stones were originally the result of a mild microbic invasion of the gall bladder, due to no fault of the bile itself and often occurring in typhoid fever. Such an invasion may die out and the stones remain latent in the gall bladder, producing no symptoms, but through a mechanical irritation of the gall stones we have a favorable condition for re-infection to occur. And the pain and inflammatory symptoms of gall stone disease are the result of this re-infection or blazing out of a smouldering infection.

Therefore, the "ideal" operation in gall stones producing symptoms is illogical in that it eliminates only one offending factor and leaves the chief element of danger, the infected biliary tract.

The Value of a Negative vs. a Positive Diagnosis in Vesical Calculus.

BY M. L. HEIDINGSFELD, PH. B., M. D.,

Professor of Dermatology and Syphilis in the Cincinnati Polyclinic and Post-Graduate School of Medicine, Cincinnati, Ohio.

J. K., aged forty-eight, came under my observation in June, 1898, with symptoms of obscure urethritis of some ten or fifteen years' duration, dating back possibly to an old gonorrheal urethritis of some fifteen years' standing. Patient had been under the care of a number of physicians and without any beneficial results. Careful examination at the time revealed, by means of a searcher, the presence of a vesical calculus., This diagnosis was confirmed by a cystoscopic examination and a stone the size of a hazel nut determined. The patient was advised to have same removed by means of an operation, lithotomy or lithotripsy, as indicated upon the operation table. The patient was a lawyer, who was about to take his summer vacation, and asked that operation be deferred until his return early in September, to which arrangement the writer readily acquiesced. The patient failed to return at the appointed time, and when casually seen during October or November of the same year, he stated that he had been examined by four or five eminent surgeons and physicians since that time, and was informed by all, with one exception, that no calculus was present and that operative interference was entirely contra-indicated. One physician, who did not interest himself to the degree of making a personal examination, stated to the patient that if a calculus was detected by the searcher and confirmed by a cysto-

scopic examination, it was unquestionably present and should be removed.

In July, 1905, during which interval obscure symptoms on the part of the urethritis (bladder symptoms having been continually absent), the patient came under the observation of a physician, who again confirmed the diagnosis of vesical calculus.

At this time the patient consented to an operation, and a calculus the size of a hen's egg was removed.

This case is of interest in reference to the importance of a positive diagnosis of this character over a negative one. And, second, that vesical calculus can be present when the ordinary clinical symptoms are apparently absent.

A case of obscure simple urethritis should not be passed over with an examination limited to the urethra, and attention to the male genitalia in obscure cases should be made as complete as possible.

This case also demonstrates that the physician is sometimes placed in an uncomfortable position, not to say in an unfavorable light, by the unjust sneers and scoffs of his confreres when his position is clearly a correct and proper one, and that a positive diagnosis in almost every condition, whether it is vesical calculus or otherwise, should never be passed over without the most careful, painstaking and scrutinous examination.

For a period of six or seven years this patient experienced a sense of skepticism, not to say of distrust or lack of confidence in his examining physician, and all without cause, as subsequent events have justly demonstrated.

An Interesting Case of Adenoma.

(Illustrated.)

BY RHETT GOODE, M D.,

Professor of Anatomy and Operative Surgery in the Medical Department of Alabama University.

Mobile, Ala.

The interesting features of this case are the unique appearance of the tumor and the neglect to make an examination in the recumbent posture. The cuts taken from photographs show the general form and shape of the tumor, and also the appearance of the part after recovery from the operation.

E. S., colored woman, aged fifty years, presented herself for examination, suffering from a tumor located on the right buttock. On the first examination the tumor was found to be hard, firm, and the surface was marked with enlarged veins coursing over it. It was considered to be of a very vascular nature, and appeared to be firmly attached to the bone.

The history of the case was that it had been growing slowly for a period covering four years. It was decided to operate upon this case and extensive preparations were made to arrest hemorrhage, and for

this purpose long needles, such as are used in amputation at the hip joint, were in readiness. A difficulty was anticipated in removal of the growth on account of the anticipated hemorrhage. At the time of the operation, after the patient was placed on the table, and the tumor was lifted, held, and elevated into position for some time, allowing the blood by pressure to pass out of the tumor, which was found to be freely movable, so much so that an Esmarch rubber bandage could be placed around its base, then an incision was made into the tumor, and very much to our surprise it was found to be a simple

adenoma. The operation of removing the tumor was performed with no difficulty,

only a few small arteries necessitating ligature, and the patient made a rapid

and uninterrupted recovery, being confined to bed only ten days.

[Written for the MEDICAL BRIEF.]

Lessons Learned from 1905 Yellow Fever Epidemic.

BY GEO. H. TICHENOR, A. B. (TULANE), M. D., (TULANE).

Yellow Fever Expert Louisiana State Board of Health; Nominee of Nicarauguan Minister to United States for Yellow Fever Institute; Member Editorial Staff Dixieland Magazine; Official Organ United Confederate Veterans, etc. New Orleans, La.

QUARANTINE REGULATIONS—LACK OF UNIFORMITY.

The lack of uniform quarantine regulations between the States and ignorance of local health boards regarding the mosquito theory, proper health certificates, proper fumigation and sanitation, screening houses and cisterns and oiling of pools of water and cisterns together, in some instances, with the total disregard to the laws regarding quarantine and the establishment of shotgun quarantines has terrorized the public, prevented physicians and nurses from attending the afflicted in a satisfactory manner, has been a means of spreading the epidemic by lack of proper precautions and thoroughly convinced the public that war may be hell, but there is no doubt about quarantine, under present conditions, and a need for uniformity of regulations and their enforcement.

HEALTH OF NEW ORLEANS.

Yellow journalism has had ample opportunity of exaggerating accounts concerning the distress of infected districts and make it seemingly appear that the people were dying like flies, particularly in New Orleans. Whereas, the truth of the situation is as follows: In the next thirty days from to-day (Sept. 21st) the fever will be practically over, and the deaths will not probably exceed, at present ratio, more than four hundred and forty-five, which is the same as our annual deaths from pneumonia in 1903, and has in some years run as high as six hundred and seventy-four. The biennial report of the New Orleans Board of Health shows that in 1903 the deaths from tuberculosis were one thousand and one; heart disease, six hundred and fifty-one; Bright's disease, six hundred and eighteen; diarrhea, four

hundred and sixty-five; pneumonia, four hundred and forty-five; the total deaths from all causes amounting to six thousand seven hundred and fi[illegible]. The mortality of the white population of the city in 1904, exclusive of the Charity Hospital, was only 12.73 per thousand. To the physician these statistics prove conclusively that New Orleans is not such a death trap as she is frequently spoken of and will recall to his mind that the salt in the soil and ocean breezes are the chief factors in disinfecting her filth and promoting health.

Again, I venture to say that statistics will probably show for the next year, notwithstanding the deaths from yellow fever, the total deaths for one thousand of the white population of the city will be much less than that of many of our large cities, simply due to above stated facts, and also that these statistics prove we have mastered the disease and can institute proper precautions to stop its spread.

I am optimist enough to believe that the American people will waste no time in securing uniform quarantine regulations when these facts are known and they get over their fright. Then, and not until then, will trade be enabled to go on without interruption, as it is now being conducted in Germany with present cholera epidemic, and the afflicted properly cared for, and proper precautions instituted to stop its spread.

Mosquito Theory Proven.

Facts have been brought to light during this epidemic which are undeniable evidence of the correctness of the mosquito law under which we have been working.

Dr. White, of M. H. S., furnishes the following instances: "There occurred in the State of Mississippi a case of yellow fever at Lumberton on the 19th of July, in the person of a refugee from New Orleans. This case was not known until the 29th, but, nevertheless, with regular precautions, it was obliterated, and there has been no case at Lumberton since." "There was also a case at Summerall, Miss., near Lumberton, discovered only after the case had convalesced; same measures taken, and the same results occurred in either place, thus assuring the success of the undertaking." "In Louisiana, Dr. Corput found about eighteen cases at Reserve plantation, and, having the backing and confidence of Mr. Godchaux, he established a hospital, moved in all the cases, disinfected all the houses, with the result that the infection was obliterated in fifteen days, no cases having occurred on that plantation since." "This was again shown with the Peters avenue and St. Ann street focus in New Orleans."

The following are instances in my own experience:

The infection at Bon Ami, La., was due to a dago arriving there secretly and mingling with people while sick. After the proper number of days had elapsed three cases followed, all Italians, subjected to the infection by living in the neighborhood of first case. Several physicians besides the local physician pronounced the cases yellow fever before my arrival. On my arrival I found that Drs. H. Z. Barnett & Son, local physicians, had burned the houses the dagoes died in, and had moved them out of the town limits, and all the Italians were quartered in tents. A thorough fumigation of every house was begun, every pool and cistern oiled and screened, and every house properly screened. The fumigation was kept up until danger was passed—that is, twenty days after last case.

I may say here, by way of diversion, that I have found in cases where it was difficult to stop up the cracks in houses, it is best to use pyethrum powder first, which overpowers the mosquito quickly, and then sulphur; because, if you use sulphur first, it will drive the mosquitoes out of the house. In the open air tar barrels and waste pine lumber burnt around a house will drive them very effectually away. The waste lumber was burnt every night on the edges of the town to keep the mosquitoes out of the town, as the place was surrounded by the piney woods and on slightly rolling ground, and my experience in observing the habits of the mosquito was that they did not migrate, but would be blown by the winds a distance of a number of miles. I have noticed stegomyiæ blown out at sea the distance of fifteen miles, and I have observed prior to their coming that there was not a single mosquito on the ship. I have noticed them several times when the ship was closer to land. Coming back to our

subject—the Italians were placed into two camps, one at each end of the town; their temperatures were taken twice a day; finally, after the proper number of days passed, a case of an Italian boy, son of the Italian who died, developed symptoms. He was immediately screened at first rise of temperature and put in a house isolated from the detention camp in which he had been. The result was that no other cases developed in either camps or town and the boy got well. The people in town were requested to put a mosquito bar over them with the first rise of temperature from any cause and to send for a physician. This was the only case which occurred at Bon Ami after isolation, and the fever was promptly stamped out. The prompt and energetic assistance in every instance of Mr. H. Smith, manager of King-Ryder Lumber Company; the valuable assistance of Drs. Barnett & Son, together with the prompt co-operation of Dr. D. C. Isles, President Calcasieu Board of Health, and his board, enabled me to stamp out the fever at once, which would have been a very difficult undertaking, considering that Bon Ami was a lumber town of twelve hundred population. The record of only one case after four had died of the fever prior to my arrival, shows what can be done under present system. This instance shows by contrast a great difference with that of the Tallulah situation. I arrived at Tallulah on September 5th, and stayed seven days. The place had not been properly fumigated, oiled and screened, and the people, in my opinion, did not and would not accept the mosquito doctrine. Finding a lack of satisfactory co-operation with local health authorities, although I had that of Dr. Gaines, parish health officer, who did all he could to aid me in my work, and the disease rapidly spreading, due to the fact that some people would not screen, oil and fumigate properly, after a stay of seven days, in the meanwhile organizing two hospitals and starting similar organizations to those in effect in New Orleans, I requested the board to be recalled, for above stated reasons. It is a well-known fact that Tallulah had twenty cases on my arrival, and, perhaps, between fifty and sixty on my departure, and when Dr. Von Ezdorf, of M. H. S., arrived two days later he found that the infection was all over town, as I had reported, and he immediately began a thorough fumigation, but he was too late. Notwithstanding his efficient service rendered good work with skilled fumigators, which I did not have, the infection, as he later reported, had spread to adjoining plantations. I had found a case at Omega, thirteen miles from Tallulah, prior to his arrival.

After leaving Tallulah, I was sent by the State Board to Berwig, and resided on J. N. Pharr & Son's plantation. On my arrival I was called in consultation with two local physicians, Drs. Berwig and McLellan, and we pronounced the case yellow fever. The local health board enforced rapidly the quarantine regulations according to the mosquito doctrine, and not a single case developed after this one.

I instituted the precautions against yellow fever according to the mosquito doctrine and not a single case developed on the Pharr plantation under my supervision. The Pharr Brothers spared no expense and time in lending me assistance.

[Written for the MEDICAL BRIEF.]

An Age That Craves a Stimulant.

BY PATRICK T. MELDON.

An Experimental Medical Scientist.
San Bernardino, Cal.

This is an age of extreme mental activity, and its increase is so great one can expect the child to have more mental and less physical forces than either of his parents. An active mind consumes the physical forces—the source of its own sustenance—and then craves for a stimulant; tobacco was found to stimulate the mind, and is now the most used for that purpose; coffee and alcoholic liquors come next.

Tobacco is set down as a narcotic, and is, when medicinally used, but when its use becomes a habit, particularly in smoking, its effect is the opposite—very often inducing wakefulness to the extent of insanity. It is used, as every one knows, almost entirely in smoking and chewing. One man will smoke and another chew, as a matter of choice—the choice made being always subject to an instinctive desire of

the mind. Smoking is preferred by those who are mentally active, and chiefly by those who have more mental activity than mental capacity. Large, clear minds are seldom in need of a stimulant—they are masters of thought and of work without it.

Chewing is preferred by those who have sluggish digestive organs and slow mental action.

Mental activity is everywhere on the increase, and so is smoking—the former desires the latter. The stronger the nervous tension and mental endurance the stronger the tobacco and the greater the quantity required for the smoker. The Irish are the only race of people strictly specialized in their use of tobacco; they are smokers. Other nationalities smoke it and chew it, and some of them use it as snuff.

Tobacco reduced to the form of smoke is most readily absorbed by the brain, and in that form it affords its best and quickest stimulant; it is readily diffused throughout the entire nervous system, but its effect is woefully bad. It always tends toward shattering the nerves, and never fails to irritate a nervous disorder of any kind; it acts severely on the heart, and very often terminates fatally. It weakens the cardic muscle, impairs the circulation and causes the lungs to congest; the result is a low, stiff, hacking cough, and, even in very hot weather, waves of cool sensations are felt passing up and down the spine, particularly between the shoulderblades. The shoulders incline forward; the step becomes weak, unsteady, and the heels trudge and scratch the ground.

The cigar and pipe is the safest way to smoke tobacco; the smoke from either one is too strong to inhale and send direct to the brain. It must first be brought in contact with moist glands that somewhat refine the smoke. Those glands absorb, dissolve and eliminate a certain per cent of the nicotine.

The cigarette is the most deadly way that tobacco can be used. It affords a comparatively light, fresh smoke, that can be endured while drawing it into the lungs and forcing it out through the nostrils. The smoke of the cigarette, containing all of its raw and irritating nicotine, is then sent direct to the vital tissues of the lungs and brain—the result being a weakened heart, impoverished blood, nervous irritability, imbecility, or a certain form of the insanities.

Only recently the writer met with a man who had been an inveterate cigarette smoker for years. He was suddenly taken with a dull pain in his left ear. This was soon followed by a copious discharge of a lymphoid tenacious fluid that had the ill-fetor of tobacco in remarkable concentration. The discharge left that ear permanently deaf; and the only reasonable conclusion reached was that the auditory sac had for a long time absorbed the nicotine, while its irritating effect diseased the wall of the sac and caused it to burst.

Tobacco will aid digestion when its use is commenced for that purpose, but it will impair the digestive organs when its use is commenced while they are in a healthy, or normal, condition. Chewing has by far the strongest effect on the digestion, and yet smoking is best adapted to the case of some individuals.

Finlanders are known to scrape the granulated nicotine from the wall of pipes and not only chew it but actually swallow it; some of them even crave for such a deadly poison. One should expect its effect to be deadly, and yet it merely stimulates in them a sluggish digestion and an appetite that is more than the ordinary.

It is generally supposed that tobacco remains in the system for years after its use is discontinued. That, on account of its solubility, might be questioned. But, then, the appetite that it cultivates and its ill-effect on the nervous system usually perseveres for years.

Coffee and the smoking of tobacco have about the same effect on the nervous system, except that a long conntinued use of the former so often ultimately impairs the digestion.

Alcoholic liquors afford the most rapid and direct stimulant that the mind can risk to continue, as men continue stimulants through time. Its fluidic, gaseous and aromatic properties adapts it to instant absorption. It deeply impresses the vital tissues, softens their texture and in a short time brings down the whole structure in a mass of ruins. Its remarkable gaseous nature suffocates the mind, or sus-

pends its influence over the body and leaves its victim in a helpless condition. This is technically called "drunk" when the case is a man and "paralyzed" when the case is a woman.

Women have strong desires for stimulants—probably stronger desires than men—but their finer sensibilities are the fortunate cause of their avoidance of tobacco and alcoholic drinks. They tried gum probably as a stimulant, but as it did not have the desired effect the woman that chews a cud is now seldom met with on the street. Coffee is their favorite stimulant, and it is to be hoped that nothing worse for them will ever cross their path. It brings on indigestion, has a wrecking effect on the nervous system and induces a petulant disposition that is hard for others to endure.

What a miserable world this would be should women fall into the line of using all kinds of stimulants as do men. Coffee is already beginning to show its bad effect upon them. We very often hear a woman growl about her coffee; her grocer cheated her on her coffee; he gave her bad coffee, adulterated coffee—a mixture of burned bread and coffee; or she forgot to buy her coffee when there was nothing but coffee on the tip of her tongue. Men growl at their wives because they do not find a cup of strong, hot coffee when they come in; some one ought to enroll the coffee drinkers that apply for divorce.

It is a hard thing to convince some people of the ill-effect of that which they like best; both men and women will deny the bad effect that coffee is having on them, and yet, as a result of coffee, they never tire in telling us about their ills, real and imaginary.

It is generally supposed that a man can quit tobacco if he has the will power to do so. Men have done this—"apparently," but there must have been more in the want of a strong appetite for the drug than there was in the will power that quit it. When a man has long habituated himself to a stimulant, the stimulant is all there is to his will power; he must have his stimulant to give him nervous energy, or will power, in anything.

If you will have an inveterate user of tobacco quit it at once, you can look for one or two results; the man will likely grow sleepy, stupid and fat, but he is most likely to go mentally erratic.

A gradual weaning off tobacco or off any stimulant is the safest and best way to quit it. It is apparently harder to quit smoking than it is to quit chewing tobacco. The smoker should learn to smoke slowly and go considerable of the time with the unlighted pipe in his mouth. He should go out intentionally without his pipe and pass all the time he can afford in the presence of those having finer sensibilities. And if he will make it his rule never to use tobacco in the presence of a woman—no matter how familiar he is with her—it will do much to wean him off the drug.

The awful increase in the use of tobacco bids fair to vitiate if not exterminate the entire human family, for, as a last remark, men suicide in smoking to a late hour at night, and especially before their morning meal.

Treatment. The following prescriptions are only tonic drinks, but they will aid a man in weaning himself off a stimulant and also promote recovery from its ill-effect. The prescriptions should be alternated with one another about every week:

℞ Sparteine Sulphas.....1/6 to 1/4 grain.
Citric Acid.....2 grains.
Saccharose.....2 drachms.
Aquæ.....4 ounces.
M. Sig.: To be taken in one dose three times a day.

℞ Dil. Phosphoric Acid.....30 drops.
Citrated Caffeine.....1/4 grain.
Saccharose.....2 drachms.
M. Sig.: To be taken in one dose three times a day.

These prescriptions are best taken between meals. And as they should be mixed at the time of taking them, it will be best to let the patient have the drugs and instruct him how to mix them. Tincture of nux vomica in medicinal doses is also a very useful remedy in the treatment of those cases.

[Written for the MEDICAL BRIEF.]

The Cause of the Tides.

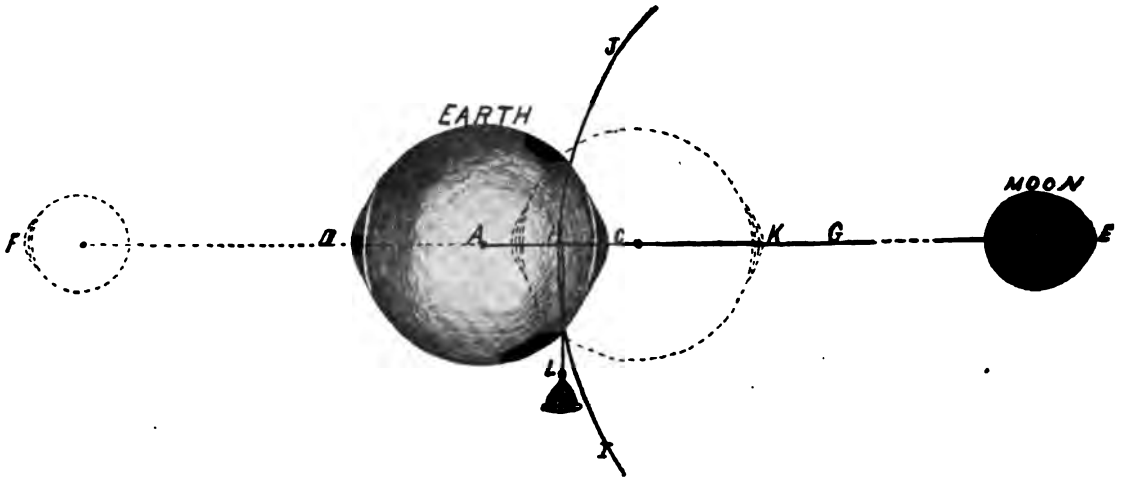
BY E. R. ELLIS, M. D.,
Detroit, Mich.

In several recent numbers of the BRIEF writers have sought to persuade us that "the tides" have a great, if not decided, influence in determining the sex of the human race. Without having any definite

knowledge or expressing an opinion thereon, I would like to convey to the readers of the BRIEF a new idea as to the cause of the tides, especially that which occurs on the opposite side of the earth from the moon. This, I believe has never been explained in a philosophical or understandable manner. And as physicians are in a high degree teachers, they might well be in a position to give light on this heretofore obscure subject.

That it is the direct attraction of the moon which raises the water and thus causes the tide directly under our satellite is very plain to all. But what should cause a tide on the opposite side of the earth from the moon? For it is well known that there are two tides every twenty-four hours. Sir Isaac Newton's theory, propounded two hundred and fifty years ago, has prevailed to the present time. Which is that "the moon pulls the earth away from the water on the opposite side." Modern astronomers, including Lockyer, of England, and Newcomb, of this country—the foremost in the world, of this generation, fall in with this theory and give it prominence in their works for our schools. Newcomb, as late as 1902, goes into quite a complicated explanation, but admits that "this perplexes those who are not expert in the subject." In order to make this understandable to any person of moderate mechanical ability, I will refer to the above diagram.

A represents the earth, and B the moon—bodies two hundred and forty thousand miles apart. The moon has a diameter of two thousand miles, and the earth eight thousand. Thus the earth, in its cubic contents and weight, is sixty-four times larger and heavier than the moon. Now, these two bodies, in their relation to each other, are as if connected by an inflexible bar, as G. The moon swings around the earth once a month, in a circle, of which the radius is two hundred and forty thousand miles. At the same time the earth swings around the moon in a smaller circle, of a radius from H to D—about seven thousand miles. All bodies, when free to act, as are heavenly bodies, act and react upon each other in exact proportion to their density or weight. With these two bodies the point of equilibrium, one being sixty-four times heavier than the other, would be about at the letter H, or nearly one thousand miles below the earth's surface.



This point of equilibrium, being at H, it will be readily seen that the moon, in its revolution, would describe a large circle, and at the same time, the earth makes a smaller circle, of which the radius would be from H to D. Supposing at new moon the earth and its satellite are in the positions represented by the dark objects. At full moon, or two weeks later, both bodies would be found at the dotted circles, as at K and F.

The result of this is that there is a powerful centrifugal motion on the opposite side of the earth from the moon, as at D.

It will be noted by reference to the diagram, that H is the point of equilibrium, or balance, between these two bodies—the earth and the moon—and is the point which follows the true circle, or orbit, of these bodies in their annual passage around the sun. The earth and moon, in their annual circle, form wave lines, the first but a slight wave, whereas the latter has a much greater wave, or irregularity, but both these wave lines are always concave to the sun. This is owing to the enormous distance which they travel, being fully fifty million miles in one month. This will be understood when it is considered that in conjunction a new moon is but two hundred and forty thousand miles from the earth's orbit and, two weeks later, is at full moon, or disjunction with the sun, making the difference in this wave line but four hundred and eighty thousand miles, a mere trifle compared with their forward motion of fifty million in one-half the same time.

Now, it is clearly evident that it is this centrifugal motion, and nothing else, which raises the tide on the opposite side of the earth from the moon.

While the moon is the main cause of tides on our earth, there are several other influences in a smaller degree. Thus the sun is one of these and when it co-operates with the moon, as it does at a new moon, we have increased tides called "spring tides." Atmospheric pressure also may have a powerful effect. Thus, if the air is very rare or light at a place near the shore, and very heavy some miles distant. This it was which is reported to have recently raised waves (tides) six to eight feet high in Lake Michigan, near Racine, Wis. Most likely this atmospheric difference had much to do with the destruction of Galveston, Texas, a few years ago, as well as the enormous tides which sweep far inland on the Atlantic coast occasionally.

Astronomers inform us that our moon has lost its rotary motion on its own axis. What could have effected this? Nothing but the enormous tides which the earth would raise on its inner surface and the powerful centrifugal force on the outer or opposite face. These high tides, as they surged against the islands and continents of the moon, served to check its rotary motion, and, in the course of ages, brought it to a standstill, or one face only to our earth, which is all we ever see of that body. It may also be stated that no water is now discoverable on the moon, its former great seas having disappeared in the cracks, crevices and extinct volcanoes arising from the cooling and shrinking of it.

The Negro Problem.

BY J. A. HOUSER, M. D.,
Indianapolis, Ind.

This ever-recurring question has lost none of its gravity since the emancipation of the colored race, though it is now studied as a social question more than a political one, as in the past. The advanced thinkers of both races recognize the race problem as one that will some day, possibly in the near future, tax the statesmanship and philosophy of the nation more seriously than it did during the days of reconstruction.

Some write of utopian dreams of loveliness when education has elevated the colored man to a higher citizenship, while others, with seemingly the same force of reason, conclude that such an intellectual advancement of the negro would greatly increase the hate of the white race, as it would increase the independence of the black man and at the same time bring him into sharper competition with his white neighbor. Booker T. Washington seems to hold this belief, and, though striving to educate his race, at the same time urges them to be content with the humbler paths in life and remain, though educated, the "hewer of wood and drawer of water," and not compete with the white race in the higher walks of life. This position of the great colored educator is bitterly assailed by a very large number of his own race, and Washington denounced by some of them as an enemy of the negro. The black opponents of Washington urge that the negro forge to the front and demand

recognition in every avenue of human industry, from the highest to the lowest positions.

There is a class of white writers, who, figuring upon the increase of the colored race, seem to prove that in time the blacks will so far outnumber the whites that they will have supreme control over the United States, first politically, then socially. This last theory finds much force in the fact that since 1860 the birth rate of the white race has declined, letting the colored race gain proportionately. Were it not for the foreign influx of white people, among whom the birth rate is higher than it is with the native born, the difference would be greater than it now is.

The theory that the negro will ever be highly advanced in education and culture is barred by the one great physiological fact that has stood at the gateway of human greatness for thousands of years, and will as long as the negro is on earth. I refer to the difference in the brain of the white and black race. The white man has, on an average, fifteen cubic inches more of brain matter in the upper and front part of the head, than is possessed by the negro. This difference is in the region of the intellectual part of the organ of mind. For this reason the dark man is not the equal of his fair-skinned neighbor in the power to reason out the problems of his race, with the mind to direct the destinies of his people. He lacks the intellectual genius that conquers nature by mechanical skill in inventions, that span the great rivers with bridges, tunnels mountains, or launches ships upon the sea. No race can lead the world, or even keep abreast of its front ranks, without the faculty to invent and construct. It must also have the ability to lead its kind in moral development. The negro lacks this. He still lacks more. He is not the builder of empires, nor does he rear the lofty domes of republics. It is true that here and there are to be found negroes of intelligence; indeed, some of a high order of intellect, but the aggregate is not sufficient for the demands of a great race. Most all, if not quite all, of the leading intellectual negroes have a considerable portion of white blood in their veins and from this source comes their increased brain power.

It is often said that the negro race has never had a chance to be a great people. This is not true. Chance is but the ability to embrace opportunities. This they have had. They have had one of the greatest and best parts of the world almost entirely for thousands of years, surely ample time to build a nation that would vie with the greatest on earth had the brain power been equal to the demands of Africa. The negro, in his native land, simply rose to the level of his brain power, just as every other race has done in every other part of the world. And he has lived there better than he could live in a more rigorous climate without the aid of a white man's superior brain. In this country the negro is held above his mental level by the influence of the mental power of the white race, but removed to himself he would soon sink to his natural position.

After all, this question, as all of life's problems, is one of cerebral convolutions. It is not a question of color, nor muscular force, it is the battle of mind.

But as to the final results of the two races on this continent, natural forces seem to point to either extermination of the negro or amalgamation of the two races. The first is too awful to contemplate, and the last too repugnant for whites to admit. Nevertheless, they lie in the path of the Great Republic.

Looking from the lurid flames that rise above the black victims and fall upon the savage faces of the hate-frenzied whites, that so shockingly and barbarously put the black offender to death, it does not require a great stretch of imagination to see the blacks retaliating, and in so doing bringing on a race war that would spread like a contagion till the whole country would be infected with the murder-mania. When the clearer skies of peace once more bend above us, it would not need a second look to decide which race had passed by with the past.

So far this catastrophy has been averted by the better judgment of the leading whites and the patience or indifference of the great body of negroes. But will this always obtain, since the worst negroes have not learned to respect the white women as sacred from black hands?

The more probable solution of the race question in this country, though disgust-

ing as it seems, will be miscegenation, and be solved by the morally and socially indifferent virile, young, white men, and the more attractive young colored women. The millions of mulattoes of all shades and degrees, put this fact beyond argument. It is exceedingly rare for one of these hybrids to be born of a white woman. Another proof of the fact that the social morality of the white woman is far above that of the white man.

This debasing condition has been more common in the South than in the North, in the past, but the difference is now in less degree. The influx of the negroes to the North has thrown them in closer relations with the whites, and removed much of the social prejudice, and the animal in this relation more easily dominates the esthetic in the white man, while his superior mind and social position, with financial or other resources, control the dark woman only too often. This regretable state of affairs is perhaps more common in Chicago than in New Orleans.

As amalgamation becomes more common it will likewise be less objectionable and inter-marriage will follow in the wake of the years of illegal association. When the black race is thus absorbed by the whites the color line will grow dim, socially first, and finally the color itself fade to the pale face of the Caucasian and give way to the redeveloped and regained Anglo-Saxon superior mind, with its redeveloped, large brain.

This change will not take place to-morrow, nor next year, but must be the organic work of tireless centuries, and be wrought out in all the world, and result in the obliteration of the oldest race on earth. Following the footsteps of other races with their teeming millions, that long since were hushed in the silence of the eternal past, the negro race will take its place in the voiceless procession, whose noiseless footsteps have wandered beyond the paths of the living.

Relics of Witchcraft.

BY C. E. BOYNTON, B. S., M. D.

Los Banos, Cal.

In many little towns all over the United States relics of witchcraft ideas yet remain. The witches of Salem and of the middle ages were frequently, yes, almost always, women more intelligent and sometimes prouder-spirited than their neighbors. Women, in some cases distinctly superior in many respects, objects of jealousy and coveted by men they would have nothing to do with. It was as late as 1896 that this conversation took place in whispers at church about a lady of perhaps twenty-nine years of age, one handsome and gifted. The minister being away, she volunteered to lead the meeting. Two uncomely visaged women were holding the whispered conversation about Mrs. Wells, the lady in question, who had offended form somewhat by marrying and then refusing to live with her husband.

"Isn't Mrs. Wells a wonderful woman?" said Mrs. Sopy. "Yes," said Mrs. Sour, "but she is dangerous." "She magnetises me," said Mrs. Sopy, "when I am in her presence I am charmed; I can not take my eyes off her." "That is why she is so dangerous," said Mrs. Sour. "I tell you, Mrs. Sopy, us women should watch our husbands when she is round. Why, the men are all crazy after her, and how folks do talk. She is as slick as a snake; I feel as if a snake were charming me when she catches my eye."

"She knows a great deal," said Mrs. Sopy, "more than any woman in town. Hear her talk now. What a voice; how easy and graceful she is! But, Mrs. Sour, there must be the power of the Evil One in her or she could not be as smart as she is. Oh, dear, I like her, but I am afraid of her. She is dangerous."

This conversation really occurred. Mrs. Sopy repeated it to Mrs. Wells. Mrs. Wells jokingly said: "Yes, you women *better* look out for your husbands around me." As a fact at that time Mrs. Wells was and had all her life been a sexual, and of all women she was the farthest from feeling any desire for the masculine element of any woman I had ever known.

It was years ago when I settled in the bigoted environments where Mrs. Wells made her home.

I learned that she was a very gifted and scholarly woman, and so we became friends. Then the tongues began to wag. I let people talk to me that I might make the case a study. Mrs. Wells, in nearly everybody's opinion, was about all that used to pass for a witch. "With a glance she could bring discord into the home of any man. She could bewitch him and craze him. She was *bad*—of course she was bad. Everybody said she was bad. She should be driven out of town." "Look out, Doctor, you will suffer if you befriend her."

To make a long story short, a masked mob met me one night and their firearms, held in trembling hands, were cocked and aimed at me. "In three days *you*, Dr. Boynton, and that woman must get out of this town. She has made trouble enough, and you defend her. We won't stand it," said the mob. After that all whom I met held aloof from me for fear of the mob that had proclaimed that all who befriended us should be served as we were served. The mob also declared that they would make a special raid on this woman if *she* did not leave.

For a time we departed from that town. We returned to it, however. We were feared, but not molested.

I could recount other incidents. A gifted woman of musical ability, located with her husband in the town of Wheatsville.

The lady lectured and sang on public occasions. She belonged to the church choir. Mr. Park, who belonged to this choir, sent in his resignation. The lady of whom we speak and two other members of the choir were appointed to try to influence him to withdraw his resignation. The others of the committee fell out, and this "new woman" met Mr. Park alone in the church. He abused her; told her she had hypnotised the town, but she could not fool him. She talked quietly to Mr. Park for about ten minutes. He asked her pardon, withdrew his resignation and became her friend. Had the lady been single and had circumstances not favored her when she met Mr. Park all might have gone the other way and the respect of those people been turned to dread. The peculiar element in witchcraft is feminine superiority, attributed to the "Evil One."

Such superstition still remains in many a small town, and the incidents I have given are authentic, and they could be multiplied, while only a limited field has come under my observation. One would be amazed to interview the old ladies of any small town and learn how strongly they believe the "Evil One" is acting upon those whom they see and can not understand. Subjects like these are for medical men to consider. The doctor is very narrow who thinks he has no business reflecting upon things outside of fevers and prescriptions.

A Case In Obstetrics.

BY N. M. MARSHALL, M. D.,
Butler, Okla.

While scanning over the MEDICAL BRIEF for January, 1905, I ran across an article of a peculiar case in obstetrics. Now, brother, I have an experience of about twelve years' practice, and, of course, have run on to many knots. I think your treatment was not only good, but very good, until you began the bichloride solution as a douche. Then and there was when the mischief was done; that was what caused the swelling—and that was what caused death, I am sure.

Having the nurse to keep up the douche daily, and you do not say what strength the solution was. I was treating a case, once, of multiple neuritis, and the boy's leg was so badly inflamed that I thought I would try and allay inflammation with a one two-thousandth solution of bichloride, and when I next saw the boy his leg was swelled taught and the skin was shiny and slick as glass. I set about to counteract the poison, and I laid the bichloride solution aside, and it has not been used from that day to this. It stands to reason that it would poison an internal surface much quicker than it would an external one. All this has been said good-naturedly and with the kindest feeling towards the brother. We all have our ups and downs and our mistakes in life; let us profit thereby.

[Written for the MEDICAL BRIEF.]

The Evolution of An Idea—My Present Methods of Treating Uterine Disorders and Spinal Irritations.

BY VIRGIL P. ENGLISH, M. D.,
Cleveland, Ohio.

Before my graduation I had decided to make a special study of nervous diseases and the diseases of women. Immediately after graduation I took a post-graduate course, giving my principal attention to non-surgical uterine affections.

When I began practice, I met with highly gratifying success in many cases, but soon encountered some serious difficulties. These difficulties proved to be so great that I could not surmount them at that time.

One of the first cases that defeated me was that of Mrs. P., a divorced widow of, perhaps, twenty-five. When she first consulted me, an examination, or rather, an attempted examination, disclosed the fact that the vagina was so badly inflamed, sensitive and tender, that it was impossible to make a satisfactory examination without an anesthetic. By the use of a galvanic battery three times a week, the negative electrode in the vagina, and sponges of wool saturated with medicated glycerin, the inflammation of the vagina was soon reduced so that a speculum could be inserted and treatment given directly to the womb. This organ was also greatly inflamed and it was displaced.

Everything progressed satisfactorily until the inflammation was entirely reduced. I then encountered a difficulty that I could not surmount. The prolapsus persisted in spite of all that I could do. It seemed to me that the womb was almost abnormally small. It was certainly small enough and light enough in weight. It was not an abnormal heaviness of the organ that caused its displacement. The prolapsus was evidently due to a weakened, lifeless and relaxed condition of the tissues. This I was unable to overcome and the prolapsus was not cured.

Another case that defeated me was the case of Mrs. B., the wife of a working man. She may have been thirty. After she had come to the office a few times for treatment, I was called to her home, the messenger saying that she was feeling very bad. I found her in bed and suffering severely. She had been washing. It was a clear case of spinal irritation and a bad one—severe aches and distress in occiput and base of brain—a sensation that she described as a "pulling and stretching of cords in the neck"—neuralgiac, cramp-like pains throughout the trunk—a peculiar, indescribable distress; pains and distress in the limbs and feet, besides other distressing symptoms peculiar to spinal irritation.

Well, I did not know what to do. I thought that the distress and pains were reflex symptoms from the uterine disorder, but I did not know how to relieve them except by deadening the sensations by the use of opium. So I advised the patient to remain in bed and keep quiet, assuring her that she would soon feel easier.

There was in this patient a general weakened and relaxed condition of all the tissues. It was a very bad case. The abdominal muscles were relaxed and distended. The abdomen was protruding and pendulous, although the patient was not a portly woman.

I encountered several other cases of spinal irritation, the symptoms varying in the different patients. In one case there were occasional convulsions quite similar to epilepsy. This patient never ventured out alone. Her husband came with her to my office.

I was having fine success with most of my cases, so far as the uterine disorders were concerned. But in the reflex symptoms (?) I was more or less of a failure. The patients usually reported improvement but no cure.

Soon after this time, a pamphlet, by Dr. Kellogg, of Battle Creek, Mich., came into my possession. In this pamphlet it is insisted that in most cases of uterine displacement, there is a general weakness and relaxed condition of other tissues besides those of the uterine system. The treatment that he recommends is physical culture—exercises; and if I remember correctly, baths. A number of cases are cited in which the results are highly gratifying.

Dr. Dio Lewis obtained similar results in the same class of cases by exercises in connection with travel, horseback riding and other open air treatment.

It seemed to me that these suggestions threw a little light upon the reasons for a part of my failures.

Not long after I read Dr. Kellogg's pamphlet, a book by another writer came into my possession. The book is long since out of print, the author deceased, and the copy of the book that I had is out of my possession.

In this book a mechanical brace is recommended for the class of cases that Dr. Kellogg and Dr. Lewis were curing by hygienic measures. The same kind of cases that had defeated me. One of the instruments recommended in this book is an abdominal supporter made of spring steel. To my personal knowledge, these instruments gave fine results as an assistant in some cases. Here, then, was another method of treating a part of the cases that had caused me so much trouble and perplexity. But this latter method is a method of relief rather than a cure. It supports the abdomen, rests and relieves the parts very much as lying in bed would rest and relieve them.

It is explained in the book last mentioned that in the cases of distended and pendulous abdomen, the relaxed condition of the abdominal muscles, permits the bowels to protrude forward and downward, thus removing the natural support from under the liver, stomach, heart, etc. That all the organs in the trunk are thus permitted to descend, and that this displacement of these organs permits them to drag and pull upon their points of attachment, causing pain and distress throughout the trunk.

These ideas seem to accord with those of Dr. Kellogg and Dr. Dio Lewis, and to some extent, at least, all three of these gentlemen had obtained favorable results. One of the three, by supporting the abdomen and thus relieving the displacement and dragging of the organs within the trunk; the other two, by strengthening the abdominal muscles, through exercises and other hygienic measures, and thus enabling these muscles to assume their normal position and properly perform their natural functions. Each one of the three methods of treatment corrects the displacement of the organs above the true pelvis, thus removing one of the causes of uterine displacements. And the two hygienic methods strengthen and invigorate the uterine organs and all parts of the body, as well as the abdominal muscles, thus exerting a general beneficial effect.

In the book last mentioned it is also explained that many cases of uterine displacement are caused by the weight and pressure from displaced organs above the pelvis. That when these superior organs become weakened and relaxed, the bowels often descend into the pelvis and exert an abnormal pressure upon the womb and its appendages, thus causing a displacement and irritation of the uterine organs.

I have tried each of these methods of treatment, and with more or less success. The braces before mentioned, with proper modifications, are also used for the cure of hernia. Previous to my acquaintance with this system, I had supposed that hernia is an actual rupture, tear or laceration. But the book already mentioned explains that most cases of hernia result from the distention or stretching of weakened and relaxed muscular fibres surrounding a natural opening in the muscular walls of the abdomen. That relief from the excessive pressure upon this opening will enable the weakened parts to gradually regain their normal strength and tonicity, provided the hernia is properly retained at the same time. That when the fibers surrounding the internal ring have become strengthened and invigorated, and have assumed their normal positions, a case of oblique inguinal hernia is cured. Other varieties are cured upon the same principle of strengthening the walls of the hernial passageway and decreasing its diameter.

These instruments being abdominal supporters, they relieve the excessive pressure of the viscera into the hernial canal. There is then but slight pressure into the hernial canal, and the hernia is retained by a very slight pressure of the hernial pad. This, it is claimed, affords the relief that enables the parts to cure themselves. I used these instruments

with highly gratifying results, so far as a truss is concerned, but did not secure a very large per cent of actual cures.

During the time that I was taking the greatest interest in these instruments, I met a practitioner, past middle age, and of excellent standing, who informed me that he had cured hernia with medicine administered internally. I had considerable confidence in him and his statements, consequently they made so decided an impression upon me that I distinctly recollect them.

The instruments before mentioned, with certain attachments, are used for the relief of spinal irritation. The inventor's idea of spinal irritation is, that the disease results from pressure upon the roots of the spinal nerves. That the intervertebral cartilages become weakened and compressed, permitting the vertebræ to settle down so close together that they compress the roots of the spinal nerves that lie between them, thus causing distress and impaired function in the area supplied by the branchlets of the compressed nerves.

These braces relieve spinal irritation by supporting a part of the weight of the head, shoulders, arms, trunk and its contents, thus decreasing the weight supported by the spine, lessening the compression of the intervertebral cartilages and the consequent pressure upon the nerve roots. These instruments rest upon the inside of the crest of the ilia, and beneath the axilla, receiving, like a pair of crutches, enough of the weight of the upper portions of the body, to relieve the excess of weight upon the weakened intervertebral cartilages and nerve roots between the vertebræ. (See illustration.)

So far as relief is concerned, these instruments are a grand success. But there are several unpleasant and unsatisfactory features attending their use. The instruments are very expensive, difficult to adjust and unpleasant to wear. Only those in easy circumstances can procure them without inconvenience. But the promptness and thoroughness of their relief is often astonishing.

As an example, I will mention the case of Miss H., a young school teacher, of Columbus. She had been in one of our Cleveland hospitals for some months, under the care of one of our most prominent surgeons. The coccyx has been removed, the womb curetted and she had received other treatment with but little benefit. The attending surgeon eventually sent for me to adjust one of these instruments.

The patient was a well nourished girl, as being nourished is usually considered, but she had a bad case of spinal irritation. She was in bed when I called, but arose and stood for perhaps ten minutes, while I took the measurements for the

A perpendicular post extends from the arch above the ilium to the piece beneath the axilla.

instrument. The excitement of a new doctor and a new method of treatment, in connection with the pressure upon the spinal nerves resulting from her erect position for the short time required to take the measurements, caused a great increase in her suffering. The aching and distress in occiput and base of brain became intense, and there was great exacerbation of other symptoms. She was in bed until the time when the instrument was adjusted. Within two or three days after it was adjusted, when I called

to see her, the patient was walking around the hall in comfort and talking with the nurses. In two or three days after that she took a street-car ride.

This method of treatment, however, gives only relief. It is not curative. The cure must be effected by other means.

I soon began trying electricity in these cases. The Faradic current was applied to the spine, and for a few inches upon each side of the spine, causing a contraction of the muscles as the electrode passed over them. This was decidedly helpful but not entirely satisfactory, so I continued to cast about for some method of treatment that would give satisfactory results in these cases. At the same time I was endeavoring to devise a more satisfactory method of treatment for certain classes of uterine affections.

I spent several months studying the matter, in addition to the years previously spent, and eventually reached a few conclusions. It seemed clear that the real wrong which renders spinal irritation possible, is the weakness, lack of tonicity and responsiveness in the tissues. More especially, in the intervertebral cartilages. But a similar lack of tone and resistance usually exists at the same time in the muscular fibers and other surrounding tissues of the spine, and also in the muscles of other parts, especially those of the abdomen. This is the condition in those cases that are not the result of an injury. If the disease is due to an injury of the spine in a person previously strong, the weakness that permits the irritation may be confined to the parts injured.

It also seemed clear that a very large class of the cases of uterine disorders results from this same general weakness of the tissues. That, when the spinal irritation patient is a woman, and the spinal irritation is not due to an injury, uterine affections almost invariably accompany the spinal irritation. That the symptoms which are often considered as reflex, from the uterine disorders, are in reality symptoms that are caused by spinal irritation or the dragging and pulling of displaced organs upon their points of attachment. That cases of uterine displacement that are not due to the congestion and heaviness of the womb, are usually accompanied by spinal irritation. That a general weakness of the tissues is what permits both diseases. Many of the cases in which the womb is congested and enlarged are also complicated with spinal irritation.

It seemed clear, then, that weakness, relaxation, lack of tonicity and responsiveness in the tissues is the real wrong in a large per cent of cases, that renders both diseases possible. That this is the condition in many of those cases of chronic uterine affections in which the patient is better and worse, but is never cured. She still suffers year after year. Local treatment relieves the local inflammation, but it appears again in a few months or years, and the patient has never been entirely cured of the reflex (?) symptoms.

It looked to me as though it ought to be possible to satisfactorily treat and cure these cases. And that a treatment which would cure spinal irritation would also cure a part of the wrongs in a large per cent of the cases of uterine affections. That a satisfactory treatment for uterine disorders would also cure spinal irritation. That there is such a relation between spinal irritation and certain classes of uterine affections, that a satisfactory treatment for the one, would also be a satisfactory treatment for the other. Or, at least, a valuable assistant in the treatment of the other.

I proceeded upon this basis, talked with my friends among the physicians, and studied the materia medica. I had not forgotten what had been said to me relative to hernia being cured by medicine taken internally. It seemed clear that, if it is possible to cure hernia in this way, the cure must be effected by imparting vigor, resistance and tonicity to the tissues surrounding the approach to the hernial canal. That if it is possible to cure this weakness in this way, the remedies which will do the work ought to be of assistance in the work that I desired to accomplish.

Eventually the problem was solved to the extent that I considered it time to begin testing my theories. The results have been highly gratifying. In studying the materia medica, I found a large num-

ber of remedies that seemed to have some property or some action that would be of assistance in the work I was endeavoring to accomplish. I have probably used thirty or more. But those that I consider of most assistance are fewer in number. Some of the more important were given in my article on spinal irritation which appeared in the October number of the MEDICAL BRIEF. Of course, the complications that are encountered must be met with the indicated remedies.

In developing the system of treatment for spinal irritation and uterine affections as partly explained in my article in the October issue of MEDICAL BRIEF, an effort was made to combine, as far as seemed practical, all of the individual methods and assistants that had proved successful in the particular classes of cases that I was making an especial effort to reach. Cases in which the usual methods of medical treatment, as I understood them, had not been a satisfactory success at my hands.

It seemed that some of the particular features of these cases in which medicines, as I was then using them, had not proved a success, were being satisfactorily cured by other methods. It seemed that some of the particular features of these cases in which medicines were doing the least, were being reached by sanitarium treatment at the hands of Dr. Kellogg. Dr. Lewis had been accomplishing about the same kind of results by in-door and out-door exercises—travel, walking, horseback riding, boating, etc.

An acquaintance of mine had cured hernia by imparting tonicity to the weakened tissues through the use of medicines. Hernia had also been cured by an easily fitting truss pad in connection with an abdominal supporter. Certain features of uterine affections had been cured by an abdominal supporter, alone, or in connection with medicines. In many cases, this support of the abdomen seemed to be the one thing necessary, in addition to the usual methods, to effect a complete cure. Spinal irritation was relieved by the use of supports or braces. It was also benefited by electricity. Some temporary relief in spinal irritation was also secured in hospitals, by stretching the spine by means of straps under the armpits and under the occiput and chin, connected with a line running over a pulley in the ceiling, the line being pulled by an attendant until the desired degree of spinal stretching had been secured. Magnetic healers and masseurs had also done some good work in spinal irritation and in the cases of uterine disorders in which weakness and relaxation of the tissues were one of the principal wrongs to be overcome.

It seemed that a satisfactory method of office treatment, and even a treatment to be used in the patient's home, could be constructed by combining the best and most practical features that could be selected from all these various methods of treatment. This is what I have done. I have drawn from these various sources the features that seemed to be most practical for my purposes, and have combined these various features into a system of treatment for these disorders. Of course, the usual methods of medical treatment are included. Osteopathy and chiropractic were not considered. I did not even know that there were such methods of treatment for these disorders. But from what I now know of osteopathy, I understand that the osteopaths are using some of the same methods.

My present methods of treatment, then, are a combination of the best features selected from the different methods that have proved most successful when used singly. Other practitioners who will take the trouble to give a like systematic and thorough treatment, will cure a great many cases that their neighboring physicians are not curing.

The various hygienic measures that are valuable assistants in these cases, if they are such that the physician can readily employ, are combined with the most effective of the tissue builders, and whatever additional remedies that may be required to meet the peculiar features of each individual case. I do not use the braces, but often recommend a towel or other home-made abdominal supporter. If money is no object, a higher priced supporter may be used. But most patients are soon improved so much by the treatment that no supporter is needed.

Local treatment is used in the usual way to relieve local inflammation. The

indicated remedies, internally for the systemic wrongs, suppositories or capsules for local treatment, are given to patients who live in the country, or who, for any reason, can not visit the office, or who can visit the office only at remote intervals.

In the treatment of these cases, certain facts are kept constantly in view. One is the fact that in cases of spinal irritation that are not due to an injury to the spine, and in cases of prolapsus, relaxed and pendulous abdominal muscles, etc., the real causes of the disorders are two in number. One is a lack of the tissue elements that are necessary to properly build the intervertebral cartilages. The other cause is the failure of the parts to properly appropriate the requisite tissue elements when they are present in the blood.

The rectification of both of these wrongs is provided for. The elements necessary to build the intervertebral cartilages and other tissues are supplied with the remedies. Their proper appropriation is provided for by the rubbing necessary to apply a part of the remedies that are incorporated in a cerate, by exercises especially adapted to these cases, by general physical culture, etc.

Some Abnormalities of the Bladder and Prostatic Urethra Due to Hypertrophied Prostate.

BY M. R. BARKER, M. S., M. D.,
Chicago, Ill.

According to the most carefully prepared statistics, about thirty per cent, or nearly one man in three, who has reached the age of sixty years, has hypertrophy of the prostate gland. It is, however, true that only sixteen per cent, or one man in six, who has reached the age of sixty, has urinary trouble, due to this condition.

There is not a nook so isolated, nor a hamlet so small, that it may not contain its prostatic. This disease chooses its victims from every class of humanity. The poor and the rich, the bond and the free, the dissipated wretch, the abandoned outcast, the most virtuous of men and the holiest of saints, suffer alike. It is the most cosmopolitan of maladies. It is at home wherever the man of advanced years resides, his race or color being matters of indifference.

The histology and gross anatomy of the prostate body in health and disease is known. Its position and functions among the genital organs is understood. The tissues that enter into its structure and their relations to each other in health and disease have been determined. It seems that there is nothing concerning the physical nature of this gland in health and disease that has not been discovered. But one problem connected with this gland still remains unsolved, the solution of which has been more diligently sought than all others. Why does this gland, at a certain universal period of life, take on this condition of hypertrophy? Many theories have been advanced, some of them doubtless within the neighborhood of truth, but lacking that foundation of fact necessary to elevate them from the category of theory. Hence, today we are about as much in the dark as to the etiology of this malady as we have ever been. With propriety we may ask: Would the knowledge of the etiology of this condition help us? It would be a great satisfaction to know, but if the knowledge did not afford us a way of discovering some system of prophylactic therapeutics, we would not be much benefited by it.

Perhaps there is no other condition that causes so much suffering among the old, and shrouds in gloom the declining years of men as does this. It comes to men after they have borne the burdens pertaining to life through youth and middle age. It attacks them when courage and physical force are on the wane; at that time in life when, in accord with natural laws, man should be free from vexatious cares and physical disabilities. It changes that period of life which should be the most peaceful into years of apprehension, pain and, in many cases, actual torture.

It is our purpose in this paper to illustrate and describe some of the deformities and pathologic conditions of the bladder and prostatic urethra, caused by hypertrophied prostate.

In the type of large, soft prostates, of which we have spoken in a previous paper of this series, the enlargement is quite uniform. That is, the whole gland enlarges uniformly and, as described in a previous paper, becomes very large and heavy, and the abnormalities and pathologic conditions caused by it are not confined to the prostatic urethra alone, but the musculature of the bladder wall and the nerves that supply the same are disarranged and destroyed. In this type we believe the urinary troubles caused by it are due more to these pathologic conditions than to mechanical obstruction, and that in this class of cases we may expect, sometimes, post-operative enuresis, not due to the handling of the parts during the operation, but due to the damage done by the gland before it is removed. We speak of this type as the large, soft prostate. It is only relatively soft. To the touch, while in the body, it seems as hard as a piece of wood, but when removed and stripped of its capsule it is relatively soft. The manner in which especially this type of enlarged prostate destroys the normal action of the bladder has been fully described in a previous paper, and need not be mentioned here.

In the other most common type of enlarged prostate, which is known as the fibromuscular, or myomatous type, because of the hypertrophy of the muscular and fibrous tissues, it is most common for this form of enlargement to be made up of multiple myomas, each surrounded by a capsule. For this reason this type is liable to be very nodular and hard. These nodules may project from either lobe of the gland, or from all the lobes, at any point and in any direction. Sometimes the projections are very marked. When the projections are towards the urethra, or, in other words, push themselves into the urethra, they bend and distort it in such a way as to close its lumen and obstruct the flow of urine. Figure 1 illustrates one of our cases; two projections from one lateral lobe and one from the other, in such relation to each other as to close the prostatic urethra. In this case there was no middle lobe enlargement, but the urethra was wedged in between the projecting nodules of the lateral lobes and bent almost at a right angle. It is also elongated to twice its normal length. It can be readily understood how this condition completely closed the urethra, and how impossible it was to pass any instrument into the bladder through the prostatic urethra. We believe, in most cases of this type of enlarged prostate, the urinary troubles are due to mechanical causes, and the removal of the prostate cures the case at once.

In the large, soft prostate we often have middle lobe enlargement. The hypertrophy of the middle lobe will be of the fibromuscular type, as the middle lobe does not contain prostatic cells. In such cases the urinary troubles may be due, in part, to mechanical obstruction of the prostatic urethra.

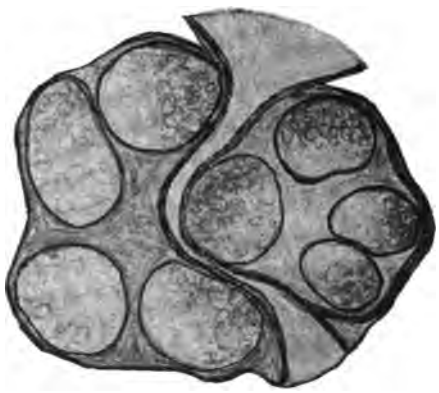

Fig. 1. Showing multiple myoma of both lateral lobes, with bending and lengthening of the prostatic urethra. Lateral section.

The middle lobe, normally, is a muscular commissure connecting the lateral lobe's posterior to the urethra. When this enlarges and causes trouble, the urethra is encroached upon from behind and is pushed forward, thus bending the urethra from behind forward.

The reason for the fact that only about one-half of the number who have enlarged prostates are troubled with urinary difficulties, is probably this: In the fibromuscular type, the nodules frequently do not project from the lobes towards the urethra, but away from it; thus the urethra is not encroached upon by these nodules, and so not distorted nor occluded.

In the other type of fibromuscular prostates, in which the whole gland becomes

universally myomatous, instead of multiple myomas, the prostate does not present the nodular appearance, but enlarges in all directions quite uniformly. This type

Fig. 2. Shows uniform enlargement of both lateral lobes projecting into urethra from each side, and narrowing its caliber laterally. Also multiple myoma of middle lobe projecting into urethra posteriorly, bending the urethra forward and elevating the urethral outlet. Front view.

often mechanically closes the urethra by the enlarging lobes approaching each other and compressing the urethra between them. In one of our cases we had uniform myomatous enlargement of both lateral lobes, projecting towards the urethra, narrowing its lumen laterally and multiple myoma of the middle lobe, projecting forward into the urethra, bending the urethra forward and greatly elevating the urethral outlet. Figure 2 illustrates this case very well. There may be any combination of these projections from the multiple myomatous lobes. One lateral lobe may be uniformly enlarged, while the other lateral and middle lobes may be nodular. As a rule, the nodular lobes distort the urethra most, yet we may have uniform enlargement of one lobe and no enlargement of the others and the urethra pushed to one side. In all hypertrophied prostates the prostatic urethra is lengthened.

As before stated, the middle lobe is the muscular commissure connecting the lateral lobes posterior to the urethra. In nearly all cases the fibres of the sphincter vesicæ that surround the mouth of the prostatic urethra blend with this posterior commissure, and when this commissure or midde lobe hypertrophies, these fibres of the sphincter are pushed forward into the lumen of the urethra, just beneath the mucous membrane, and forms the so-called muscular bar that crosses the urethra just before the bladder is entered. This bar, at times, causes great trouble in passing instruments into the bladder, the catheter or sound passing over it with a distinct jump. Through this bar false passages are often made by too zealous attempts to pass instruments. Figure 3 illustrates a case of ours in which a metal catheter had been passed through the middle lobe. After removing the gland the middle lobe was found punctured as above.

In all forms of hypertrophied prostates, the urethral outlet is elevated by the enlarging prostate. This is much more marked when the middle lobe is involved. The larger the prostate the more the elevation. Figure 4 illustrates this condition. The intra-vesical pressure, due to the obstruction of the urinary flow, causes the bladder wall to distend at the point of least resistance, or at the point where the pressure is most constant. This is always more marked when the bladder wall has been weakened by the disarrangement of its musculature at the neck of the bladder and its nerve supply damaged. The place of distention is just behind, or posterior to the enlarged prostate, where

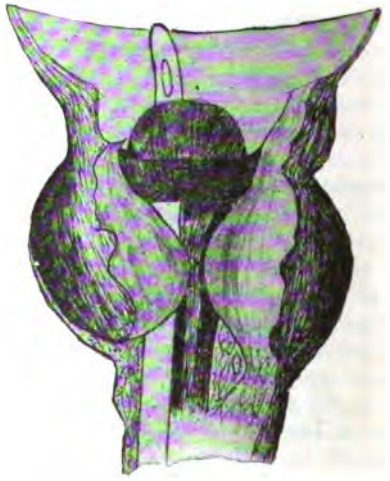

Fig. 3. Showing muscular bar pushed forward in middle lobe hypertrophy and false passage made by nearly straight metal catheter. Front view.

a sack is formed. This sack fills with urine and cannot be expelled, hence is known as residual urine. This residual urine varies in quantity from one to six

ounces, and predisposes to vesical catarrh, from which disease these patients always suffer. In a previous paper we have described the manner in which the fibres

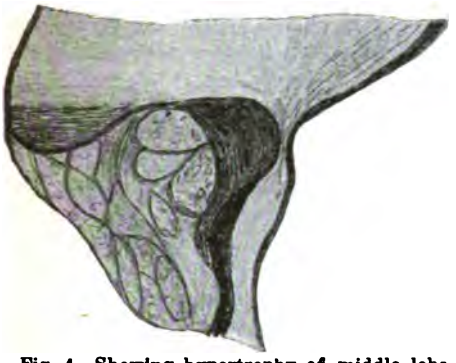

Fig. 4. Showing hypertrophy of middle lobe pushing forward into urethra and elevating the urethral outlet. Also showing sack behind the prostate full of residual urine. Sagital section.

of the detrusor urinæ muscle at their origin and insertion are widely separated by the enlarged prostate. In some cases this gives rise to a sacculation of large portions of the vesical mucous membrane. The mucous membrane loses its tone, as it were, by reason of being over-distended with urine for long periods of time, and the fibres of the muscular tissues sur-

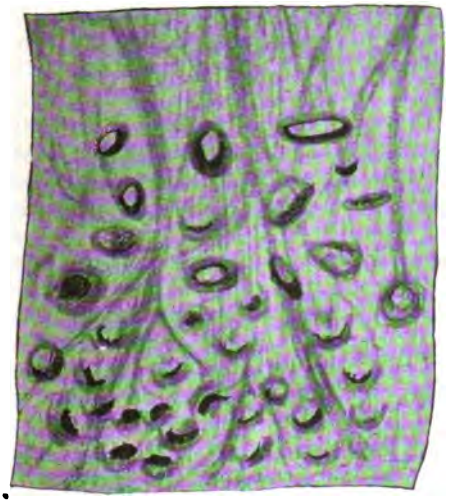

Fig. 5. Showing saculations of mucous membrane of bladder.

rounding it being separated, the mucous membrane pushes through these meshes, so to speak, and forms numerous small sacks. The urine collects in these sacks, predisposing to vesical catarrh. Figure 5 illustrates these sacculations.

Of the thirty cases in this series which we have operated upon, there were twenty-two of the large, soft type, or seventy-three per cent of the number treated and eight of the fibromuscular and fibrous types. This would seemingly show that the large, soft type was much the more numerous. In fact, however, it does not demonstrate this, for the reason that the proportion of the large, soft type, that causes trouble, is far greater than in the fibromuscular type. It is probably true that ninety-five per cent of the large, soft type cause trouble because of their enormous size, while it is also probable that less than fifty per cent of the fibromuscular type cause any trouble; hence, the surgeon does not meet half the cases that exist in one type of this trouble, while he practically meets all of the other type.

[Written for the MEDICAL BRIEF.]

The Secret of Health and Its Possession.

BY AXEL EMIL GIBSON, M. D.,
Los Angeles, Cal.

(Continued from page 833.)

Food Not Energy in Itself; Only a Conductor of Energy.—It is, however, a mistake to consider foodstuffs as generators of inherent, intrinsic force. Food is merely a carrier of force, and the facts ascertained in connection with what is termed "nitrogen equilibrium," by which is meant a condition of an animal in which, within a definite period the amount of nitrogenous food taken into the system covers exactly the loss of nitrogen sustained by the organism during the same time, demonstrates that the foodstuffs in passing through the circuit of metabolism in the body have lost nothing of their elementary substance. On the other hand Pfluger, Voit and Pittenkofer have succeeded in maintaining the general metabolic equilibrium of a dog while feeding him on an exclusive proteid diet. When we further realize that the food-value available in meat is made up by proteids, while elements not less necessary for animal life, such as fats, sugar, starch, etc.,

must be extracted from other substances, it follows that in order to maintain a prolonged general metabolic equilibrium on an incomplete diet the organism must draw means of sustenance from a source not suspected. Furthermore, it has been demonstrated that the losses sustained by the organic tissues during a process of starvation are of an entirely mechanical, not chemical character, involving quantity of bulk, rather than quality of substance. In the last stages of starvation it has been found that the blood still retains its original percentage of composition.

A consideration of these facts leads to the conclusion that there must somewhere be found a reservoir of vital energy, in which is held suspended every potentiality of form and expression. And as it furthermore has been shown that this vital energy, in its action on growth and existence, is unmodified by diet and general hygiene, it must follow that its seat and center is in the very air itself.

If this be so, the various foodstuffs by which we are sustained are mere agents or carriers of vital energy from the air to the body, temporarily changing and modifying this energy into states of vibrations available to the developing organisms. But these agencies depend for their action on the presence of microbes, by whose industry the primary changes are initiated, leading up to the final transformation of elementary potency into organized substance. For at the gateway of organic growth stands the microbe, elaborating and condensing the subtle, elemental energies of air into organic constituents. Some of these microbes and their specific action have been most unmistakably demonstrated, as, for instance, *micrococcus nitrificans*, whose service is enlisted in the elaboration of free nitrogen of the air into organic compounds in the structure of the vegetable. And these elaborations are not limited to the element of nitrogen, but extended all along the border lines dividing the mineral from the organic zones of Nature.

Is There Any Possibility of Living on Pure Air?—On the strength of this fact, the question may be raised whether in the first place the mineral kingdom is an indispensable intermediary between the vegetable and its food, and, in the second place, whether the vegetable in its turn constitutes a stage of organic chemistry through which the life-holding elements of the air have to pass in order to be utilizable in the construction and support of the human-animal organism? Through a series of painstaking experiments, with the soil in the Valley of the Rhine, Dr. Wohltmann, Professor of the Agricultural Institute in Bonn-Poppelsdorff, Germany, has ascertained that wherever the soil is rich in nitrogenous fertilizers, preferably ammonium nitrate, the leguminous plants are found to grow and absorb nitrogen without the presence of bacteria. From this fact the famous scientist draws the conclusion that "the association of the plants with the bacteria is in the nature of expediency—an evolutionary departure, indicating life processes, which are aiming at permanency."

Future Independence of All Forms of Cookery.—Hence, it is only under stress of compelling circumstances that the vegetable, assisted by bacteria, obtains nitrogen directly from the air. Surrounded by favorable conditions, Nature abides with ancient methods, but is ever level to any emergency arising from the presence of true needs or necessities of its creatures. But necessity again is merely the name of an evolutionary departure, which, under the scrutiny and appreciation of self-consciousness, rises into a force and self-chosen act.

Hence, by the human being voluntarily placing his body under conditions similar to those present in the poorly nourished vegetable, *i. e.*, by gradually reducing his ordinary diet to the border of nutritious insufficiency, the individual may find at his disposal the same powers of direct atmospherical absorption through bacteria as is at present available to the vegetable. To gradually and carefully abstain from food, followed by a living realization of the power of the organism to absorb nourishment directly from the air, means to unlock or uncover powers which shall in the course of time make men independent of nourishment in its present vegetable or animal form. The atmosphere will open its storehouse of life and powers to the man who, in place of filling his stomach with gross, nerve-and-mind-exhaustive substance, aims at maintaining

the balance of organic supply and demand by deep, rhythmic respirations, and small quantities of water. When in a some more or less distant future, the individual reaches a state where such diet is possible for the sustenance of life, his vegetative expenditure will not exceed the price he at present pays for his not less necessary life and health-sustaining indulgence in sleep.

Like all forces, life moves along the lines of least resistance. Hence, by offering inducement for the action of this life-force in one or other direction, we gradually succeed in conducting its energies along the desired channels. Thus undue indulgence at the dining table, if continued, means a gradual closing of every avenue of life and vital power, save the grossest, most laborious and most time-and-energy-wasting of them all—eating. Eating is an expediency adapted to the needs of physical evolution, sustained and increased through the grossness of our desires and indulgencies, and resulting in the subsequent low tone of cellular vibrations which attune the metabolism of the body to the action of nourishing life.

The Value of Water in the Assimilation of Food.—An advanced step in the list of ideal forms of nourishment is found in the water which through its absorption by the animal organism gives rise to none of the laborious, wasteful processes involved in the absorption of solids. Like air, water contains in its substance every element required to sustain vegetative existence, though its inability, so far, to supply our bodies with adequate nourishment is due to the failure of the body-cells to respond to the subtle vibrations through which life finds an expression in that element. Yet there are cases on record where existence has been sustained for weeks and months, in absence of any other nourishment than water. The invigorating action which water exerts on the growth of plants is found in its quality of vehicle for the all-sustaining principle of life. Hence, the nearer a nourishment approaches the forms of liquid, the less expenditure is connected with its absorption. Thus starch is largely indigestible because of its impenetrability by water, while fruits with their large percentage of water are the easiest digestible of all foodstuffs. The same principle holds good with regard to oils and fats which are subject to absorption only when reduced to a state of emulsion.

A diet on fruit and nuts, in which oil is held as an emulsion would, therefore, be in the order of evolution as preparing the way for a pure water diet, with the subsequent departure of diet into the metrix of all life-sustaining energy, the zone of pure air, with the metabolism reduced to the transforming action of the microbes.

For it must be granted that there can be nothing in the soil not transmitted to it by water, air and light, while furthermore there can be nothing in the water which is not potentially present in the air and light. Corporeal substances are mere carriers or transmitters of life.

Hence, the whole process of growth depends on the harmonious co-operation between an impelling life force and a responsive physical basis. Life is the performing artist, and always perfect, always true, while the bodily instrument—"the harp with its thousand strings"—may or may not be true.

Hence, like an artist who, notwithstanding his genius, depends for his success on the accuracy of his instrument, so the genius of life for its manifestation in perfect health and virility depends on a completely equipped and full-toned instrument. Sweeping over the strings of the human harp, the harmonies of life can be elicited only where there is a perfect response to its vitalizing touches. In other words, if the cell which is back of every function is impaired and incapable of response to that special phase of life which manifests in a certain functional power, the latter becomes arrested with the subsequent result of disease. Hence, the failure of food, be it ever so nourishing, to generate health and strength if the cell is incapable of eliciting and utilizing its vital principle.

Hence, the entire question of life and health is involved in the power of the cell to respond to the incoming messages of Nature's vitalizing impulses. The higher this power, the higher and subtler will be the forms of existence arising under its action, until in the course of an ever-accelerated evolution the whole chain of progressive forms of nourishment can

naturally be dispensed with, leaving to the cell itself the function to obtain its building material directly from the atmosphere.

Eating to Be Made a Moral, Rather Than a Physical Act.—The processes leading up to this high vegetative state are engendered by a careful selection of foods, with quality ever placed above quantity, and end above means, thus gradually turning eating into a moral rather than a sensual act. To eat in response to necessity rather than to the craving of a more or less exaggerated appetite, and by constantly keeping in view the supreme fact that eating never was intended to constitute an end in itself, but a means by which an end may be attained, forms the basis of all sane and truly progressive existence. For appetite is an animal rather than a human quality—the impelling force by which Providence guides its unreasoning creatures of the lower kingdoms along paths of unfailing, because of instinctive safety; while the human individual is equipped with faculties of thought, reason and volition, by which he is enabled to choose for himself and in perfect independence of a craving, which, owing to artificial and abnormal modes of living, is mostly irrational and misleading. As an exponent of self-consciousness it behooves the human being more and more to assume control of his vital processes, and bring his functions to yield ever higher results in the course of a constantly intensified evolution. The control of appetite and eating is not less important in the pursuit of health and progress than the control of breath and motor muscles. It must be within the power of man to gradually assume complete control of every function and faculty of his nature, and wield them in the service of universal progress.

Physical Culture of No Value If Divorced from Usefulness.—But the way to attain this power lies not in any exercise carried on for its own sake. Swinging with dumb-bells, punching the bag, or any howsoever elaborate stretch of muscles, etc., is powerless to accomplish what a useful, purposive exercise in the open air will accomplish. Usefulness, creative work, universal purpose, are the levers of universal power which yield the greatest and most permanent results.

It is in the midst of nature that life exhibits its greatest results. To mingle with her forces, to coöperate with her efforts and unfold in the direction of her aims and purposes, turns the mere mechanism of action into the dynamics of universal usefulness. Unselfish motive, embodied in vigorous purposive action, is the key by which the individual may open up Nature's sanctuary of health and power. "Not what I have, but what I do, is my kingdom."

[Written for the MEDICAL BRIEF.]

Asthma.

BY J. H. JERGESEN, M. D.,
Milwaukee, Wis.

[No. II.]

True asthma, or spasmodic asthma as it is also called, is supposed to be of a pure neurotic nature; it comes on, apparently, without any cause and leaves without leaving a clue to its factors.

Asthma caused by a visible or traceable cause is therefore not true asthma. To the form of asthma having a traceable cause belongs emphysematic asthma, bronchial and catarrhal asthma, renal and uterine asthma. Hay asthma must also be considered in class by itself, and so must hysterical asthma. Cardiac asthma, which is, strictly speaking, not asthma, may properly be classed as a mechanical form.

The earliest writers recognized two forms, one which they called ἄσθμα (short breathing) and another called ζωπγοια (short of wind.)

Emphysematous asthma very similar, in some particular, to spasmodic asthma, but very different in many particulars. The symptoms of emphysematous asthma differ chiefly from the spasmodic in that it seldom leaves the patient entirely; it has its permanent pathological cause, dependent on destructive changes in the lungs, and, in cases of long standing, a malformation in the chest-walls. Such destructive changes being progressive, produces as a consequence anatomical deformities in sympathetic organs—such as the heart.

The well-known deformity, always present in emphysema, and which carries its name—the emphysematous chest, and the right ventricular dilatation are (can) stand pathological deformities found as a result of emphysema of long standing. Tricuspid insufficiency, hypertrophied sterno-cleido-mastoid muscles, dilated jugulars, and cardiac epigastric shocks. These, with others, are permanent symptoms, which are always present in emphysema.

Emphysema exists when the minute anatomy (histology) of the alveoli and air cells of the lungs are permanently changed, and their physiological functions interfered with in such a manner that the whole or part of the lungs are incapacitated from bringing the venous blood in the intralobular capillaries in immediate contact for aeration and oxygenation by the air in the infundibular. As a consequence of this destructive change we have on the slightest provocation an attack of emphysematous asthma. Here, therefore, we have a visible or traceable cause and is therefore not "true asthma," or spasmodic asthma, but emphysematous asthma.

Emphysema may be caused by whooping coughs, bronchitis and spasmodic asthma as well.

A paroxysm of emphysematous asthma might be induced by exertion (walking, climbing stairs, coughing, catching cold, etc.) and it may come on any time and anywhere, under all circumstances, whereby the systemic blood circulation is accelerated, and in consequence the blood current is insufficiently oxygenated, so that carbondioxide is found to excess in the blood irritating the respiratory centers, and a cry for oxygen from every nerve and tissue-cell in the whole economy is impressed on the respiratory centers and dispatched over the pneumogastric nerves to the lungs; they immediately increase their action, though without relieving the condition. The paroxysm, however, although like true asthma in many features, is unlike it in the nervous phenomenæ being absent; (the patient must be protected from cold air); he is able to raise mucous and cough under paroxysm. There is an absence of the large quantity and often voidance of clear and limpid urine; the paroxysms are of much shorter duration; comes on oftener, and at all times, night or day, and as often as provocation is at hand, while true asthma is purely a nocturnal affair.

Under ausculation vocal fremitus can be heard over all of the upper half of the chest, moist râles and gurgling sounds are constant symptoms, and undue exertion will produce sibilant notes. Percussion elicits hyper-resonant notes at all times. In emphysema expiration is never complete. In collapse the lungs are found to be expanded as much, as would ordinarily be the case, when in health inhalation is complete.

The respiratory function consists as much in the collapse as in expansion—emptying the lungs of air, as it does in filling them. Therefore, if the power of normal contraction is lost, and therefore unable to empty itself of its contents, and if the power of expansion is still normal, and forcible inhalation takes place—the lungs already being full—the natural consequence must be an over-expansion of the air-cells, and, if continued, a permanent dilatation takes place. The lungs lose their resilient elasticity and hypertrophy is the consequence.

The lungs are divided into lobes, each of which is a lung in miniature, consisting of several infundibulas, with their nerves, arteries, veins and lymphatics. Such an infundibula is normally one-third larger than their areolas opening into them, but, by this permanent expansion they become proportionally much larger. The alveoli themselves next enlarge and their septas wither and lose their elasticity from lack of proper blood supply. The lungs having lost, in that way, their normal elasticity no longer tend to further contract to complete expiration, so that a large volume of residual air remains in the lungs.

The thoracic walls and the diaphragm, instead of being drawn in and upwards by the traction of the recoil of the lungs, simply collapses to their position of rest, and are thenceforth a dead weight to the expiratory muscles, instead of aiding the action of these muscles through their elastic rebound. From that we see, in emphysema, the inspiratory act begins, where in health, calm inspiration should end.

The deformity of the thorax, or the so-called emphysematous chest, is without a doubt caused by the pathological changes of the histology of the lungs. It has been considered congenital or hereditary, but it is so invariably present that pathologists look for it as an undisputable symptom or condition in emphysema. That that condition is caused by the abnormal condition of the lung seems to be agreed to by all modern teachers of etiology, reasoning in this way: Impairment of lung texture will render any dilatation, howsoever induced, more or less permanent, and an enlargement to the chest will result. Thoracic resilience must also, by degrees, be impaired. When, therefore, thoracic recoil does not pass beyond a certain point the chest must assume this as a permanent position; because of the tectural changes in the cartilage induced by non-use, as is natural in all tissues. Is this position first fixed? It is. Does the recoil never pass beyond a certain point? Ossification at that point must take place. Such changes having taken place and we have the deformity commonly called by its name "emphysematous chest."

The chest is rigid, the ribs are straight and seemingly broader, the intercostal spaces are diminished, the chest capacity is much enlarged, it is uncollapsible beyond a certain point.

In a paroxysm of asthma the chest is seemingly enormously distended, the epigastris is drawn high up under the ensiform and ribs, and apparently it does seem as if the uncollapsability of the chest wall were the only cause of the trouble.

Bronchial or catarrhal asthma is another form of asthma which is liable to be confounded with true asthma. As a rule, it is not difficult to differentiate between the two diseases. Catarrhal asthma has its own history of daily coughs, hoarseness and harshness of the voice, the face is bloated, bags under the eyes. He complains of pains in the chest, a fulness and tightness, which is often described as a girdle sensation or a band around the waist, and weight on the sternum, which, in many cases, are very uncomfortable symptoms.

A paroxysm of catarrhal asthma is, as a rule, ushered in in the form of a common cold, but not as a cold that passes through its initial stages in forty-eight to twenty-four hours; but it passes through all its stages in one to two hours, and I have seen cases of it that passed through all the stages and developed into a severe attack in less than fifteen minutes, caused by drinking a glass of cold water on a warm summer day. It was cured nearly as quickly as it came on by forcing the patient to drink a quart of water at the same temperature as that which caused it.

The first knowledge a patient has of an approaching paroxysm is a dryness of the mucous membranes of the nose. Progressing, there is an uneasiness between the shoulders, the tightness of the girth sensation, and that the otherwise copious expectoration has become scant and his cough, instead of being vigorous and successive, is one long-drawn wheeze, and soon his spell is in full force; but is unlike spasmodic asthma in nearly every aspect. The only thing the two patients have in common is that they are both struggling for breath. In this case the pulse remain full, and often bounding, the skin is hot and suggestive of fever, the face becomes more bloated, increased soreness of the chest. The patient, instead of bending forward, prefers to lean backwards, and have the chin raised. The most prominent difference in the two named diseases is that in true asthma the impediment is to expiration, whereas, in catarrhal asthma the impediment is to inspiration. After a paroxysm is ended, as a rule, there is a profuse expectoration of a thick phlegm, yellow, and often tinged with blood. This seems to indicate that the reverse is the cause to that of true asthma.

In this case it seems that there are at all times an overabundant secretion of the bronchial glands. This, from one cause or another, becomes impeded in the bronchiolas, whereby free access of air to the air-sacs is prevented and a mild form of asphyxia issues, and a struggle for breath is at once in full force.

In true asthma, as we have seen, the reverse is true—a patient may complain

of an uncomfortable dryness of the chest; he often feels the necessity of coughing, but is unable to raise anything and relieve the sensation. When a paroxysm ends there may be a small pellet of mucus expectorated, but beyond that expectoration is scant.

The Effect of Vacination on Small-Pox.

BY ANSEL STRICKLAND, M. D.,

Cumming, Ga.

I have just read and re-read the article on page 677, of August BRIEF, written by Dr. P. S. Ayers, entitled, "The Effect of Vacination on Small-Pox."

Now I will say in the beginning that I did not write the piece on chicken-pox in April BRIEF to get up a discussion through the medical press, nor for notoriety, but for the benefit of the profession at large.

As the Doctor seems to be in doubt as to what his patient had, and asks for information, I will endeavor to make it a little more clear to him.

In the first place, I put down seven points to look after in forming a diagnosis between a case of chicken-pox and a case of small-pox, and if these directions are strictly followed, he can have no doubt. The Doctor says that in all of his cases the period of incubation was fourteen days, dating from the day of desquamation, until those that were exposed came down. Now then, the desquamation in a case of chicken-pox begins on or about the seventh day, that alone would make all of his cases chicken-pox, for seven and fourteen makes twenty-one; now as chicken-pox is conveyed through the breath, then it had to be caught, or could be caught before desquamation began.

To make it plain, A and B sleep together on the night of the first day of August. B starts to his home the next morning. On that day A has what he thinks to be a bad cold, and stays more or less sick for a day or so, and on the 7th he breaks out with what the doctors call small-pox. Now, if it is small-pox then you go to B's house on the 14th of the month and you will find him sick, but if it is chicken-pox that A has, then on the 21st you will find B sick.

Then the Doctor seems to think I put the death rate too high in small-pox. To that I will reply that the lowest death rate in cases of small-pox that I find put down by any writer of note, is thirty-three per cent, under the best of treatment. Dr. Eugene Foster, of Augusta, Ga., who was a noted writer on small-pox, and had a lot of it to deal with, said the mortality among infants was ninety per cent; old age, seventy-five per cent, and middle-age, forty per cent.

A few miles east of here, three out of four died, although they had the best of attention; south of here, seven out of eight died with it, and they had the best of attention; that is what I call small-pox. Now we have in this county about fifty cases of chicken-pox a year, with no deaths. I know of a number of cases of chicken-pox in this town now, and we use no quarantine whatever. Those that take hot teas or drink whisky have it badly, and those that take nothing have it lightly.

A lady wrote to me from a town of about four thousand inhabitants, and said that there was a lot of small-pox in her town and none were dying. I wrote her to not be alarmed, as a single case of small-pox in a town of that size would depopulate it inside of twenty-four hours. In a few days after that I received another letter from her, saying that an expert said it was chicken-pox.

The Doctor further says that inside of thirty days after his patients got well their skin was smooth and no marks left. Now that showed chicken-pox. Then he says it was slightly contagious, some members of the family not having it at all. That pointed to chicken, as small-pox is the king of all contagious skin diseases. What seems to trouble Dr. Ayers most was that some of his patients had a similar eruption some three months before this. While I did not see your cases, yet I would say that they had in November what the older writers called febrile lichen, and in January they had chicken-pox.

Now if the small-pox gets among those patients of yours that had the so-called small-pox, you will see them die like sheep. I want to call your attention to one thing, to-wit: If that eruption you write about is small-pox then why vaccinate at all; for any of them will tell you that they had rather have it than to be vaccinated. If you think that was small-pox, then you should at once quit blowing your vaccination horn.

I want to call the profession's attention to one thing: If the doctors do not stop this calling of chicken-pox small-pox then vaccination will soon be a thing of the past. You will get the people to thinking there is no danger in having the small-pox, and you can not get them to be vaccinated at any price. Chicken-pox is to small-pox what a mosquito is to an elephant. If the Doctor wants to visit a patient that has small-pox I would advise him to get a clothespin and put on his nose, that you may not smell the most sickening of all odors, and a rubber stopper in each ear that you may not hear the groans, and a handkerchief over your eyes that you may not see the fright that no pen can describe. You may think that I am putting this down rather magnified, but you go and see a case of small-pox and see if you don't think I am correct.

If chicken-pox is small-pox then I say away with your vaccinations, for your remedy is far worse than the disease.

[Written for the MEDICAL BRIEF.]

A Plea For Liberality.

BY B. B. USSHER, M. D.,
Dedham, Mass.

The enlightenment that is brightening the dark places of the earth and ever illuminating the pathway of the belated churches, has seemingly failed to flood the profession which has needed it most, and the practitioners of medicine, as a whole, are moving slowly and painfully in a black procession that indicates the presence of the ball and chain of narrowness and bigotry, which hinders progress and reveals its presence by the clank of its links. What business have we to imitate the churches in their sectarianism? Is it not our part as scientists and apostles of helpfulness to sweep away the barriers that make us a laughing stock? What right has the allopath to label himself or be known other than as a physician? Has the homeopath stuck so closely to his creed that today he can boast of loyalty in his practice to "*similia similibus curantur* and the attenuated triturations and dilutions which were once the war cry of his 'pathy? Does the eclectic find it necessary to shout the Thompsonian shiboleth of "heat is life and cold is death," in order to proclaim that his medical sect is the only only? Does the educated hydropath, the competent osteopath, find it necessary to shout "Eureka" over his medical wares?

Shame on us, gentlemen of the medical profession, that we are not content to stand before the world as all-round men, wise enough to use any remedy that promises relief for human suffering. Shame on us for our unnecessary multiplication of medical colleges wasting our substance which, better spent, would mean higher education. Shame, thrice shame upon us that in these "United" States we are so divided medically that a reputable graduate of a reputable college becomes a criminal if he pursues his legitimate profession beyond the jurisdiction of his own state board. We have enough to bear without the gibes of the public over our divisions and ignorance of what is valuable in all schools. Let us be capable physicians, no more no less, and being that, bearing the credentials furnished by an accredited school of medicine, let reciprocity be the watchword of state boards, and the college diploma and home state board certificate be all that is necessary for the medical member to practice his profession anywhere under the flag of the American nation. The state board knows its own colleges, and its certificate should be a guarantee of fitness and a sufficient protection for the public. To be pathists is to be at the tail of the professions of science, and in this country there should only be licensed graduates, whose liberty to practice in any State of the Union should be one of the evidences of our departure from those antiquated notions that violate our dignity as educated gentlemen.

J. Edmund Stubbert.

M. D., Professor of Special Medicine, Pulmonary Diseases in the New York Post-Graduate Medical School and Hospital; Visiting Physician to the Edgemont Sanitarium, Liberty, New York; Fellow of the Academy of Medicine, American Climatological Association, American Medical Association. etc., etc. New York City.

Editorial.

The Practical Man.

The practical man is the one who succeeds in life because he has a definite purpose to accomplish. He is alive to the opportunities which present themselves because he looks at life through his own eyes and does his own thinking. Sentimental considerations do not weigh with him. The practical man refuses to let anybody lead him. He accepts life as it is, and makes the most of actual conditions.

The practical man knows that he must look to himself for all the real help he will ever get. All the assistance any union, combine or other organization will give is purely theoretical; the actual restrictions and prohibitions laid down by them cramp a man's energies and narrow his opportunities.

A practical outlook on life and a strong individuality equip a man for the struggle according to Nature's plan. No artificial scheme of man, no organization, can compete with it. A man must assert himself, he must face the facts of life fearlessly; he must make his own plans and carry them out dauntlessly. No man can do this unless he early trains himself to be self-reliant, and to think logically, so that he is prepared to make rapid and just decisions.

No man, least of all the doctor, can avoid emergencies. They are thrust upon us from the most unexpected sources and at the most inconvenient times. Then the long-time habit of independent thinking, directed to accomplishing practical results, is invaluable.

Aspirations and ideals are good things in their way if a man has the requisite commonsense and knowledge of life to be governed by practical considerations. Too many men allow themselves to be diverted from the main issue by sentiment, or forfeit their rights as men to some self-constituted leader. Such men are to be pitied because they miss the joy and meaning of life through which they pass blind and deaf to its possibilities.

The practical bent of mind has always an eye to results. Progress and achieve-

ment are the things which interest the practical man. He is always on the lookout for new methods and better ways of accomplishing things. The practical man applies the test of merit every time. If he is a doctor he uses the remedies which give him results, no matter who makes them, or what anybody says about them. He takes the journals which give him information and help him in his practice. He even takes the journals of other pathies than his own, for the practical man is very broad-minded.

The practical man can not be made a fool of by anybody. No political party, union or other form of organization can use him.

Dangers.

It is always necessary to guard against the know-it-all crank, who has an axe to grind. There are a lot of fellows who are always talking about analysis. Do not forget that analysis is yet in its infancy.

The doctor's main concern is to cure his patient. Never lose sight of that fact. When the doctor finds by experience that certain drugs, whether compound or single, meet certain pathological conditions, commonsense says use them without regard to the prejudices of others.

Another important thing is to see that the patient takes precisely what the doctor prescribes. This is a matter of real importance in this day when there is so much sophistication of drugs.

It is nonsense to say that the best medicines are confined to one manufacturer. Each manufacturer excels in a few particular remedies on which he makes his reputation. This is true not only of drugs, but in every department of life. The discriminating man or woman learns where he can obtain the best values and buys accordingly. Wherever the doctor finds a reliable remedy in a particular form, let him use that one and no other. Do not let yourself be prejudiced or led by outside parties. Never use something "just as good." There is no such thing. It is either better or worse, and in this connection it is invariably worse.

Guard against the bigotry of those who want to use you. Take the trouble to think for yourself. Never be indifferent as to who makes the preparations you use. It is just as important to know your medicines are prepared by a reputable house as to know your coffee or your omelet are made by a qualified cook.

Another thing to guard against is the man who offers us laws to remedy our troubles. There is too much legislation in this country right now. Be on the lookout for the man who wants to use you politically.

Germany is reported to have the highest death rate of any nation. This is generally attributed to the large consumption of beer by the Teutonic race, as all heavy drinkers of this beverage must absorb an injurious amount of salicylic acid—the latter being used in the manufacture of beer to prevent fermentation.

A certain publication, largely read by the old women of both sexes, recently established the awful fact that there is more alcohol in a tablespoonful of many medicines than there is in an equal quantity of beer. The writer of the article referred to does not condescend to consider that beer is not administered by the drop or tablespoonful, but is usually taken by the glassful and sometimes even by the quart.

Food In Health and Sickness.

The question of food is an important one, and should be faithfully and conscientiously studied. The doctor is supposed to be able to say what is best to eat, varying according to ailments and constitutional conditions. He is often puzzled by a lack of knowledge as to the component parts of the ready foods on the market and he should, without delay, read up and be ready to say at a moment's notice what is best suited to the conditions, and if he is giving remedies, what would be the least antagonistic to results from such. We all know that the finely bolted flour from which our bread is made—the whiter in appearance, the better it sells—must necessarily show that the outer covering of the grains of wheat are eliminated in order to produce

this whiteness, and the cellulose is thus left out.

There are many prepared foods on the market, and the physician should become familiar with their make-up, and thus be able intelligently to commend them, as they are marketable at any time, while others, such as vegetables, are at times out of season, and, of course, at such times they are not good to eat because of forced growth and hot-house production.

Little Things in Treatment of Little Folks.

BY LINCOLN PHILLIPS, M. D.,

Professor of Pediatrics in the Pulte Medical College, Obstetrician to the Bethesda Hospital, and Consultant to the Protestant Home for the Friendless and Foundlings, Cincinnati, Ohio.

With a tremendously decreased birth rate among the well-to-do classes, and with an increased death rate among the middle classes, due to the overcrowding in our large cities, we may well consider the question of race suicide.

At the present time about twenty-five per cent of all deaths occur in the first year of life, and thirty-five in the first two years. Are these figures not a little alarming? I fear the pathetic little white hearse is making too many trips to the graveyard. No one can question the fact that many of the poor, deserted, unclaimed waifs of the city, burdened by the heritage of sin and disease, are far better off dead than living. At the same time, we must not forget that these are only a small part of the great total.

This is the age of specialists, and I believe that those physicians who have a natural skill in treating infants and children should make a special study of the subject. Still the physician can not do it all, he must have the co-operation of city officials and citizens.

The two leading causes of the large death rate in the cities are (1) unsanitary surroundings and (2) a poor milk and water supply.

The proportion of infants requiring artificial food is steadily increasing, and we are all aware of the fact that that means more deaths, even under the most favorable circumstances; but when the noise and vitiated air of the densely populated centers, together with the poor water and bad milk, are considered, the prospect is far from encouraging. In the sweltering heat of the summer, the drawn, emaciated little ones make a pathetic picture indeed. The societies that are laboring to furnish a better milk supply and fresh air for the little ones are worthy of support and confidence. Our cities are not as keenly alive to the evils of unsanitary surroundings as they should be; if the profession of medicine had never done anything else than to demonstrate the necessity of pure air and sanitary conditions in the stamping out of disease, it had not lived in vain.

Referring to the little things in the treatment of little folks, I would say that so far as the physician himself is concerned, tact, keen power of observation and attention to small details are prime requisites of success. The infant's symptoms are objective ones, and how much does the treatment hinge upon the power to observe closely! I believe there are very few physicians, myself included, who are really suited to practice among children. He who has not real love and sympathy for children, who can not enter into their little pleasures and thoughts—can never hope to make a success with them. At a very tender age they can "read us like a book." Tact in handling children is a jewel of brilliant lustre. To observe, examine and do whatever is needed without the little one knowing what is being done is skill of a high class. The general practitioner can scarce take the time that is needed in making this call. Suppose he enters the house when the child is cross or angry. It is crying and nervous; the mother is nervous, and it makes him nervous, and in trying to get at the condition, they all get more nervous. What can be accomplished under such circumstances? Obviously the thing to do, unless the condition is one demanding immediate attention, is to retire to some other part of the house until the ruffles can be straightened out and the waters calmed; then and then only can the picture be obtained. Here patience is indeed a virtue.

It takes twice as long to take the case as it does the adult case. Why? Because the adult can tell his own story, but the infant has to depend upon the story of the nurse or mother and his own little mute signs.

Every detail must be gone into. What is baby eating? When? How much? When does he sleep? How does he sleep? And a thousand and one little things, as to fresh air, habits, etc. Many of these things you must actually see for yourself or the nurse, or even the mother, will mislead or deceive you purposely or not. Stripping the child will oftentimes render a diagnosis easy where before it was hard.

Insist, and again insist, upon regularity in method as to feeding, sleeping, bathing, etc. It is surprising what can be accomplished by judicious training. The little folks acquire knowledge by what we teach them and by their own observation. A baby can be taught to go to sleep at a certain hour in its own bed, without breast or bottle and without a light just as well as it can be taught the opposite.

Noise, excitement, irregular hours and habits make sick babies. For the first year of life the great nervous system is developing at a marvelous rate. It is a mine ready to explode on the least provocation. How important then is regularity and quiet. I have no patience with parents who want to drag a baby from one place to another, let every one handle it, trot it, and excite it. Another point along the same line: We do not do our duty when we neglect to instruct parents in reference to punishment of children, telling the children the policeman will get them, cut off their ears, etc. Many an idiot and nervous wreck is the result of such training.

Raising babies on artificial food in our cities is a fearfully discouraging task. Above all else, here is where attention to detail and little things count—attention not for a day, but weeks and months. The majority of sick, emaciated, rachitic, deformed children, brought to my clinic are the result of poor artificial feeding. As to the little things in diagnosing babies' troubles—what a mine of information we have in the sleep, the cry, the gestures, and the expression. The single sharp, shrill cry in the dead of night—tuberculosis of brain or bone; the suppressed cry—pleurisy; the "quack-of-the-duck" cry—post-pharyngeal abscess; the sudden and long-continued cry, with every evidence of pain—ear-ache or colic. And so we might go on indefinitely.

As to the prognosis—"babies get sick quickly and get well quickly"—but we must never lose sight of the fact that with the unstable nervous system little troubles may prove fatal.

As to treatment—Holt has taken good advice from our school when he says: "Never give a dose of medicine to a child without a positive indication. Never give a nauseous dose of medicine when a pleasant one will do. Small doses frequently repeated are better than one large dose and are not so apt to upset the stomach."

I feel as he does that children are drugged too much, that better results can be obtained by other means.

To sum up: The children's doctor must be especially fitted by nature, ability and rigorous training. Neglect or carelessness in regard to little things marks the distinction between a mediocre man and an expert.

Asclepias.

BY A. B. ERWIN, M. D.,

Bangor, Ala.

Having just read your editorial on asclepias in October BRIEF, I am pleased with your article. I have used asclepias twenty-five years, in colds and fevers. I cut short those continued fevers, typho-malaria (not typhoid), sponge patient, and give liver medicine, if necessary. When fever is lowest, which generally occurs in the latter part of the night, give quinine in three or four portions, and when last portion of quinine is given then give Dover's powders and asclepias t. i. d. (of crude root), enough to start perspiration; hot as patient can drink and enough to keep up perspiration until evening; repeat next day to keep fever from returning. The Dover's assist the tea in perspiration. I have it always on hand, never without it.

[Written for the MEDICAL BRIEF.]

States of Mental Depression.

BY T. OUTTERSON WOOD, M. D., F. R. C. P. (EDINBURGH), M. R. C. P. (LONDON),

Senior Physician to the West End Hospital for Nervous Diseases, Welbeck Street W., and President of the Medico-Psychological Association of Great Britain and Ireland. London, England.

Apart from the tendency towards melancholia resulting from the invasion of the consciousness by morbid thoughts, before touched upon, there are certain definite states of mental depression of varying degrees of intensity which are noticed among patients whose mental condition is in other respects free from disorder. Patients suffering from these states of depression form a fairly numerous class in the out-patients' room of our hospital. They apply for treatment on account of this depression because they are "so low spirited" that they are unable to follow their ordinary avocation or to take an interest in the daily round of life. This condition seems to affect both sexes equally, and to appear at various ages, and in a large number of cases no apparent cause can be found to account for it. Yet these states of "mental dejection," "despondency," "loss of heart," and the "giving up of hope," are found lying on the very threshold of melancholia, and are the opposite to the state of exaltation and the delirium of grandeur which usually usher in conditions of mania, especially the mania of general paralysis of the insane, megalomania, and the like.

The disorder (for it can not in this incipient form be called a disease) is characterized by a feeling of unhappiness; all natural feeling of buoyancy of spirits, and the healthy, hopeful looking onward, are damped, while the power of fighting against the weight of despondency is diminished. The appearance of the patient is in keeping with the mental state; the expression of the face is that of unhappiness and uncertainty, and the attitude of the body is that of listlessness and want of energy, thus showing a flaccid condition generally as distinguishing it from the well-known condition of flexion so typical of the pronounced melancholic. Another striking difference between this state of depression and melancholia proper is that in melancholia there is a characteristic tendency to tears. The melancholic is "full of tears," either loud weeping and wailing, or a steadily constant lachrymose condition that remains and persists during the waking state, excepting, of course, certain cases of melancholia with stupor.

Again, these patients, before strangers, and even in the presence of those more intimately associated with the affairs of their daily life will not show this substratum of depression and unhappiness—it is carefully masked. The patient will

say: "I can not understand this peculiar feeling, yet it exists, and I suffer intensely; but it is no use mentioning it to those around me, for they can not appreciate it. When I have communicated my miserable feelings to my friends, the only comfort I get is 'Oh, you must pull yourself together and throw it off.'" And so our patient goes on and suffers. The conditions of civilization have, however, throughout his life taught him to control his features and to avoid giving way to his emotions, in order that the expression of his face may not be an index to his feelings, or, as Shakespeare so aptly puts it, when Macbeth gives way to the intensity of emotion, and Lady Macbeth warns him: "Your face, my thane, is like a book where men may read strange matters." Thus it happens that the feelings of depression are hidden from his friends and associates. This, however, can only be for a time. No man can for long be unhappy, whatever may be the cause, without it affecting his general health. For soon the evidences of malnutrition appear, and the disordered functions tell their own tale in the lack-lustre eye and the altered complexion of the skin, while the coated tongue and the dry, cracked lips, plainly tell of the failing appetite and the envolvement of the gastro-intestinal tract in the general condition of physical deterioration. By degrees the depression, which at first was intermittent (but which under the influence of change of scene and cheerful surroundings could for a time be kept out of consciousness), gradually becomes more or less continuous, and invades a period which should be devoted to rest, so that sleep becomes fitful, unrefreshing, and disturbed, the general health becomes more and more undermined, and there is a loss of the usual energy and capacity for work.

It often happens, on inquiring into the history of these cases, we find that either one or the other of the parents has been nervous or subject to attacks of "lowness," and that the patient himself has suffered from these attacks more or less all his life, but that this one has been of longer duration and greater intensity, and has not given way to simple remedies as formerly. Again, these cases of mental depression are frequently found among the members of families who are neurotic, sensitive, highly-strung, emotional, uncertain, unstable—always at the top or bottom of the circle, rarely at rest "on the center."

Obviously, the danger in these cases is for the attacks of depression to recur and persist until they gradually and almost imperceptibly sail over the line of disorder and drift slowly away into the depths of melancholia. Melancholia is an insidious disease. It does not burst out into violent manifestations, and by vigorous physical display proclaim the mental storm raging within, as in a case of acute mania. Melancholia is of slow growth. It begins as depression, unnoticed and unrecognized (as in the cases we are now considering), and when the disease is developed the friends will tell us they have noticed a gradual change coming on for a long time—maybe months—before we are consulted.

In these cases of depression we have as a disorder the earlier symptoms of what may develop into disease. Fortunately, the patient retains the power to act, and by coming for advice give us proof that the substratum of depression is a shallow one, and the prognosis is, as a rule, favorable.

As illustrating the class of cases under consideration, the following brief notes are interesting: The case is that of a gentleman seventy-three years of age, of independent means, and possessed of everything calculated to make him happy. For years he has suffered from attacks of mental depression. Between them he is remarkably cheerful, eats well, drinks well, and for his age, is a brisk and energetic man, who will walk his six or eight miles a day with ease. The first time he consulted me—some four years ago—he walked into my consulting room, erect and firm on his legs, and certainly, from his facial expression, depression was the last thought to enter my mind with regard to him, yet he unfolded to me a plain and finely descriptive account of his mental distress. He said he felt so miserable at times he did not know what to do, that he was afraid he might become paralyzed, or that his mind might give way. His physical condition was excellent, and with the dynamometer his right

hand grasp was eighty and the left seventy-five. the heart's action was somewhat weak, pulse eighty-four, arteries soft and compressible. The exhibition of liq. strychninæ (three minims) sp. chloroformi (ten minims) tinct. aurant. (one-half drachm), aq. (ad. one ounce), t. d. s., soon strengthened the heart's action, and in a short time, after a trip to the seaside, he was as well as ever again, but ever and anon he was the victim of attacks of the same mental depression, which in due course, under appropriate treatment, disappeared.

One might go on enumerating *ad infinitum* similar cases which, in the great majority of instances, run a brief course toward recovery. Doubtless, now and then the symptoms deepen and go on to melancholia, becoming a veritable insanity, and they then leave the range of the cases under consideration, and fall under the class of developed mental disease, which is not within the scope of this paper.

With regard tc the general principles of treatment, the first indication is to improve the general health. Encourage a healthy action of the various excretions, and, removing as far as possible the exciting causes—if one may so express it—of depression, induce a healthy mental tone. This is best accomplished by a change in surroundings, change of the ordinary round of daily life, and by transplanting the individual into a healthier (mental) atmosphere, encourage a return to the nomal. With regard to specific medicinal treatment, much will depend upon age and temperament of the patient. My experience goes to show that we must not look to "drugs out of a bottle" to do much beyond the storing and keeping well up to the normal line the general health of the individual. Let him live as much as possible in the open air, take as much exercise as he can short of over-fatigue, and engage in some useful and congenial occupation. If it can be managed, a change of work will often have a most salutary effect, and act as a strong mental tonic.

Enclosed find one dollar. I enjoy reading the BRIEF.—THOS. SHOCKLEY, M. D., Nebo, Mo.

[Written for the MEDICAL BRIEF.]

The Care of the Eyes in Health and Disease.

BY E. LUCAS HUGHES, M. R. C. S. (ENG.), L. R. C. P. (LOND.).

Ophthalmic Surgeon to the Hope Street Hospital, Liverpool; Fellow of the Royal Institute of Public Health, Liverpool, England.

There are several points connected with the anatomy of the eye which are of interest. As regards the relative size of the eyeball to the orbit, the eyeball takes up only about one-half the actual space, because of the large space behind, between the eyeball and the optic foramen. Besides the eyeball we have the optic nerve, muscles, blood-vessels, lymphatics, and a large amount of adipose tissue, which cushions the eyeball, permits of movements and prevents injury. The limiting membrane between the cellulo-fatty tissue and the eyeball, Tenon's capsule, is also behind the conjunctiva, and reaches behind this membrane almost to the margin of the cornea.

We can readily see from this description how much accommodation there is for an abscess, for a tumor, or for a foreign body in the orbit; indeed, a tumor can grow to a large size before it begins to seriously press upon the eyeball, and foreign bodies can lodge in the fat for a considerable time without causing disturbance. The eyeball is nearer the upper and lower margins of the orbit than it is to its sides, and the greatest interval between the eyeball and the orbital wall is on the outer side. Therefore, it is easier to reach the interior of the orbit from the outer side; in enucleation, however, the optic nerve of the left eye is, for other reasons, more readily divided from the inner side.

The orbital fascia is interesting chiefly for its forming the check ligaments, internal and external, the capsule of Tenon, and the suspensory ligament, which latter forms a hammock-like sling supporting the eyeball and preventing it from sinking downwards. In operations requiring the removal of the superior maxilla, the attachments of this suspensory ligament should, if possible, be left intact. The check ligaments prevent excessive action

of the recti muscles, and when these muscles are divided they prevent them from retreating far back into the orbit.

For all practical purposes the capsule of Tenon envelops the posterior two-thirds of the eyeball, although some authors give a larger envelopment; indeed, they say only the cornea is uncovered by it, a thin film of it reaching under the conjunctiva to the limbus of the cornea. It is a thin, translucent, fibrous membrane, formed by the posterior lamina and part of the anterior lamina of the orbital fascia, practically extending from the insertion of the recti muscles over the sclerotic to the place of entrance of optic nerve, where it is reflected backwards over the sheath of the optic nerve to the apex of the orbit. It does not blend with the nerve, and there are two lymph spaces formed by it in communication with one another, one between the capsule and the eyeball, called Tenon's space, and the other between the capsule and the sheath of the nerve, called the supra-vaginal lymph space. There is loose areolar tissue which permits free movement, and the eye may be said to form a sort of ball and socket joint, the capsule of Tenon lining the socket. The eyeball is held in position in the socket by the recti muscles, and the socket, or capsule of Tenon, is held in position by the attachments of the orbital fascia. The muscles being partly attached to the capsule are able, therefore, to move the stump after enucleation.

The extrinsic muscles of the eyeball consist of the four recti, which pass forward on each side and are inserted just in front of the equator of the eye. There are also the levator palpebræ superioris, and the two obliques.

The interesting thing about the levator palpebræ is the way in which it forms a broad aponeurosis between the two portions of the lachrymal gland, and then splits into three lamellæ. The uppermost lamella blends with the superior orbito-tarsal ligament; the middle lamella, the most easily seen, is inserted into the anterior surface of the upper border of the tarsal cartilage; and the lower lamella is attached to the conjunctival fornix. The usefulness of this arrangement is obvious. The margins of the tendon being attached to the margins of the orbit prevent excessive action.

The superior oblique is peculiar on account of its very familiar little pulley or trochlea, which enables it to rotate the eyeball inwards, and draw the cornea downwards; in fact, in a direction which is that of an axis, set at an acute angle to the direction of the force exerted by its own fibers.

The inferior oblique differs from the other muscles of the eyeball by having its origin in the front part of the orbital floor; its fibers, therefore, pass backwards as well as outwards and then upwards, embracing the eyeball so as to be inserted upon its upper surface, and so situated

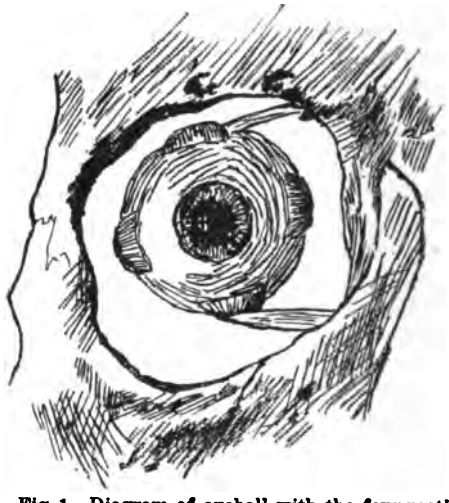

Fig. 1. Diagram of eyeball with the four recti muscles cut off near their insertion showing the ample space in the orbit. The tendons of superior and inferior oblique are left entire.

as to directly oppose the action of the superior oblique. The two obliques together act somewhat in harmony in abduction. The action of the other muscles is obvious.

The eyeball is an apparatus for bending the rays of light, so that they theoretically form pencils coming to fine points (foci) upon a sheet of delicate nerve tissue (the retina), specially adapted to receive them. In this way the impression is concentrated, so as to be conveyed to the brain. The endings of the optic nerves are arranged so as to be out of the way of ordinary nerve stimulation. There is some extremely sensitive arrangement by means of which the ether waves we call

light affect the nerve terminals of the retina. Just as death is the negation of life, so darkness is the negation of light. We see objects because they reflect to us more or less light. If light be absent we fail to see the object, because there is no light for the object to reflect; that is, assuming that we have normal visual powers. No matter what the stimulus may be, electric, mechanical, or the stimulus produced by the ether waves of light, the sensation of light is always sent to the brain by the nerve terminals, the rods and cones of the retina. A familiar example of mechanical stimulation is that flash of light experienced from a blow.

Strange to say, these end organs of the nerve-fibers, the rods and cones of the retina, are not pointed towards the light as it streams through the pupil, but are pointed backwards towards the sclerotic, so that the light waves traverse the translucent nerve-fibers and the cellular and granular layers of the retina before they touch the rods and cones themselves. The rods and cones are, therefore, the specific organs for taking up the influence of the waves of light; they are present everywhere in the retina, except where there is the blind spot, which latter corresponds to the entrance of the optic nerve.

The greatest sensibility to light exists at the little pit to the outer side of the entrance of the optic nerve, the fovea centralis. The radiating nerve-fibers here bend towards their rods and cones, and none of them pass over it. The retina at the fovea, in fact, is represented only by the layer of rods and cones, the other layers of the retina being absent. As we get towards the ora serrata, the periphery of the retina, sensibility gets less and less; that is to say, there is a duller, less distinct sensation, and the form of things can not be so clearly distinguished. It is entirely with reference to central vision that we test the refraction, accommodation, and the visual acuity. For perception of movements, however, as well as for slight differences of luminosity (the light sense), the periphery of the retina is actually more sensitive than the fovea centralis. Our visual sensations are of three different kinds: We take cognizance of the form of an object (the space sense); the color of an object (the color sense), and the brightness of an object (the light sense). Peripheral vision is of use in orientation; it enables us to guide ourselves and avoid obstacles; to take, so to speak, our bearings. If, for example, as we are walking, we look straight before us and there is a stone lying in our path, the latter forms an image in the periphery of the retina; in this case in the upper part of it. The stone, to be sure, is not

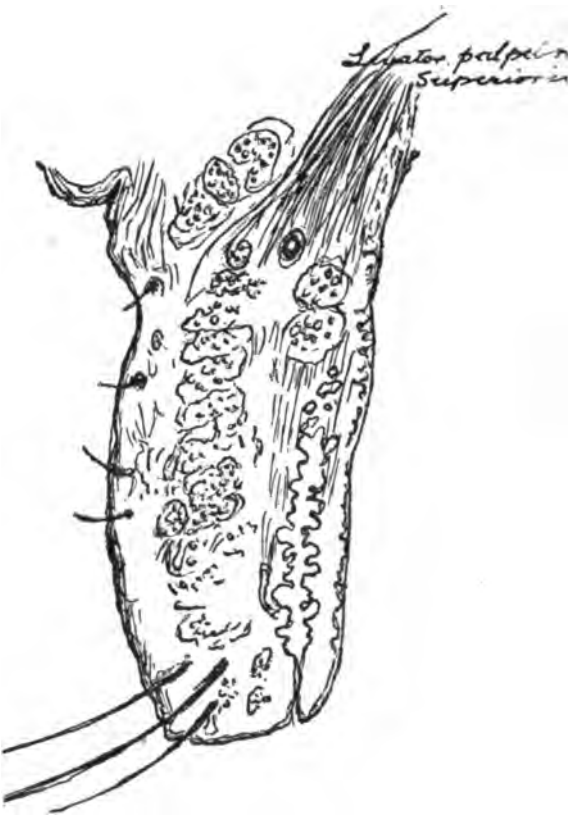

Fig. 2. Section through upper eyelid showing the way in which tendon of levator palpebræ superioris splits at its insertion. It spreads in the form of a fan and then divides into three lamellæ as shown in cross section. Other structures of eyelid faintly indicated, glands, muscle fibers of orbicular, etc., cut across. The blood vessel cut across at insertion of middle lamella into tarsal cartilage is the arcus tarseus superior.

distinctly perceived, but still it excites our attention. Our gaze is directed at it, it is then seen distinctly, we recognize it as an object and avoid it. The same thing happens if we go out in the street and men come towards us from one side. The images falling upon the periphery give us warning signals, which make us cast our eye directly upon the objects which excite

the images, and it is precisely moving objects that are most sure to excite our attention; since, as just stated, the peripheral portions of the retina have a high degree of sensibility for the perception of movements. It is almost impossible not to "turn the eyes" the moment anything peripherally lying, or especially moving, does catch our attention, the turning of the eyes meaning that rotation of the eyeballs as will bring the foveæ under the objects image.

Accommodation is the focusing, or sharpening, of the image looked at. This is brought about by the contraction, or relaxation of the ciliary muscle. The crystalline lens grows more convex when a near object is looked at, and becomes flatter when the object recedes. This is due to the antagonism of the circular ligament, in which the lens is suspended, and the ciliary muscle. When the muscle is relaxed the ligament assumes a spread-out shape, which keeps the lens rather flat. When the muscle contracts the ligament relaxes its pressure on the lens, and the lens, being highly elastic, becomes more convex. Thus, the lens is more refractive when the muscle relaxes. Accommodation for near objects is thus the more active change; when we look far off we simply let our eyes go passive. Contraction of the pupils and, also, convergence, accompanies the accommodative act. Time will not permit my going into the question of binocular vision, suffice to say that it entirely depends upon corresponding points of single visual direction, which exist upon the two retinæ.

The Perception of Distance.—When we look about us our eyes are incessantly moving, converging, diverging, accommodating, relaxing, and sweeping over our field of vision. The field appears extended in three dimensions, with some parts more distant and some more near. For perception of distance to be perfect it needs the two eyes. Soldiers in judging distance for shooting have to use the two eyes, although one eye is closed when actually taking aim. Distance, subjectively considered, is an altogether peculiar content of consciousness. According to Professor James, convergence, accommodation, size, degree of brightness, all give us special feelings which are signs of the distance feeling, but not the distance feeling itself.

The Perception of Size.—The dimensions of the retinal image determine, primarily, the sensations on which conclusions as to size are based, and the larger the visual angle the larger the retinal image; since the visual angle depends on the distance of an object, the correct perception of size depends largely upon the correct perception of distance; having formed a judgment, conscious or unconscious as to that, we conclude as to size, from the extent of the retinal region affected. Most people have been surprised that what appeared a large bird in the clouds was only a small insect close to the eye; the apparent large size being due to the previous incorrect judgment as to the distance of the object. The presence of an object of tolerably well-known height, as a man, also assists in forming conceptions (by comparison) as to size: artists, for this purpose, frequently introduce human figures to assist in giving an idea of the size of other objects represented.

The System of Colors is a very complex one. If one takes any color, say green, one can pass away from it in more than one direction, through a series of greens more and more yellowish, let us say towards yellow; or through another series more and more bluish towards blue. The colors have this peculiarity, that many pairs of them, when they impress the retina together, produce the sensation of white. The colors which do this are called complementaries; as examples, we have spectral-red and green-blue, spectral-yellow and indigo-blue. Green and purple again are complementaries. All the spectral colors added together also make white light, such as we experience in the sunshine.

The Duration of Luminous Sensations.—This is greater than that of the stimulus, a fact taken advantage of in the making of fireworks. An ascending rocket produces the sensation of a trail of light, extending far behind the position of the bright part of the rocket itself at the moment, because the sensation aroused by it in the lower part of its course still persists. So shooting stars appear to have luminous tails behind them.

By rotating rapidly before the eye a disc with alternate white and black sectors, we get for each point of the retina alternate stimulation (due to passage of white sector), and rest (when a black sector is passing). If the rotation be rapid enough the sensation aroused is that of a uniform gray, such as would be produced if the white and black were mixed, and spread evenly over the disc. In each revolution the eye gets as much light as if that were the case, and is unable to distinguish that this light is made up of separate portions reaching it at intervals; the stimulation due to each lasts until the next begins, and so all are fused together. If one turns out suddenly the gas in a room containing no other light, the image of the flame persists a short time after the flame itself is extinguished. If we open our eyes instantaneously upon a scene, and then shroud them in complete darkness, it will be as if we saw the scene in ghostly light through the dark screen. We can even read off details in it which were unnoticed while the eyes were open. This is the so-called primary positive after-image. According to Helmholtz, one-third of a second is the most favorable length of exposure to the light for producing it. Negative after-images are due more to complex conditions, in which fatigue of the retina is usually supposed to play the chief part.

Intensity of Luminous Objects.—Black is really an optical sensation. We have no black except in our field of view; we do not, for instance, see black out of our stomach, or out of the palm of the hand. Pure black, however, is only an abstract idea, for the retina itself (even in complete objective darkness) seems to be always the seat of some internal changes which give some luminous sensations. This is what is termed "idio-retinal light;" it plays its part with all after-images when the eyes are closed. Any objective luminous stimulus must be strong enough to give a sensible increment of sensation over and above this "idio-retinal light." Another point is that there must be a certain amount of luminous intensity in an object for its color to be anyway distinguished. Thus, for instance, in the dark all cats appear grey. As the light increases we distinguish the colors, first the blues, and last of all the reds and yellows are seen, up to a certain point of intensity, then they grow indistinct again through the fact that each then takes a turn towards white. At the highest bearable intensity of light all colors are lost in the blinding white dazzle. This has been spoken of as a mixing of the sensation, white, with the original color sensation; however, it is not a mixing of sensations at all, it is a replacement of one sensation by another, due to a changed neural process.

Amongst reprehensible and idiotic practices there is nothing, perhaps, worse than that of blinding young children by making them live in an environment of everything white, one may call it "color starvation;" the baby is clothed in white garments, it sleeps in a white bassinette, the nurse is dressed in white, the child is sent out in a white perambulator, in which it lies in the summer time in the glaring

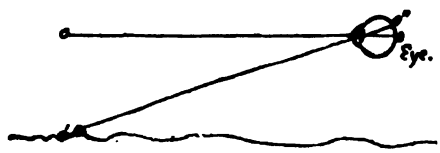

Fig. 3. Diagram illustrating peripheral vision, or arientation of objects in space, *i. e.*, the ascriptions of objects seen to the place where they acually belong. O is object looked at, O′ is another object such as a stone is the path O″ image of same on the upper edge of retina within field of vision.

sun, staring at the sky; then the mother wonders what is the cause of something going wrong with the eyes, and it is, indeed, a providence if the cause is checked in time by a wise doctor, and the mischief is nothing more than acute conjunctivitis.

Another foolish proceeding is the producing of extreme convergence by the frequent holding of bright and attractive toys quite close to the child's eyes. This is a great cause in the production of squint. As the child grows older it becomes more and more necessary that he should not be over-exercised in his powers of convergence. Indeed, the first ten years of life are a critical time for the eyes, and the more out-of-door amusement a child has, the less he pores over books, threads beads, and in other ways exercises his accommodation, the more he is likely to escape having to wear glasses for some error of refraction. Some of the kinder-

garten schools are very objectionable on this account. Whatever advantages to civilization there may be in compulsory education, there is no getting away from the fact that the eyesight of our people is deteriorating by our increased education. The superior shooting of the Boers, in the late war, over some of our soldiers was due to this fact. Poor children are sent to school in the morning, sometimes without any breakfast; they are made to pore over books and writing in dusty rooms, perhaps the rooms very badly lighted, and there is the strain of competition; the general health suffers, and is it to be wondered at that the eyes can not bear the strain?

Dr. Norton wisely observes: "The school life of a growing child should be so regulated as to secure the best mental advancement and, at the same time, the best physical development." Is this done by our great educational system, which compels parents by the law of the land to send their children, weak, badly fed, and unhealthy, to schools where their eyesight is practically at the mercy of, maybe, a careless and thoughtless teacher? When the mischief is fully developed the poor child is sent to an ophthalmic hospital, where, perhaps, an over-worked staff has to deal with great numbers, with insufficient time to go thoroughly into each case. This results often in anything but an accurate prescription for glasses, which are obtained cheap, badly fitting, and of the poorest quality. The parents may be too poor to afford anything better.

Examinations are now made in the primary schools, and nearly all the children enter with normal eyes, but they soon begin to develop errors of refraction. In America and Germany there is more myopia, in this country more hyperopia, and astigmatism everywhere is exceedingly common. This latter is the worst of all to deal with, and needs the more expensive glasses, as the lenses have to be specially ground by a skilled workman, and with a machine that costs the manufacturing optician about twenty-four hundred dollars. In American universities the percentage of myopia has reached seventy per cent, and in the higher-grade schools twenty-five per cent. This shows that the number of near-sighted pupils increase from the lowest to the highest schools, and in direct proportion to the length of time devoted to the strain of school life. The only way to prevent all this is the making of careful and frequent examinations of the eyes. Schoolmasters and teachers should have a card of simple test-type letters against the wall, and at the proper distance of twenty feet, the child who can not see the type should be at once sent to an oculist. If the child complains frequently of headaches while studying, or seems to be getting nervous, anemic, etc., the teacher's duty is to suggest to the parents the wisdom of consulting a doctor. We can get very acceptable false teeth when our own are lost from neglect, but the same can not be said of artificial eyes.

All children with inflamed eyes should be kept from school, not only because an inflamed organ must be kept at rest, but because many inflammatory affections of the eyes are infectious, and one can not always at once say which are the infectious cases. A very severe form of acute conjunctivitis is highly contagious, caused by the Koch-Weeks' bacillus, and vulgarly known as "pink eye."

There are many other faulty conditions in the upbringing of children, and in school life—badly-printed books; home lessons often done late at night, with a very poor artificial light, and when the body is tired and the brain sluggish; a hard and fast curriculum, whereby weakly children are made to compete on equal terms with the strong and able; cramming, insufficient out-door exercise, bad light, bad air, too close and prolonged application; these things both permanently damage the general health, and this most important of all special senses, the eyesight. There should be a frequent change in educational work, the blackboard should be much used, and there should be frequent intervals of rest. Children should be sent early to bed, and not allowed to sit up reading sensational papers and novels. The flood of more or less trashy literature in this country is doing great harm to the eyesight of young people.

School buildings should be built away from narrow streets, so as to have good light and good air, and a surrounding

large, open playground. Dampness should be avoided, and the ventilation and drainage perfect. Sufficient light is of the utmost importance. Cohn says: "The quantity of light can not be too much;" while Javal says: "That every portion of the room should be so flooded with light that the darkest place will have sufficient illumination on a dark day." According to Risley, the window surface should never fall below one square foot for every five square feet of floor space, and that this should be exceeded in many localities, on the north side of buildings, and on the ground floor. The color of the walls should be of some light shade of green, blue, yellow, or grey. The furniture should be of a light color, and roller shades of the same color as the walls should be lowered over blackboards, when the latter are not in use. The direction of the light is of importance, objectional cross-lights should, of course, be avoided, and, if possible, the light should be to the left and rear of the pupils. Dr. S. D. Ridley has drawn attention to the faulty construction of school desks and seats, placed at a wrong angle, which not only produces, according to orthopedic surgeons, spinal curvature, but, by excessive strain upon accommodation and convergence, becomes a source of grave danger to the eyes. The seat and desk should be so arranged that the child will find it easier to sit upright at his work than in any other position.

All that has been said as regards children in school applies equally to the adult. The eyes should only be used for near work when the body is erect; reading when lying down is bad, and the light should be good and fall on book or paper from the left side. A reading stand is not only a luxury but a necessity for those who do much reading. The best light is daylight, next the Welsbach, incandescent, or the electric light properly shaded and protected by globes. Gas and kerosene are good, but should be shaded by globes, colored white on the inside and tinted green on the outside. People ruin their eyes reading in the dusk, and in insufficient and unsteady light. The poor print of cheap newspapers, so frequently read by the dim light of a railway carriage, is very bad; also, the dangerous habit of reading in bed by candle-light. To those who indulge in these foolish practices one can not cry don't too often. Dr. Bell Taylor has published a strong condemnation of smoking as being a potent factor for evil to the eyes. Although excessive smoking is undoubtedly injurious, I am of opinion that if the digestion is good and the general health unimpaired, the smoking of good tobacco is not of itself such a *bête noir* as Dr. Taylor would have us believe. I think tobacco in any case is far less harmful to the eyes than the reading of the small print of newspapers by the wretched, unsteady light of railway carriages. Alcohol in excess, morphine, cocaine and other drugs are harmful. That nicotine does act harmfully upon the retina there can be no doubt, the eyesight of persons employed in tobacco factories is often greatly damaged, but smoking by sensible men, who are not enslaved by it, and who smoke in moderation, seldom does any harm to the eyes. It is very excessive smoking I deprecate. A man runs a great risk; he may establish a tolerance, or he may, like some of the arsenic-eaters of Styria, break down in the attempt. Sixteen or twenty cigars a day, with blindness to follow, is hardly to be desired, no matter how great our appreciation of the weed. Among all classes there is a prejudice against spectacles, although of late years this seems to be dying out; the use of the correct glass to those suffering from refractive errors, is one of the greatest boons to humanity. It is really a necessity in all but very slight cases. Glasses are frequently treated with great roughness and carelessness by their wearers. They are thrown about, they become scratched and dirty, and even well-fitting frames by rough handling are put out of shape. The centers of the lenses should be opposite the central vision, otherwise the patient is looking through prisms, and not benefiting by the accuracy of the prescription. The frame should fit the bridge of the nose and the face as a glove fits the hand. Folders are wretched things; if worn they should never be folded, for they easily get scratched and misshapen. It is most important that the best quality only of lens should be obtained. The best crown glass is better than a pebble, and the

frames should be carefully adjusted by a thoroughly competent optician. Often the careful work of an oculist is undone by a careless tradesman. The custom of allowing incompetent opticians, jewelers, chemists, watch-makers and peddlers to test the eyes and fit glasses can not be too strongly deprecated. Said a little working watch-maker to me one day, when I found him in his shop testing, in his ignorant way, a woman's eyes, "If they are such fools as to come to us, sir, let it blind them. Others do it, why shouldn't I?" The prevalent habit of going without glasses for reading late in life is also bad. The public should be taught that in all normal eyes glasses are needed for near vision after forty.

In conclusion let me say that the health of the eye depends greatly upon the general health of the body. By obeying general laws of hygiene the usefulness of the eyes will be best maintained.

Tent Life in the Treatment of Tuberculosis.

BY J. EDWARD STUBBERT, M. D.,

Professor of Special Medicine, Pulmonary Diseases in the New York Post-Graduate Medical School and Hospital; Visiting Physician to the Edgemont Sanitarium, Liberty, New York; Fellow of the Academy of Medicine, American Climatological Association, American Medical Association, etc., etc. New York City.

During the past two years tent life for consumptives has become very popular among the patients themselves in the eastern section of the country. Although such method of treatment was practiced quite extensively for a long time in the Western and Southern States, an idea seemed to be prevalent, at least among the profession, that tent life would be safe and advantageous only in dry, more or less warm, climates. The results obtained, however, by observers in the New England and Middle Atlantic States, have disproved that theory, just as experience has demonstrated the fallacy of many other therapeutical ideas.

During the summer of 1903, the writer placed a number of patients in tent life in the mountains of Sullivan County, especially at Liberty, and the beneficial results obtained, as compared with that of house, hotel, or sanitarium life, were so marked as to induce quite a number of patients to continue this out-of-door life even through the inclement weather of the unusually severe winter which we have just passed.

During the coming year tent life will be carried out very thoroughly in Sullivan County, notably at the Edgemont Sanitarium, and also in private camps.

Where tent life is not possible, more or less the same benefits are attained by directing the patient to sleep on open verandas in the country, and fire-escapes and roofs in the city.

There is an erroneous idea that unfortunately possesses the minds of many patients, viz., that sleeping in a room with open windows is as beneficial as absolute out-of-door life.

It is important that the tents in which the patients live should be properly constructed. Many forms of construction are recommended, but in most there is too great a tendency to copy the construction of a house. The idea of a canvas roof seeming to be all that is necessary to persuade the patient that he is enjoying tent life.

In this section of the country platforms should be erected about six or eight feet above the ground. On this platform should be pitched the tent, the roof of which should be fixed on, but all four sides should be capable of being rolled up, or at least drawn out as flies during the day time; in fact, they should not be closed at all, except during the hours which the patient requires for privacy in dressing, etc.

The arrangement of the tent must be according to the individual taste of the patient. There is no reason why he should be compelled to sleep on a cot, unless he so desires, and he may be surrounded with all the comforts of a room at home, minus the protection of its four walls.

The location of the tent is another important factor. It is better that it should be pitched on the side of a hill, where drainage will be perfect, and also avoid too violent winds. Too much shade from trees should, however, be avoided, and, therefore, the tents should be pitched in

the open, rather than in the forest. Sunshine will not only keep the tent in a sanitary condition, but is one of the most valuable therapeutic agents we have in the treatment of common tuberculosis.

The fact that the patient is enjoying out-of-door exposure and tent life does not preclude the necessity of medical supervision and appropriate symptomatic treatment, which should be just as thoroughly carried out among these patients as those in the sanitarium.

Where colonies are established it is well to have the tents as widely separated as is consistent with convenience of sanitary administration. Camps occupied by a considerable number of patients should be well furnished with nurses, and as careful a supervision of the patients and methods of life maintained as in a sanitarium.

Where it is possible and expense not a matter of consideration, it is well to erect a chimney on the weather side of the tent, with an open fireplace, which can be utilized during the very chilly or rainy weather, for the double purpose of giving comfort to the patient during dressing hours, and also a means of drying their wearing apparel.

Some of the tents occupied by patients of the writer during last summer were furnished in this way, and, in addition, were fitted with electric lights and provided with bath rooms and toilets, which were built on the windward side of the tent, and thus leaving it possible to open up all of the other three sides.

How to Develop the Breasts.

BY T. HENRY WHITING, M. D.,
Elgin, Ill.

To harden and give formation to the same bathe the breast with the following lotion:

℞ Alum (Pulv.)..... ½ drachm.
Spirits of Camphor..... ½ drachm.
Tinct. of Myrrh..... ½ ounce.
Alcohol..... 1 ounce.
Peppermint Water..... 3 ounces.
M.

After using the lotion with gentle pressure the skin will glow and new life will be felt coming.

The Treatment of Psoriasis.

BY HENRY M. DEARBORN, M. D.,*
Professor of Dermatology New York Homeopathic Medical College and Hospital; Professor of Principles in Medicine and Clinical Professor of Dermatology in New York Medical College and Hospital for Women; Visiting Physician to the Metropolitan Hospital; Attending Dermatologist to the Laura Franklin Free Hospital for Children; Consulting Dermatologist to the Flower Hospital, the Women's Hospital of the Women's Medical College, and the St. Mary's Hospital, Passaic, N. J. New York City.

From ancient times psoriasis has been considered an incurable disease, an affection that could be relieved for months at a time, but was likely to recur. Within a few years experience has prompted us to amend our former prognosis, and feel decidedly more hopeful regarding its permanent cure. In order to establish any systematic or clear indications for treatment we must study the disease in all its relations. This may be done under three heads:

1. The character and peculiarities of the patient. This may include the family history, occupation, habits of life, as regards diet, exercise, and other features which go to make up the individual environment.

2. We need to study the peculiarities of the disease as to the primary location, tendency to invade other regions, the evolution of the eruption, its relation to seasons, especially the division of warm and cold parts of the year, and the subjective sensations, if any; the peculiar modalities, such as relief from warm bathing or cold bathing; aggravation or relief from exercise; changes due to diet and the condition of the organs, especially the eliminating organs. Frequently there is inefficiency of the kidneys, and in a certain percentage of cases very defective elimination from the intestinal tract. Not infrequently patients affected with this disease take an inadequate supply of fluids, and are rarely troubled with thirst, even to a normal degree.

The clothing is also to be considered as to its relation in increasing an undue warmth of the surface. In this direction

* Deceased.

it is to be recognized that almost everyone is over-clothed and the skin too thoroughly protected from the outside air. Occasionally it will be found that some type of headache furnishes knowledge of the constitutional condition. Here again we must make a careful inquiry regarding previous eruptions and the eruptive history of other members of the family in the direct or collateral branches. Occasionally a clear history of eruptions in the preceding generation may be obtained, or even in two or three removes we may find something significant.

3. We must study the peculiarities of the eruption, whether it is superficial with abundance of scaling; what the evolution has been as to the rapidity of development and change; the amount of infiltration and degree of redness; the aggravations or ameliorations which occur in connection with the formation of lesions or the scales which cover them; the peculiarity as to the course of the disease in itself; infection of the skin, whether beginning upon the head and spreading downwards, or upon the trunk and spreading to the extremities, or on the extremities and involving the trunk or head later.

Having learned all the details possible under these three lines of inquiry, we will have gained a pretty clear picture of an individual case upon which we may base some plan of treatment. Here the element of time must be considered, and sometimes we may discuss the question with the patient of methods to promote a rapid disappearance of the lesions; or, on the other hand, a method of treatment looking to a permanent cure. The first may give quick relief to the objective features; the second may give an enduring result. If the patient fully understands the degree of his affection and the objects of treatment on one plan or the other, he is very likely to select the one which will give the most enduring result, although it may be slow and cover many months in duration.

With the first object in view of clearing the skin as rapidly as possible, we may use the well-known application of chrysarobin in proper strength, or salicylic acid, or beta-naphthol, resorcin or the more recent empyroform, or we may go still further and make a trial of the X-rays. One of these methods is pretty sure to effect a decided improvement in the course of a few weeks, but we can not give the patient any assurance of more than a temporary effect.

The second method of treatment looking to a cure must be founded on not only the ordinary features of the disease as manifested in the individual, but on its permanent peculiarities. These peculiarities may appear under one or all of the lines of inquiry already briefly outlined. For instance, if we find a history in the previous generation of a similar eruptive disease, we may use such constitutional remedies as aurum or kali-iodide. On the other hand, if we find some marked peculiarities regarding the disease itself, such as aggravations in summer rather than in winter, we may think at once of such deep acting remedies as sulphur, or of the more superficial acting remedy, ammonium muriaticum. If we find the modalities characteristic of great intolerance of the lesions to local irritation, we may also think of arsenicum. This remedy also is indicated for the very marked periodicity either in the eruption or in the manifestations of other symptoms.

Then to illustrate the third line of information, if the eruption begins on the head primarily, we may think of phytolacca. In a general way, if we find evidences of defect in the glandular functions, we may think of remedies which have particular relation to these structures, such, for instance, as thyrodin.

If we have reason to believe that there is a specific taint, kali-iodide will probably prove helpful either used intermittently or continuously in small doses of one or two grains three times a day.

Lastly, a vegetable diet is often indicated in cases of this disease; not invariably, because occasionally the patient is found anemic, but the majority are well nourished. In short, we might say a vegetable diet, with abundance of fluids, is indicated by the majority of individuals afflicted with this disease

The Undeveloped Uterus.

BY RALPH ST. J. PERRY, M. D., LL. D.,

Surgeon to Dr. Perry's Sanitarium; Formerly Professor of Dermatology and Genito-Urinary Surgery, University of Minnesota; Ex-President American Association of Orificial Surgeons; Past Surgeon-General Sons of Veterans, U. S. A.; Formerly Surgeon to the African Missions of the Protestant Episcopal Church; Physician to H. R. H. Bara Kapaidy, Sultan of Veyland; Hon. Surgeon-Major Liberian Army, etc., etc. Farmington, Minnesota.

Observation and experience, during the past decade, have led me to believe that the undeveloped uterus is seen oftener than it used to be. This may be due to an actual increase in the number of cases, or to the fact that young women are to-day more willing to be treated for their genital ailments than were their mothers, aunts and older sisters. Whatever the actual cause, it is true that a condition which was rarely mentioned in the text-books of twenty years ago is quite commonly found amongst the young women and pubescent girls of to-day.

The term "undeveloped uterus," as used in this paper, applies in its broader sense to that organ which is markedly smaller than it should be, considering the age, general physical development and family history of the patient. If a uterus be less than two-thirds the normal size it is bordering on the undeveloped, and if it be half, or less than half, its normal size, it is most decidedly undeveloped. Both of these conditions call for more or less remedial treatment.

The existence of an undeveloped uterus can be suspected in all cases where women, otherwise matured, present flat breasts, or undeveloped mammary glands. That flat breasts are quite common is evidenced by the large sales of bust developers, bust forms, and similar devices and nostrums calculated to remedy or supply the deficiencies of Nature. From my own personal experience I would not hesitate in saying that every young woman suffering from undeveloped breasts has a more or less undeveloped uterus.

When a young woman who has lived an ordinary life, without overwork or undue exposure to inclement weather, and who is otherwise healthy, suffers from chronic dysmenorrhea, amenorrhea, or vicarious menstruation, it would be well to inspect her uterus. When a young married woman remains sterile after oft-repeated exposures to the germs of maternity it would be well to inspect her uterus, after having first examined into the testicular history and possibilities of the husband.

In making physical examinations of virgins the physician now has at command much smaller and more appropriate instruments than were in use some years back. It is possible now to get speculums of sufficient smallness to enter any virgin vagina without rupturing or seriously injuring the hymen. Unless the physician has a small finger he should not undertake digital vaginal examinations, but should make digital examination through the rectum. The smallest size of Grave's speculum on general sale at the instrument-makers' is much smaller than the average forefinger, and with this the virgin vagina can easily be entered and dilated, sufficiently exposing for examination the uterus. With a small-sized sound the uterine depth and cervical dimensions can be measured. A general anesthetic may be administered, or not, as needed or desired. Local anesthesia may be needed in cases of vaginismus, atresia, and interfering or intractable hymen.

The prognosis in ninety-nine per cent of these cases is good. I would not hesitate to promise a satisfactory outcome in any ordinary case where treatment was begun during puberty, or early adult life, and persisted in faithfully for a sufficient length of time.

The treatment is remedial and prophylactic. One of the best remedial measures is vibratory massage, applied directly to the organ by means of cup-shaped applicators, or by the intra-uterine stem applicator. At the outset of the treatments this massage can be applied by rapid manual vibrations at the rate of from two hundred to three hundred per minute; later on, as the organ and the patient become more tolerant of the treatments, the vibrations can be applied by means of the electric or compressed air apparatus at a rate of from two thousand to seven thousand per minute. These direct vibrations should be given for only a

minute or two at a seance, and not oftener than once or twice weekly. Where the physician has no electric or compressed air vibratory apparatus the manual vibrations may be repeated several times weekly.

Supplemental and adjuvant to the vibratory massage there can be used certain of the Thure-Brandt movements. With the left index finger in the rectum, or vagina, firmly fixing the uterus, practice gentle circle-rubbings with the fingers of the right hand upon the abdominal wall over the uterus, starting with small circles and gradually enlarging them until they include within their field the ovaries and bladder. This form of massage may be continued for fifteen or thirty minutes, with intervals of repose. Follow this abdominal massage by a gentle, brisk and firm hand tapping over the roots of the sacral and lower lumbar nerves, or by electric vibratory massage over the same region. Also have the patient practice thigh rolling while in a half-lying position. Finish the massage by using the gentle, soothing stroking with the finger tips over the parts operated upon. This resembles the so-called "magnetic touch," and its effect is doubtless as much psychic as physical, but none the less effectual.

Some cases which resist the vibratory massage will respond to pneumatic massage, applied by the alternating vacuum machine used in massaging the ear and eye; using, of course, special forms of cups to fit the cervix uteri. Pneumatic massage can be applied daily, or every other day, in five-minute seances. Some beneficial effect is also secured through reflex action by massage of the breast, using the circle rubbings around the nipple and gradually enlarging the circle to include the entire breast area. Titillation of the nipple and the application of the breast pump, cupping glass, or vacuum developers will be of benefit in some cases.

In the line of medication there is not much to say. None of the women who have served as provers for our extensive *materia medica* have ever reported atrophy of the uterus, nor has any case of accidental poisoning or involuntary proving ever been followed by an atrophy of the uterus, so far as known. In the absence of more definite remedies the physician can test those commonly used in amenorrhea. More satisfactory results can be secured from those drugs known to possess a direct physiological action upon the involved organs, and of these my best results have been attained through saw palmetto. For ten years past I have been using saw palmetto, and have had no cause for complaint.

In addition to the measures here laid down, the patient must also adopt others, dependent entirely upon herself and her parents for their successful issue. As these same measures are, to a great extent, preventive against undevelopment of the uterus, they are here discussed as the prophylactic treatment. The prophylaxis of undeveloped uterus is a topic upon which a book could well be written, involving as it does matters of heredity, clothing, food, sleep, constipation, outdoor and indoor exercises, over-study at school, and many kindred topics bearing upon the development of the child, girl and woman. Lest this paper be prolonged to the brain-fagging limit let me summarize these points.

All clothing worn during the pubescent years should be suspended from the shoulders, and so arranged that there is no pressure or dragging down upon the pelvic organs, or abdominal muscles, or viscera. The food should be plain, simple and, to a certain extent, coarse. The finely ground or bolted breakfast foods, predigested foods, and other frauds upon the alimental canal should be eschewed as tending to induce gastric disturbances, establish constipation, and elevate gehenna generally in the internal economy. The patient should have at least eight hours sleep, and in many cases ten hours would be beneficial. Where constipation has already been established it should be eliminated, and one of the best eliminants for this work that I have ever used is the following powder:

℞ Sacch. Alba, Powd.....18 ounces.
Senna Fol., Powd.....5 ounces.
Licorice Root, Powd.....5 ounces.
Sulphur, Powd.....2½ ounces.
M.

One teaspoonful of this mixture at bedtime, when needed, will produce one or two evacuations the next morning, and does not tend to create a drug habit. As a general rule, the combined effects of the

massage and coarse food diet will remove the constipation without special laxative medication. The patient should have plenty of out-door exercise, boating, horseback riding, swimming, lawn tennis, croquet, golf, skating, moderate dancing, etc. Indoor games, such as hand ball, basket ball, medicine ball, etc., should be encouraged. If convenient, have the patient use an elastic exerciser, going through the leg exercises for a quarter or half hour daily. The "setting up" exercises of the United States army are highly beneficial and easily carried out. In all calisthenics, gymnastic and athletics use discretion, and do not allow the patient to overdo. A growing girl suffering from an undeveloped uterus should not be allowed to attend public schools, or other educational institutions, where she must keep up to a standard set by others. Such forcing has ruined too many lives, and it is time for parents, teachers, and the public generally to understand it. Place the victim of retarded uterine development under private tuition, where her individual capacity can be accommodated.

The physician should understand, and so caution his patient and her parents, that the undeveloped uterus is a condition requiring long, tedious, and persistent treatment; that it is impossible to make up years of retarded growth in a few weeks, and if they desire a satisfactory outcome they must be content and willing to let Nature work out her course, while the physician aids, abets and stimulates her.

[Written for the MEDICAL BRIEF.]

Etiology, Lesions and Symptoms of Scarlet Fever.

BY JAMES H. TAYLOR, A. M., M. D.,

Professor of Pediatrics and Clinical Medicine in the School of Medicine of Purdue University, Indiana Medical College.
Indianapolis, Ind.

Scarlet fever is a contagious punctate eruptive disease, accompanied by sore throat, a rise in temperature, preceded by a short stage of invasion, and followed by desquamation. The disease belongs to the group of pertussis, where a specific germ has not been discovered. Reasoning from analogy it is supposed to be due to a specific micro-organism, in connection with other micro-organisms that are found in the throat—streptococci. Some observers have gone so far as to state that it is the streptococcus that is accountable for the symptoms of this disease. Suffice it to say we have streptococci, producing infection, and there are pneumo-cocci present in the throat. We may class as predisposing factors anything which will lower the vitality and make for receptivity of the disease.

Scarlet fever occurs for the most part in children from two to five years of age. Before that age they are less susceptible, and not more than fifty per cent of those who are exposed to the disease contract it. Beyond the age of five the susceptibility is less, but the disease may occur at any age throughout life. It occurs most frequently in the fall and winter months, and is more severe during that season; just why, no one seems to know, but it is certain that the chronic conditions resulting are more liable to occur during the winter season. Children under two years of age, and particularly under one, are least susceptible to this disease.

The period of incubation is short, from two to six days; therefore, if a child has been exposed to infection, and has been kept at home from school for a week or so, and shows no symptoms of scarlet fever, it is quite evident that the disease will not appear. In many instances the period of incubation has been even shorter than two days, but the average is from two to six. As to the mode of invasion, it is for the most part contracted by being exposed to the patient. The poison may be in the breath of the patient and is certain to be conveyed by means of the secretions from the nose and throat, and from suppurative conditions, such as chronic otitis. The scales during the stage of desquamation contain this poison, as does the perspiration. The disease is infectious throughout its entire period, and it is probable that the urine and feces also contain the elements of infection. The disease is particularly infectious during the sequelæ, whether these take the form of chronic catarrhal pharyngitis, or a severe suppurating ear, which may continue to discharge for weeks after the patient

has ceased to present any other symptoms. The toys, books, and other articles that have been in the sick room, should be destroyed. I know of no other disease, barring tuberculosis, which is so easily carried in objects of this sort. Bouquets of flowers have been sent from a sick room to the hospital and scarlet fever has been the result. Curtains, upholsteries, anything used in the sick room, may be a carrier of the infection. Milk, which is one of the most easily contaminated of all our foods, has been known to carry the disease. In New York City the records of J. L. Smith show a number of cases of scarlet fever which were traced to milk infection (at the home of the dairyman). It is rare that the disease is carried by a third person, although there are instances on record where a physician has carried the disease from a patient direct to his home. And it is just as possible for a nurse to carry the disease as for the physician.

The duration of the period of infection is about six weeks, but this time may be extended by reason of the sequelæ, such as the suppurating ear, the chronic pharyngitis, rhinitis, etc. The lesions that we find in this disease are confined to the skin and mucous membrane of the nose and throat. There is at first a general hyperemia of the skin, followed by infiltration of the serum and round cells into the chorium and particularly about the blood vessels and hair follicles. Lesions pertaining to the mucous membranes vary greatly in degree, from a mild catarrhal inflammation, membranous inflammation —this latter rarely in the larynx—and gangrenous inflammation. The esophagus is usually highly congested. Lesions other than these occur elsewhere, such as fatty degeneration of the heart, focal necrosis of the liver, congestion of the malpighian bodies of the spleen, etc. We may have an endocarditis, a pericarditis, or inflammation of the tongue. There may be pleurisy, acute congestion of the kidney, or a diffuse nephritis. We may also find empyema.

When there is a severe form of inflammation in the mucous membranes of the nose it may extend to the antrum, or through the eustachian tubes, causing inflammation of the middle ear, thence to the meninges, mastoid cells, and to the brain. We have always more or less inflammation about the pharynx in the sequelæ; the most common is, perhaps, otitis. This latter ranks as the most frequent of all causes of the deaf and dumb cases which fill the institutions of the present day.

Symptoms.—The stage of invasion is short, from twelve to twenty-four hours; the child is taken sick with vomiting and sore throat, and in twenty-four hours the first stage is complete. The stage of eruption is short, the rash making its appearance first upon the neck, then upon the chest, and in twenty-four hours it has spread to the entire surface of the body. During this stage the temperature rises in mild cases from 101° to 103° F., and runs, on an average, from three to seven days. When the temperature falls we have the period of desquamation. This stage is ushered in by a fuzzy appearance of the skin at the point where the eruption first made its appearance, and if the body is not bathed and cared for the scales will be quite prominent after several days. If let alone the desquamation is at its height at the eighth day of the disease, and then begins to fade. This stage, however, lasts about three to four weeks. Where the skin is thickest it is last in peeling off, but is most prominent at these points. We have all grades of peeling, from the little, narrow strips to the entire cast of the fingers. The exfoliation during this stage is governed by the severity of the dermatitis. In mild cases there will be little desquamation; in severe cases the desquamation will be prolonged and deep.

Holt differentiates between the mild, moderately severe, severe and malignant cases of scarlet fever. In the mild case the disease is ushered in after a short stage of incubation—and the shorter the stage of incubation the more intense will be the course of the disease—vomiting will be projectile in character and often not accompanied by nausea. The child, whether it has taken any food or drink, will be seized with an attack of vomiting. This is continued for one or two hours. With this is a slight soreness of the throat. There is congestion and redness of the membrane of the throat, fauces, and tongue. The tongue is coated, the

temperature is, perhaps, 101° F. In twenty-four hours the eruption appears, and after two or three days, never later than the fifth day, the temperature has fallen to normal and desquamation commences. If the dermatitis has been mild the child will want to get up and play, and the physician who will permit this is guilty of a sin of omission in not recognizing the fact that this child can at this time transmit to another malignant scarlet fever. The rule is that if proper attention is given such a case the temperature will run along for two or three weeks until recovery, without any severe complications. The moderate form of scarlet fever is the one we usually see in epidemics. It differs from the mild form in presenting a higher temperature (103° to 104° F.); there are patches of white or yellowish white upon the tonsils, which, unlike the tenacious membrane of diphtheria, can be rubbed off. There is more difficulty in swallowing, and the symptoms of angina are more intense. There is a tendency toward swelling of the glands at the angle of the jaw. The pulse is more rapid, running from one hundred and twenty to one hundred and sixty. Eruption is more intense, of a brighter scarlet, and more liable to appear upon the face than in the milder form. There is the characteristic white appearance about the lips, the other parts of the face are intensely red, which accentuates the pallor around the mouth. At the second or third day there may be a low, muttering delirium. Later, there may be a discharge from the ear. The temperature gradually falls until the tenth day, when desquamation begins. A most important feature of the moderately severe form is the tendency to complications. One of the most common conditions (according to Pearce, of Albany) is the hyperplasia of the lymph nodes throughout the entire body, and swelling of the glandular and cellular tissue about the neck. During the febrile stage there may be septic symptoms. Unless the complications are unusually severe these cases recover. The desquamative stage is more prolonged, the urine usually shows epithelial casts, etc. Suppression of urine is one of the most ominous symptoms in this disease.

The severe form is ushered in in the same way, but the vomiting is more intense, and the temperature will reach 105° F., or possibly 106° F. This class of cases frequently have convulsions, instead of vomiting. There will be membranous inflammation of the throat. Usually, after the fifth day to the eighth, the temperature subsides. At the beginning of the second week there is usually a complication, oftenest middle-ear disease. If these cases become septic in character, due to the action of the streptococci, by the fourth or fifth day, the temperature is higher, and they become comatose and die within two weeks from a complication, such as broncho-pneumonia, pneumonia, or from heart failure. If the eruption is very marked in the beginning, there will be high arterial tension; when the eruption begins to fade, low arterial tension.

The malignant variety, which is rarely seen, is one in which the patient is overwhelmed by scarlatinal toxemia, and becomes comatose almost from the start.

A Few Points on Circumcision—Technique of Operation.

BY O. L. SUGGETT, M. D.,

Professor Syphilology; Associate Professor Genito-Urinary Diseases, Barnes University; Surgeon in Department of Genito-Urinary Surgery in Centenary Hospital and Barnes University Dispensary; Consultant in Venereal Diseases, City and Female Hospitals; Member A. M. A. St. Louis, Mo.

[Second Paper.]

The operation is the simplest imaginable and, if properly done, occasions the patient little discomfort or inconvenience.

The instruments required for this little procedure are few and simple; a soft, rubber catheter, a hypodermic syringe, a half ounce of a four per cent solution of cocaine, an indelible pencil, a phimosis clamp, a pair of strong, sharp scissors (six inch, curved on the flat, one blade pointed, the other blunt), three pairs of four-inch artery forceps, one small curved needle, needle forceps, and about eighteen inches of twisted silk, No. 8.

Needless to say that the same amount of care and surgical cleanliness is required in this minor procedure as in a major operation. This requires shaving of the surrounding parts, and a thorough cleansing with soap and hot water, followed by the liberal use of a 1-4000 bichlorid solution. A thin film of cotton, saturated with a five per cent solution of cocaine, is placed around the glans, and the foreskin drawn carefully over it. The line of incision is then drawn with an indelible pencil (the point of which has been moistened with a bichloride solution) entirely around the glans, just back of the corona. This marking must be done when the penis is flaccid and in a normal position. This is important, as the skin here is deceivingly loose and the novice is likely to draw too much of the skin through the clamp without these markings to guide. Having outlined the incision as above described, it extends farther back upon the dorsum than it does upon the under surface, where the lines from either side unite at a point nearly one-quarter of an inch below the attachment of the frenum to the cleft in the glans penis. A catheter is then tied firmly around the root of the penis, tourniquet fashion, protecting the urethra below by intervening a piece of cotton, and placing the knot on the dorsum. Before tightening the tourniquet, the prepuce is drawn strongly forward, so that the dotted line is well beyond the extremity of the glans. Removing the cocaine-saturated cotton surrounding the glans, the forefinger is inserted through the preputial orifice to serve as a guide, and to help direct the hypodermic needle between the skin and the quasi-mucous membrane, which, if successfully done, will enable you to sweep the needle about on all sides and distribute your cocaine sufficiently through one puncture, otherwise it will be necessary to inject it at several points. One syringeful, or two at the most, of a four per cent solution will be sufficient. Withdrawing the needle and gently rolling the tissues between finger and thumb hastens its absorption and anesthesia, which requires four or five minutes. Care must be taken, however, not to blur the pencil marking.

With an artery forceps the prepuce is seized in a line with the frenum below, and with another pair at a point immediately above on the dorsum, and pulled evenly and firmly forward. The clamp is adjusted, noticing that the pencilled line is entirely visible through the fenestrum in the clamp. This may be best done by partially locking the clamp and rolling the skin beneath its blades until in the desired position, then locking the clamp tightly. While the assistant exerts moderate traction upon the artery forceps, the left hand is used to steady the phimosis forceps. In this manner and with one sweeping stroke of the scissors, or a very sharp scalpel, the foreskin is cut through, immediately along the upper edge of the blades.

On removal of the clamp it will be seen that the glans is still covered with the quasi-mucous membrane in a cuff-like fashion, its inner surface being exposed to view. If the semi-mucous membrane is very stretchy (and there is great difference in the elasticity of different foreskins), and the glans is "flatheaded" (not peaked or cone-shaped) and small, I apply the artery forceps as before, placing one half way between these two, which will include in its grasp the mucous membrane of both sides, and drawing it strongly forward, apply the clamp, and with its blades gently closed, but not locked, force the glans back as far as possible before locking the blades, cutting along the top of the clamp as before, which produces a perfectly smooth and even edge upon the semi-mucous membrane, the surfaces coming into perfect apposition. This will, of course, make the mucous membrane a trifle longer than by splitting it down the dorsum and trimming it around with scissors in the usual way, and necessarily brings the scar farther back of the sulcus; but by the latter method, on account of the delicacy and pliability of the membrane, as well as its close adherence to the underlying tissue, it is well nigh impossible to trim it around as evenly as by the former method, when the traction upon it is equal all along the line of incision, and the latter is made at one stroke.

The mucous membrane is now turned back smoothly in its proper position, and

the skin drawn forward and, when perfect apposition is assured, we remove the catheter, which has served the double purpose of controlling the hemorrhage and confining the cocaine to the field of operation (an important point).

Usually the bleeding will be but slight, but in some cases it may be considerable, in "bleeders," most annoying. The bleeding points may be picked up, the artery of the frenum usually being the most important, though seldom requiring a ligature. The oozing is easily controlled by gauze wrung out of very hot water and held tightly around the entire penis. Too much time should not be lost in controlling the hemorrhage, as the cocaine rather quickly loses its effect after the removal of the hemostat, and the patient will object to the stitching. After the bleeding has been entirely checked the first stitch is taken at the frænum, and, using a continuous suture, the cut surfaces are "whip-stitched" (inserting the needle through the outer surface of the skin and the under surface of the quasi mucous membrane) all the way around, the last stitch being tied to the first.

Care must be exercised in bringing the cut surfaces into exact juxtaposition, else a redundancy will exist upon the side where you finish. Before tying the last stitch at the starting point, all the "slack" should be taken up with a small blunt hook, beginning at the starting point and tightening up each stitch in turn. Do not, however, draw the sutures too tight or it will strangulate the parts. When it occurs conveniently, a stitch taken through a bleeding vessel will check the hemorrhage from that source. Before applying ung. dressing I am in the habit of surrounding the entire penis with gauze wrung out of very hot water and compressing it firmly and evenly from all sides for at least five minutes. This checks any remaining oozing and reduces the tendency to subsequent hematoma and edema. A plain gauze bandage, one inch in width, is applied evenly, which, in the absence of any swelling, is not removed until the fifth day, at which time the sutures are removed and the parts redressed. If everything has been sterile and thoroughly aseptic, especially your sutures, this dressing may be left undisturbed until union is complete, which is generally in ten days. Executed in the manner just outlined this little operation is absolutely painless, and does not cause your patient to lose one hour from his work. Putting them to bed, as advised by some authors, is absurd. The glans, which is naturally sensitive after removal of the foreskin, may be protected for a few days with a silk or soft linen handkerchief.

Commercial Building.

[Written for the MEDICAL BRIEF.]

Hip Joint Disease.

BY JAMES A. DAVIS, M. D.,

Professor of Orthopedics in the Pulte Medical College; Attending Physician to the Bethesda Hospital, etc.
Covington, Ky.

Hip joint disease, or more properly speaking, tuberculous disease of the hip joint, has probably occupied the most prominent place in joint diseases of the body. The size and importance of the hip as a joint has made it of especial interest to the medical profession, and the fact that a perfect cure has baffled and continues to baffle the best men in the profession to-day is sufficient proof that there is still room for improvement in the treatment of hip joint disease.

Hip joint disease is a chronic destructive tuberculous disease of the hip joint that results in loss of function and deformity. The principal etiological factors are, first, the predisposition of the patient; second, the tubercle bacillus, and, third, the local condition favoring the reception and growth of the bacilli.

The predisposition of the patient is a lessened vital resistance that may be hereditary, or due to improper food and hygienic surroundings, or exhausting and depressing diseases, especially whooping cough and measles, or any condition that will undermine and exhaust the health of the individual.

The second elément is the tubercle bacillus which may find its way into the system through any part of the respiratory tract, or alimentary canal. Latent tuberculosis of the bronchial, cervical or mesenteric glands may persist and free bacilli or particles of infected tissue may

from time to time escape into the blood current and be carried to other parts of the body.

Third, local conditions favoring the reception and growth of the bacilli. This may be caused by an injury, usually slight, causing a hemorrhage into the cancellous tissue; this produces a local congestion and provides material for the development and growth of the bacilli that may be carried to that part by the blood current. Injury as a direct predisposing cause has been proven experimentally and is supported by clinical evidence in about twenty-five per cent of cases, but exact relation can only be conjectured. The disease usually begins in newly-formed bone around the epiphyseal cartilage. The circulation here is more active, is subject to greater strain, is more liable to injury, and also accounts for the relative frequency of the disease in childhood, as compared with adults.

Pathology.—The disease usually begins in several minute foci in the head of the femur, near the epiphyseal cartilage, but may begin in the acetabulum or synovial membrane. After the bacilli are deposited the irritation of their toxins causes a proliferation of the fixed cells which lie in direct contact with the germs, and around these a ring of leucocytes form; this forms a little grayish speck in the cancellous tissue. The central cells about the bacilli, increasing in number, deprived of nourishment and poisoned by toxins, die and are disintegrated to granular material and the tubercle changes to a yellow color. The multiplying bacilli escaping form new tubercles about the original foci and coalesce as the area of the disease enlarges. Meanwhile the surrounding tissue becomes congested as a result of the irritation and the fixed cells become organized, or partly so, into a feeble, ill-nourished form of granulation tissue, representing the effort of the part to shut out and expel the foreign substance formed by the disease. If this is effective the germs are surrounded and destroyed and are transformed into scar tissue. In most cases the bacilli destroy the granulation tissue and the area of the disease is extended.

If the progress of the disease is slow the cancellous tissue is represented by bone sand, but if rapid a sequestrum of bone may be formed. By the formation and coalescence of new tubercles a cavity is formed containing the debris of granulation tissue, bone sand or sequestra of bone, fluid composed of leucocytes and serum that have exuded from the surrounding tissue masses of degenerated tissue and usually of a whitish color, though sometimes red from admixture of blood and in later stages turning to a thin, yellow-colored fluid. The abscess enlarges in the direction of least resistance and may open on the neck or shaft of femur, but usually enters the joint. The tissues in the joint are involved in a sympathetic irritation and inflammation, while the disease itself is still in the bone. The synovial membrane is congested and hypertrophied synovial fluid increased, fibrin forms on cartilage and lining membrane of capsule and adhesions form. Repair may take place at any time by absorption, ejection or enclosure of the disease. When the progress of the disease ceases the granulations become more healthy, blood vessels are formed, the parts become more perfectly organized, are of a firmer consistency, and the bone becomes harder, showing evidences of repair. If enclosure of the disease occurs traumatism may cause it to break out anew.

Hip disease ranks second of all tuberculous affections of joints, Pott's disease being first. It is essentially a disease of early childhood, although no age is exempt. From eighty-five to ninety per cent of cases are under fifteen years of age, and half of these are from three to five years. Males are more frequently affected than females, and the right side more than left. Probably because boys are more active than girls and more liable to injury because of their outdoor games, and the majority of them being right-handed the right side is used more than the left.

Symptoms.—The reason the symptoms of hip-joint disease exist for some time before the patient is brought to the physician for treatment is because their development is so slow that the parents are not aware of the severity of the disease and some time elapses before they realize the child needs treatment. The symptoms

that usually first attract attention are pain and limp.

The characteristic pain of hip disease is located on the inner side of the knee, and is the terminal filaments of the obturator nerve on the inner side of the knee, giving expression to the irritation of other filaments of the same nerve which supplies the hip joint. Direct local pain and sensitiveness at the hip are unusual unless the disease is acute or the overlying tissues are involved, as in the formation of an abscess. Sudden and unguarded movement and injury aggravates the pain. It is worse at night because the joint becomes more sensitive from use during the day and muscular relaxation at night permits the sensitive parts to come into contact and the child cries out with pain and may be found holding the thigh with the hands or pressing the limb with the other foot. This condition is generally worse the early part of the night.

The limp attracts a great deal of attention and causes a change of rhythm in the gait; a long step alternating with a short step, and is considered to be due more to the sensitive joint than to any marked restriction of function. Hip, knee and ankle are flexed so as to prevent any unnecessary jarring, and is more noticeable in the morning.

Examination of joint will show reflex muscular spasm, which is the barometer of all sensitive joints. It precedes all symptoms and remains until the cure is complete. Motion is limited to a greater or less degree in every direction in proportion to the sensitiveness of the joint and, unless adhesions have formed, will disappear under an anesthetic. Slight flexion of the limb is the earliest indication of any deformity and with this is usually abduction and outward rotation. The limb seems longer than its fellow, due to a tilting downward of the pelvis on diseased side and the elevation of the opposite side and is often referred to as the stage of apparent lengthening. The next change is one of flexion, adduction and inward rotation, with actual or apparent shortening. Contractions, adhesions and changes in the muscles and fascia may persist after a cure is complete. In the first condition the buttock appears flatter and broader than its fellow. The gluteo-femoral fold is lower and shallower because of tilting the pelvis and flexion, and the inguino-femoral fold is deepened and lengthened.

Atrophy is an important sign, is demonstrated by measurement and if well marked shows that the disease has existed for some time. Its cause has been the subject of much discussion. Vulpian and Charcot claimed it was nervous and reflex, due to changes in the trophic centers of the spinal cord. Saborin claims it is a molecular neuritis. Physiological disuse and diminished nutrition also contribute their share. The opposite limb is relatively hypertrophied, because of increased work. Actual shortening of afflicted limb is a common effect in later stages and may be due to disuse of limb, effect of disease upon the epiphyseal cartilage, erosions of head of femur, or acetabulum, causing displacements or depression of neck of femur; actual lengthening seldom occurs, but is due to the stimulation of growth in the epiphyseal cartilage of head of femur. Retardation of growth is the usual condition. Debility, pallor, loss of flesh, appetite and strength, and slight elevation of temperature occur, but is more noticeable in later stages, or in infected abscesses.

A limited amount of fluid is present in nearly every case of hip-joint disease, but is not classed as an abscess unless large enough to be detected; this occurs in about half the cases. It usually appears between the sartorius and tensor vaginæ femoris muscles; it may perforate the acetabulum and enter the pelvis, or may present itself on the inner or back part of the thigh, its situation being influenced by the point of rupture of the capsule, after which it follows the course of least resistance. If found early in the course of the disease it indicates the rapid course of the disease, the joint usually being involved, and perfect function less likely to be preserved.

In making an examination for hip disease observe general condition of patient; note different attitudes and character of limp. Remove all clothing, place patient on back upon table, legs parallel and extended; notice length, size and position of each, manipulate sound limb first, test-

ing flexion, extension, abduction and adduction; compare diseased limb with it. Place patient face downward and test extension for psoas contraction, and if motion is unrestricted in all directions you can exclude hip disease.

Measure from anterior superior spine of ilium to the extremities of the inner malleoli, limbs parallel, to determine actual length of limb. Measure from umbilicus to inner malleoli to determine apparent lengthening or shortening, if limb is distorted. Determine atrophy by measuring corresponding points on each limb, being careful that an abscess is not present at point of measurement. Firm and deep pressure over joint usually causes discomfort and a peculiar resistance of deeper parts, caused by infiltration, is often present.

In making a differential diagnosis remember that hip disease is a chronic tuberculous disease; symptoms may have existed weeks, months and years before brought for treatment; is a disease of a single joint, does not get well, causes a limp accompanied by reflex muscular spasm, deformity and general atrophy of the muscles of the limb. Is usually a history of a fall, but faulty use of a limb due to a diseased joint will cause more falls than falls cause joint disease. X-ray examinations are of more value in demonstrating deformity than in establishing an early diagnosis of the disease, especially in childhood, when a large part of the upper extremity of the femur is cartilaginous.

Treatment.—In treatment we must not only bear in mind the local manifestation of the disease, but the general condition of the patient as well. As this disease is more common among the poor of our large cities than the favored class, we must improve as much as possible the hygienic and dietetic conditions and surroundings of the patient. It is almost impossible, in a great many cases, to make the desired changes in this direction, but insist upon good food, and use appliances that will permit of open air exercises. After this we must depend upon medicinal and mechanical treatment.

The object of the mechanical treatment is perfect rest and extension, so as to secure protection, to prevent friction, to relieve pain and muscular spasm, and to correct and prevent deformity. To accomplish this numerous methods have been devised, as, for instance, the traction hip splint, or American method; the Thomas brace, or English method; the plaster of paris, or German method; the weight and pulley for the bed, and the Bradford frame. Each of these has its ardent advocates, and there are cases in which a certain one of these methods is better than any other method that can be employed for that particular case; but the brace as devised by Dr. A. M. Phelps, of New York, comes nearer combining the good qualities of all than any other method. This provides a combination of lateral and longitudinal traction with splinting and stilting. A steel bar extends from the axilla to below the sole of the foot and then turns inward; two metallic bands encircle the trunk. A metallic ring fits the upper extremity of the thigh closely, and is attached to the steel bar at an inclination corresponding to the line of the groin. Three bands encircle the limb, one at the upper part of the thigh, giving lateral traction against the bar, the other two at the knee and calf. Adhesive straps, with buckles at the lower end, are placed on the limb and secured by a bandage, while straps fastened to lower end of the brace connect with the buckles, giving longitudinal traction. The brace is made adjustable at the hip, so that traction is made in the line of deformity and the brace gradually straightened as the deformity is overcome. A high sole is placed on the opposite shoe and the patient is permitted to go around with the aid of a crutch. A high chair with half the seat removed permits the patient to sit down.

The treatment of an abscess depends on circumstances. If it remains quiescent and causes no disturbance, let it alone, as spontaneous absorption occurs in about twenty per cent of cases. If abscess enlarges, relieve tension by aspiration and apply a pad and bandage; repeat if necessary. If abscess is large and symptoms acute, evacuate by a free incision, remove necrotic material, wash out with pure carbolic acid, followed by alcohol and then a copious saline solution. If necessary, remove head of femur by the lateral or pos-

terior incision. Amputation follows excision of the hip when suppuration persists and patient does not improve, unless condition of patient will not permit.

Use of X-ray has given good results in some cases and very little or none in others.

Prognosis.—Promise nothing in less than from three to five years. Direct mortality of hip disease is due almost entirely to immediate or remote effects of abscess, about seventy-five per cent being due to this cause. Death rate varies from twelve per cent in non-operative cases to fifty per cent in operative cases. Mild cases, with early diagnosis and proper treatment, recover in from one to two years; moderate cases, two to three years; severe cases, five years. Use support long after disease has remained quiescent and is apparently cured.

Etiology and Treatment of Some of the More Common Diseases of the Upper Air Passages.

BY L. C. CLINE, M. D.,

Professor of Laryngology, Rhinology and Otology in the Medical College of Indiana.
Indianapolis, Ind.

In the treatment of the upper air passages, we meet with a class of cases in which the local lesions do not furnish the evidence of the real pathological factor. To find this, experience has taught us that we must look beyond the local spot to explain the etiology often remote from the lesion concerned and adopt measures further reaching to effect a cure. We have learned that local measures alone no more effect a cure in a certain class of toxic cases than does morphine cure suppurative appendicitis; but simply acts as an analgesic and masks the symptoms for the time being. When we study the anatomical construction and the physiological functions, the intimate and delicate relations of the mucous membranes of the upper air tracts to the vital centers, as the liver, heart, kidneys and digestive tract, we do not wonder at their altered condition and appearance during the impairment of the action of these organs.

When we analyze the various departures from the normal in the air passages and study them from a broad or general medicine standpoint, excluding congenital or acquired deformities that act as mechanical irritants and obstructions, we find that a great number or group of cases have some systemic factor playing a prominent part in their etiology. All diseases of the upper air passages must have a beginning, and it is to the early incipient stage that this paper is directed, and not to the advanced lesions, as the hypertrophic and traumatic disturbances, many of which require surgical measures before any relief of consequence can be promised.

I wish to emphasize that it is not the cases above referred to, but the congested hyperemic conditions that produce pressure, irritation, headaches, and the train of symptoms that come with auto-intoxication through absorption from the intestinal tract; faulty metabolism in the liver and elimination by the kidneys. We are all more or less familiar with the congestion and glandular activity that is observed in the mucous membranes of the upper air passages in diseases of the gastro-intestinal tract, the heart, kidneys and liver.

The conditions that are most usually found in the nose and throat are those known as lithemia and auto-toxic infections. Lithemia may be defined as an irritable, congested, or inflammatory process, brought about by over-production and retention of acid urates that should be eliminated. Any excess may be carried to the secreting and eliminating structures and there retained, causing irritation. Their combination on the mucous membrane with other extraneous materials may form new chemical compounds that act as violent irritants to the sensitive mucosa, manifesting itself in what we designate as coryza, taking cold, or an attack of hay fever, rose cold, ragweed fever, or any of the different names applied to the various external influences at different seasons. The great vascularity of the mucous membranes of the upper air tracts make them peculiarly susceptible to the uric acid and other toxic influences.

The position and the action of the muscles of the pharynx in the act of swallowing make them more sensitive than other parts. When we consider the intimate relationship of the pharynx to the digestive tract, being a part of it, we can readily understand how it can be, and is, influenced by faulty metabolism in the liver, resulting in the condition known as lithemia, as well as auto-intoxication caused by fermentation and the absorption of by-products from the intestinal tract. In either case the pharynx may, on account of its exposed position, be the first place to show manifestations of their presence. These congested or inflammatory processes may not be confined to the pharynx, but may conjointly or separately involve the larynx and the nose.

Professor A. Haig, of London, by a series of investigations, has shown, first, the amount of uric acid found in the body bears a direct relationship to the amount of proteid food consumed. Second, under normal conditions of the fluids of the body, uric acid is conveyed to the kidneys and there eliminated. Third, under conditions of diminished alkalinity of the blood, uric acid is precipitated out of the blood into the tisues and joints that furnish the greatest attraction, viz., the liver, spleen, cartilages of the joints and fibrous tissues. Fourth, uric acid is constantly fluctuating, according to the increased or diminished alkalescence of the blood. Fifth, the precipitation of uric acid and urates into the fibrous structures of the joints constitutes true gout, and when deposited in the sheaths of the muscles it produces rheumatism.

When elimination by the mucous membranes, catarrhal inflammations may supervene, resulting in gall stones, rhinoliths and tonsilloliths. Sixth, when an excess of uric acid is circulating in the blood the nervous system is profoundly influenced by its presence, as manifested by mental depression, despondency, melancholia, irritability of temper and a small, hard pulse, with increased arterial tension—a condition so often found in the catarrhal subject.

The small, hard pulse, with increased arterial tension is due to contraction of the capillaries and arterioles, induced by stimulation of the vaso-motor centers in the medulla. The physiology of the sympathetic with its vaso-motor fibers gives us a key to the explanation of Professor Haig's deduction from an abnormal amount of uric acid circulating in the blood. Uric acid is an irritant to the nerve centers, but all people are not alike susceptible to its irritating influence, and herein lies the explanation that lithemia may be apparently harmless to one and a powerful irritant to another. Uric acid usually manifests itself in one of three ways, (1) a deposition in the cartilaginous and fibrous tissue, producing gout and rheumatism. (2) Deposition and retention in the pockets of mucous tracts resulting in gravel, cystitis and tonsilloliths, rhinoliths, etc. (3) By innervation or indirect action while circulating in the blood, causing functional neuroses. There is no doubt that lithemia plays a large part in the development of functional neuroses which applies to the mucous membranes as well as other tissues of the body. When there is an excess of uric acid in the blood, pathological results will follow in direct proportion to the resisting power of the nervous system. Our American people, on account of their manner of living and business methods, are doubly exposed to the invasion of toxic and lithemic troubles. The great danger of our country becoming one of lithemic neurotics was pointed out by J. M. Fothergill years ago. We have only to look to our asylums and great army of catarrhal dyspeptics for proof of his saying.

Dr. Morris H. Henry, of New York, has recently made the statement: "There can be no doubt that the errors in diet and the tendency to over-eating in this country is leading to the development of lithemia in a large class of our population." My observation leads me to believe that a great class of our people consume too much nitrogenous food and do not take water and exercise sufficient to wash away the products of tissue changes. When the liver is overtaxed, the result is uric acid formation. This leads to vascular changes, as before stated, that may express itself in Bright's disease and many of the forms of irritation that are found in mucous membranes, especially in the upper air tracts. Naso-pharyngeal inflammation, laryngitis, bronchitis and otitis in all

their forms are more or less influenced, if not entirely due, in many instances, to lithemia, auto-infection, or both.

Many of our best rhinologists recognize lithemia toxemia as a potent factor in the production of naso-pharyngeal catarrh. There is quite a revival in the investigation along the lines of the composition, the variations, and the chemistry of the fluids of the body. Also their influence as manifested by depletion and tension of the vessels and mucous surfaces through vaso-motor control. Hyperesthesia, migraine, and the various forms of neuralgia may be caused by pressure irritation. If lithemia will cause hyperemia and set up eczema upon the skin, why not in the nose?

We should not place too much stress upon the conditions and structural changes in the nose and throat; excluding all other factors as the cause of the disease, diseased turbinates may be a sequence or coincidence. Long continued disturbance of the vaso-motor supply of these parts may result in passive hyperemia which may, if continued, result in proliferation of cells in the tissues forming true hypertrophy that will serve as a nidus for irritating agents, as the faucial tonsil, for example.

The pain and discomfort of a lithemia throat can not always be accounted for by the systemic disturbance as indicated by the temperature and constitutional disturbance. One of the first and perhaps the most constant symptoms is congestion and swelling of the lymphoid tissues behind the posterior pillars of the fauces. In well-marked cases the uvula will appear congested and stiff, and in some cases edematous. Patients will complain of dryness and pain, extending to the ear, in attempting to swallow. A feeling of tightness, or constriction, and a pricking sensation is a common symptom that precedes an acute attack of migrane, articular or muscular rheumatism. The primary cause of many cases of vaso-motor coryza, pharyngitis, laryngitis and bronchitis is lithemia. These cases, as a rule, lead sedentary lives, are under-exercised and overfed. The underfed individual neither takes cold nor suffers from lithemia or rheumatism. The over-fed body is worse off than the under-fed, because it is doubly taxed to dispose of what can not be appropriated and when not properly disposed of remains to undergo fermentation and chemical changes that become elements of danger. Uric acid as found in the blood consists of sodium salts, either as a biurate or quadriurate, or in both forms. The latter are soluble in blood serum and will not precipitate in crystals, while the biurates are only slightly soluble and are readily precipitated in the form of crystals.

It is generally conceded that the uric acid diathesis is primarily due to diminished alkalinity of the blood. Therefore, the treatment must be directed toward the restoration and maintenance of the normal alkalinity.

It is not my purpose to speak at length on the treatment of lithemia further than to insist that a well-directed treatment along these lines will benefit or cure a large class that apply to us for relief from some annoying disturbance of the upper air passages, with more dispatch and certainty than by any other method. In the lithemic subject the local manifestations are the expression of a systemic disorder; local treatment does not amount to much except for its psychologic effect, and when used, should be mild in character and directed to cleansing only. Strong, stimulating and astringent applications are contra-indicated, as they only aggravate the symptoms. Mild antiseptic sprays or douches to remove the viscid secretion and hot mentholated or saline gargles are very grateful.

Our principal treatment must be directed to the cause, which we have determined is either retention and absorption of acid urates, or auto-intoxication caused by absorption of by-products from the intestinal tract. The remedies on which most reliance is placed in the treatment of these cases are, first, calomel and salines, to stimulate metabolism in the liver and clear out the alimentary tract, to be followed by the alkaline salts of sodium, potassium and lithium, colchicum, guaiacum and natural mineral waters. The object being to increase the alkalinity of the blood and stimulate oxidation, thereby retarding the formation of uric acid and the growth of pathogenic micro-organisms. Strict attention must be given to the diet.

The injunction to abstain from certain nitrogenous foods, wines, liquors and excessive smoking must be imperative. The copious use of water, both internally and externally, is of the greatest value. Baths should be taken regularly, followed with rubbing, to excite the functions of the skin. Exercise, especially in the plethoric, should be insisted upon. With these suggestions carried into effect, many of these cases will forestall surgical operations, and the physician will receive his reward in putting more sunshine and happiness into the lives of his patients.

[Written for the MEDICAL BRIEF.]

The Use and Abuse of Calomel.

BY ROBERT C. KENNER, A. M., M. D.,

Ex-President of the Louisville Clinical Association; Editor of the Third, Fourth and Fifth American Editions of Garrod's Materia Medica and Therapeutics; Ex-Secretary Muhlenburg County Medical Society, etc. Louisville, Ky.

I am convinced that calomel is more recklessly used than any other drug in our *materia medica.* An extensive acquaintance with the medical profession, especially in the Southern and Western States, has led to this conviction. That calomel is used recklessly, and in a manner altogether unwarranted by the true therapeutic scope of the agent, one has only to attend medical societies and converse with many practitioners to be convinced. Formerly—that is, when our forefathers were at the helm—calomel was employed in nearly all diseases. That this wrought great damage to their patients there can be no doubt. But it is true that calomel, in many sections of the country, is used almost as often as in the past generation.

I am sure that the mortality which attends upon many diseases is due to the lessening of the resisting powers by the debilitating effect of calomel. This fact has forced itself upon my conviction after extensive and critical observation.

Let me now take up the consideration of calomel from a purely therapeutic standpoint, and in this way make manifest what is considered the proper use as well as the abuse of calomel.

Calomel has been used locally with some degree of success. In a ten per cent ointment its application to indolent ulcers has been attended with good results. It is claimed by good observers that this ointment is valuable in eczema and other cutaneous diseases attended with pruritus. Calomel has also been applied in powder form to ulcers, chancres, etc., with success.

A full dose of calomel (five to fifteen grains) is followed usually in about eight hours by a copious action, which is mucous, brown or yellow or green. In children, the stools are almost invariably green. The peculiar color has long been thought to be due to the bile contained in the feces. This is, too, an attested fact. This fact has led many to the very incorrect conclusion that calomel increases the amount of bile by its special action on the liver. The fact is, as Curtis points out: "Biliary stools, following a calomel purge, result as a natural consequence of an assumed action of calomel in rushing down, as it were, the contents of the duodenum, so preventing that reabsorption of a considerable portion of the bile present in the intestinal contents which is claimed to be a normal occurrence." On this point Bartholow says: "The misconception of the action of mercurials on the liver as prevailed chiefly because of the peculiar evacuations produced by it. * * * The experiments of Rohrig, Rutherford and Scott on animals, and the observations of Westphalen and Ranke in cases of biliary fistulæ in man, have thrown a flood of light on the action of mercurials, and there seems to be no longer any reason to doubt the accuracy of the conclusions reached. It has been shown that calomel lessens the physiological activity of the liver, and consequently diminishes the production of bile. Instead of stimulating the liver or acting as a cholagogue, calomel must be regarded as a sedative, and as having the power to allay an irritable state of the liver. Oddly enough, this fact harmonizes in the most satisfactory way with clinical experience, for calomel has always been regarded as useful in the highest degree in those cases of biliousness characterized by a surplusage of bile, due to an overacting liver. Under such circumstances an active cholagogue,

stimulating the productive capacity of the organ, would only increase the existing complications." Calomel may be said to be the proper remedy for biliousness, but the foregoing proves how very erroneous is the belief so generally entertained that it stimulates bile-production. The statement is often heard "he needs some calomel to make his liver act." This belief is responsible for much physical woe. The number of cases of pytalism that can be traced to efforts to "get the liver to act" are very numerous, and the debility which these efforts have emphasized, has, it is reasonable to believe, proved the sufficient burden to sink the hard-pressed life vessel. It has been pointed out by several able therapeutists that calomel, even in small doses, often produces salivation. There is a degree of uncertainty following this action of the drug that renders it by no means a safe agent.

To relieve vomiting, calomel is useful in many instances. In doses of one twelfth of a grain it has been very efficacious in allaying the nausea and vomiting of malarial fevers. In persistent nausea and emesis in other diseases it has often acted promptly and satisfactorily.

As anthelmintic, either alone or in combination with santonin, calomel has some reputation. Chapman and other extensive observers, however, have not thought the action of this agent superior, or that it was constantly reliable for this purpose. My own observations have led me to place a low estimate upon calomel as anthelmintic. I have found no advantage even in combining calomel with santonin.

Calomel is used by some preferably as an antisyphilitic. When used for this it is often—generally, in fact—combined with opium, or used in fumigation.

Hutchinson uses it in combination with opium, and others have advocated it in this way, but careful study has led me to the belief that other mercurials are better adapted for internal administration in syphilis. The employment of calomel in the treatment of syphilis by fumigation was favored by the late Professor L. P. Yandell and other syphilographers of extensive experience and ability.

That calomel possesses diuretic properties there can be no reasonable doubt. It is combined with squill and other diuretic drugs in the treatment of dropsy and other conditions by many practitioners. Still the trend of the medical profession is against the employment of calomel for this purpose. The associated evil results which may flow from the employment of calomel, plus the fact that as good or better results may be attained from other remedies which are essentially harmless, are sufficient to relegate the employment of the agent as a diuretic.

A great many practitioners, for reasons already given, have the idea that calomel is appropriate and very valuable in the treatment of affections of the liver. On this point I may quote the words of Bartholow, who says, "The experience of the India medical officers has shown conclusively that mercurials are harmful in acute hepatitis, hepatic abscesses, jaundice from gall stones, acute yellow atrophy, etc. As these affections are very rife in India, an experience which has led to such conclusions should be heeded." It is thought by some physicians that in the diarrheas of infants and children, that calomel is most valuable. There is, to my mind, no greater mistake. A trial of calomel on a large scale has thoroughly convinced me that it exerts no beneficial action; but, in fact, works great detriment to the patient and often leads to disastrous results. On this point the author just quoted says, "Children are quickly poisoned by mercurials, although they are not easily salivated. The spinach-colored stools which so frequently occur in the summer complaint of children, and which are, by ignorant practitioners, supposed to be produced by the mercury administered, really belong to cases of ileo-colitis, and may, by their persistence and profusiveness, signify an increased irritation of the intestinal mucous membrane due to the remedies given." My experience has been to convince me that calomel irritates and therefore intensifies the alimentary canal, where it is administered in the various types of inflammations of this part of the economy. In a very malarious part of the Southern States, where the writer spent a year studying malarial fevers, he was told that it was impossible to attain successful results in the treatment of the various malarial fevers unless the patient was "well

plied with calomel" at the incipiency of the attack. This was found, after a thorough trial in four hundred cases, to be false. I could more quickly control the fevers when calomel was withheld. This conclusion was reached by the late Professor Austin Flint, who tested this assumption in the treatment of malarial fevers in New Orleans. It is no longer thought a wise course to give calomel in pneumonia and other acute inflammatory affections. Formerly it was given in combination with opium. The good results are now known to result from opium. Still, there are found some antiquated men who believe it necessary to "touch the gums" in the treatment of inflammatory affections.

In croup, it is believed by some that calomel is valuable. Some use it in diphtheria, but the assumption of its value is illogical, and not supported by extensive clinical tests. The same can be said of the employment of calomel in typhoid fever.

Oral Hygiene.

BY W. T. MCLEAN, A. M., M. D., D. D. S.,
Professor Oral Hygiene, Dental Ethics, Cincinnati College of Dental Surgery, Dental Department Ohio University.
Cincinnati, Ohio.

The above title signifies a condition that is everywhere prevalent in the various stages in the mouths of our people, and it is but recently that the oral specialists have concluded that the care of the mouth hygienically is an absolute necessity, and has been almost entirely neglected hitherto. The advisability of having the mouth thoroughly examined at stated intervals by a competent dentist has become a law among the better cultured practitioners of medicine. This new duty on the part of the laity is necessitated on account of the many disorders that are known to arise from a laxity of hygienic care on the part of patients. Dyspepsia, purulent bronchitis, affections resulting from the inflammatory condition of the nasal pharynx, and acute chronic rhinitis, are often the source of a very unpleasant condition—pyogenic exudation from the alveoli, caries of the teeth, destroyed tooth crowns and retained roots are the underlying cause of many of these conditions. Some authorities have called attention to the fact that the salivary excretory excesses because of gingivitis produce digestive disorders, either by the swallowing of vitiated saliva and by pathologically diluted gastric juice, cause indigestion, vomiting and possibly diarrhea, or by the escape of the saliva externally by expectoration, digestion particularly is interfered with through insufficient salivation.

There are times when patients are seen in whom the septic condition of the mouth has reached a stage in which the power of resistance in the affected tissue is completely overcome. The teeth are found to be infected and the mucous membrane is contaminated by coming into contact with them. Inflammations arise and many times ulcers of no mild degree are the result.

The medical practitioner must necessarily refer his patients that are suffering from such conditions to a competent dentist and insist upon the teeth and mouth as a whole being placed in an absolutely normal condition before such patients can possibly expect good results from systemic medication.

My experience in this field of practice is very gratifying, as I have several physicians who regularly refer patients to me for teeth and oral treatment. I am very glad indeed to notice the upward trend on the part of the medical profession recognizing the success achieved in oral treatment by dentists.

The great variety of dental operations performed by our modern dental surgeons are, to many of the laity, surprising, even appalling. The salvation of the natural teeth and their substitution by artificial means is an art well worthy of the highest appreciation. Pages might be written upon the subject, but to sum up in the most concise manner, I shall say that our physicians, irrespective of their specialty, should not forget that they should affiliate with the dentist and oral surgeon professionally, and thus facilitate the scientific labor of each in their special work, and materially aid in cultivating the respect and usefulness of both.

[Written for the MEDICAL BRIEF.]

The Diagnosis and Treatment of Femoral Hernia.

BY ALFRED DE ROULET, B. S., M. D.,

Chicago, Ill.

Formerly Professor of Clinical Surgery and Gynecology in the Medical Department of Trinity University.

A femoral hernia may be defined as a protrusion of some portion of the abdominal or pelvic viscera through the crural ring, the anatomical boundaries of which are Poupart's ligament above and in front; Gimbernat's ligament internally, the pubis and pectineus muscle below and behind, and the ilio-pectineal ligament and the portion of the fascia lata covering the femoral vein externally.

As regards the frequency of the occurrence of femoral hernia, approximately eight per cent of all hernias are of this variety, and of all femoral hernias from seventy to eighty per cent occur in women, as, owing to the greater breadth of the female pelvis, in women the femoral ring is much larger than it is in the male. Femoral hernia also occurs most frequently in early adult and middle life, approximately sixty per cent of all cases occurring between the ages of twenty-five and fifty, while less than ten per cent occur in patients under twenty-five. In young children the condition is almost unknown. In unilateral femoral hernia the protrusion appears on the right side nearly twice as often as on the left. Both sides are affected in about ten per cent of all cases.

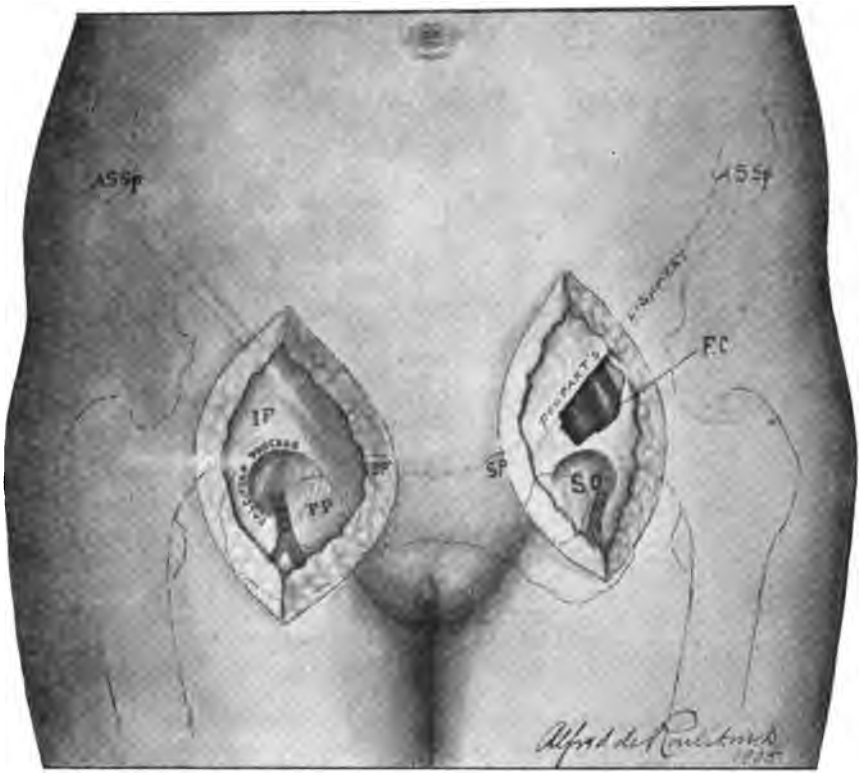

Fig. 1. AS. Sp., anterior superior spine of ilium; FC, opening through fascia to show position of iliac vessels; IP, iliac portion of fascia lata; ISV, internal saphenous vein; PP, pubic portion of fascia ata; SO, saphenous opening; SP, spine of pubis.

In the development of femoral hernia the parietal peritoneum is pushed through the crural canal to the cribriform fascia and emerges at the saphenous opening. The only landmarks of importance are Poupart's ligament above, the femoral vessels externally, and the spine of the pubis internally. (Figures 1 and 2.) Ordinarily

the hernia ranges in size from a walnut to a hen's egg, but in rare instances it may extend down the thigh, attaining the size of a man's fist. In some cases, where the line of least resistance leads upward, the hernia may override Poupart's ligament and closely simulate an inguinal hernia. This extension upward over Poupart's ligament, however, is not a characteristic of this form of hernia, neither does it occur at all frequently, consequently the statements of certain writers that this is the typical form of femoral hernia are erroneous.

The hernial sac usually contains omentum, or omentum and bowel, though in

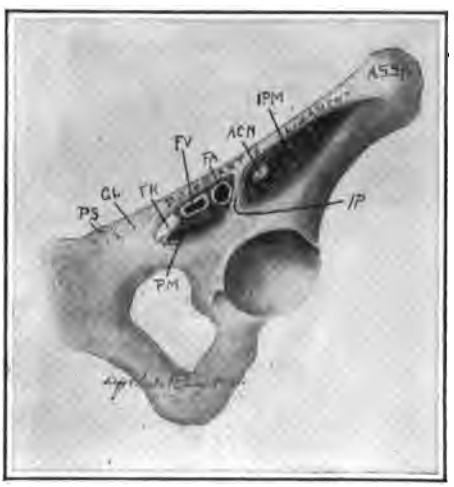

Fig. 2. ACN, anterior cutaneous nerve; ASSp, anterior superior spine of ilium; FA, femoral artery; FR, femoral ring; FV, femoral vein; GL, Gimbernat's ligament; IPM, ilio-psoas muscle; IP, ilio-pectineal ligament; PM, pectineal muscle; PS, pubic spine.

rare instances an ovary, or even a portion of the urinary bladder, has been found.

The signs and symptoms are about the same as in inguinal hernia. Pain of a more or less aching character is observed in the majority of cases, but, as a rule, it is less severe and less constant than in inguinal hernia. The pain is greatly increased by exertion. Swelling, with numbness of the leg on the affected side, is considered by many writers to be an important diagnostic symptom, but it is so rarely seen that it is of little if any value.

Under ordinary circumstances there is no great difficulty experienced in differentiating femoral from inguinal hernia, if it is borne in mind that the protrusion in inguinal hernia appears above Poupart's ligament, while the protrusion in femoral hernia appears below Poupart's ligament. In fat patients, where this ligament can not be outlined, a line drawn from the anterior superior iliac spine to the spine of the pubis, indicates its course and position. In cases of irreducible femoral hernia, where the sac overrides Poupart's ligament, there may be considerable difficulty in making a correct diagnosis, but with patience it is usually possible to determine the condition.

Inflammations of the femoral lymphatics are often mistaken for irreducible femoral hernias and *vice versa*. In adenitis there is no perceptible impulse on coughing, and in most cases it is possible, on careful palpation, to make out a more or less distinctly lobulated condition of the mass, as it usually consists of several glands matted together. Where but a single gland is greatly enlarged the resemblance to an irreducible omental hernia is so striking as to deceive even the elect. In adenitis, however, it is often possible to push the enlarged glands to either side of the femoral ring, thus proving that it does not enter the canal. In obscure cases the history will often furnish valuable aid in making the diagnosis.

Saphenous varix is another source of error in making a diagnosis. The tumor not only resembles exactly a femoral hernia in shape and situation, but it gives a distinct impulse on coughing, and is reducible under pressure when the patient is lying down. The differentiation, however, is so easy as to render a mistake inexcusable. Practically all cases of saphenous varix are accompanied by varicose veins on the thighs and legs, and in all cases of saphenous varix, after the tumor has been reduced, it slowly reappears, even though a firm pressure be applied continuously over the crural ring.

A psoas abscess may resemble a femoral hernia so closely as to render differentiation quite difficult. It may appear in the exact position of the hernial protrusion; it may give an impulse on coughing, and it may disappear on pressure. The differentiation is made by careful palpation. The patient should be placed in the recumbent position; then, with one hand pressed deeply into the pelvis, the exam-

iner makes firm pressure directly on the tumor. Instead of slipping into the abdominal cavity, the tumor is displaced into the pelvis, where it can be felt distinctly. By this method the presence of fluctuation may also be determined. In all cases where there is reason to suspect the presence of psoas abscess the spine and pelvis should be carefully examined for evidences of bone disease.

Carcinoma of the femoral lymphatics may be mistaken for irreducible femoral hernia, but, fortunately, this condition is very rare, and when found is usually secondary to cancer, involving the foot, leg, vulva, or rectum; consequently, a careful examination of these regions is necessary in all doubtful cases. Occasionally a femoral hernia on the right side is diagnosed appendicitis. The dull, aching pain in the groin, extending upward toward McBurney's point, the rigidity of the right rectus, and the exceedingly difficult and painful locomotion, together with a hernial protrusion so small as to be scarcely noticeable, is sufficient to mislead the ordinary observer. This mistake is rather more frequently made in femoral hernias occurring in men than in those occurring in women. In women the pain due to the hernia is not infrequently attributed to ovarian and tubal troubles.

As regards the prognosis in femoral hernia, owing to the frequent presence of omentum in the sac, adhesions soon form, and the hernia early becomes irreducible. Strangulation is frequent, almost a third of all cases of femoral hernia operated on are for the relief of strangulation, rather than for the cure of the hernia. In the cases operated on for the relief of strangulation the death rate is very high, being given by different authors at from twenty to forty per cent. In my opinion twenty-five per cent is a fair estimate. In operations undertaken for the radical cure of non-strangulated femoral hernia the death rate is very low, being in the neighborhood of one-half of one per cent, in skilled hands. Consequently, the patient who declines the operation is run-

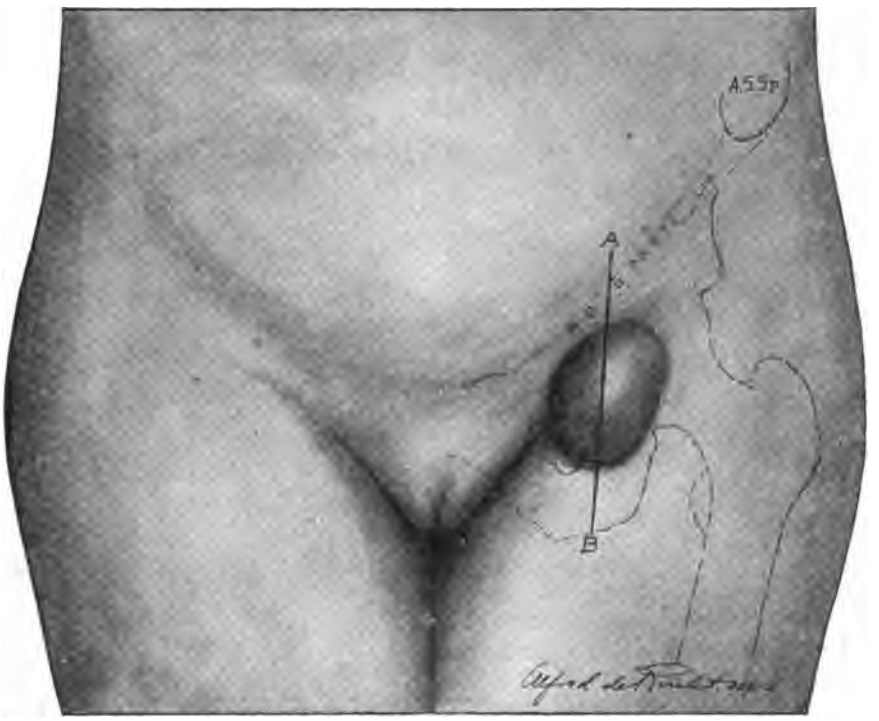

Fig. 3. Showing relation of hernial protrusion to Poupart's ligament; AB, line of incision in radical operation.

ning greater risks than the one who accepts such treatment.

Recurrences of the hernia, after operation, are not frequent, and when they do

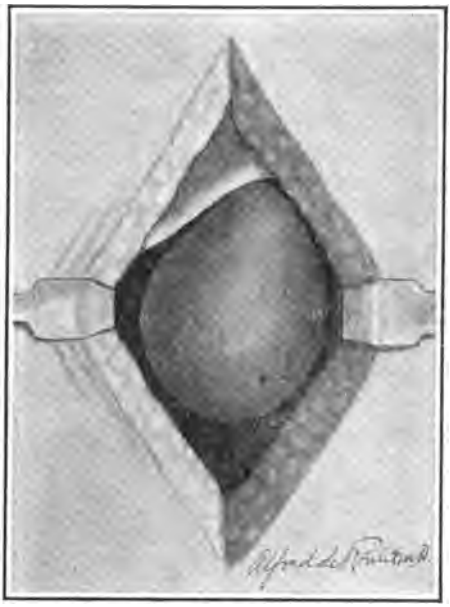

Fig. 4. Hernial sac exposed.

occur may usually be traced to some fault in the operative technique, as imperfect clearing of the canal. Occasionally, however, the recurrence may be due to causes which could neither be foreseen, nor prevented. For example, in the only case of this kind which has come under my observation the recurrence immediately followed a violent fit of vomiting two weeks after the operation.

The treatment is essentially operative. No treatment other than a radical operation has ever been known to cure femoral hernia. Owing to the proximity of the femoral vessels, the injection method is exceedingly dangerous, as well as of questionable value, while a truss is applicable only in cases of reducible hernia, after the hernia has been reduced, and even then can not be relied upon implicitly.

The particular operation employed is not of vital importance, so long as the crural ring is entirely cleared of hernial tissue before it is finally closed. An operator will secure the best results with the operation with the technique of which he is most familiar. In my hands the following operation has given the best results. It has simplicity and effectiveness in its favor, and it does not disturb the normal anatomical relations:

The incision (Fig. 3, AB) should begin well above Poupart's ligament and extend downward for about three inches, parallel with and to the inner side of the femoral blood vessels. As the skin and superficial fascia are divided the hernial sac bulges into the wound. (Fig. 4.) The sac should be freed by blunt dissection from all attachments, special care being taken to isolate the portion of the sac passing through the femoral ring. This procedure is greatly facilitated by making gentle traction on the entire hernial mass. After the sac is entirely freed it is carefully opened and the contents examined. Omental adhesions are often found, while adhesions between the sac and the bowel are comparatively infrequent. Should adherent omentum be found it should be carefully ligated and cut off, and the stump returned to the abdominal cavity. Where

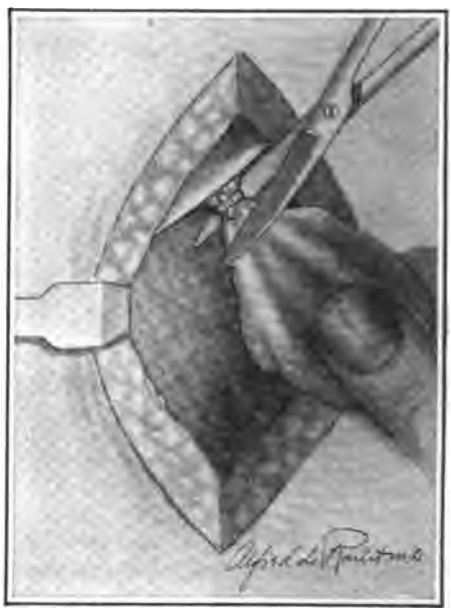

Fig. 5. Hernial sac ligated and cut off.

the bowel is adherent, if the adhesions are neither firm, nor extensive, they may be cautiously broken up, but should they prove so firm as to render this procedure dangerous, it is best to trim out the adherent parts of the sac and leave them

attached to the bowel when it is returned to the abdominal cavity.

After the sac has been entirely freed of its contents it is drawn down as far as possible, and the neck transfixed and ligated close to the femoral ring. For this purpose No. 2 catgut is the best material. The sac is now cut off (Fig. 5), and should the stump not immediately retract well within the abdominal cavity, it should be carefully pushed back. It is absolutely essential to the success of the operation that no trace of hernial tissue be left in the crural canal.

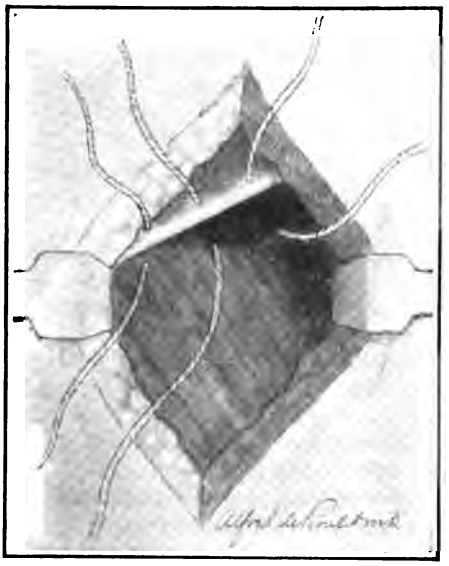

Fig. 6. Sutures placed but not tied.

The tip of a finger is now pushed up into the femoral ring to protect the femoral vessels, while the first suture is passed through Poupart's ligament, then the finger is withdrawn and the needle continued downward through pectineal muscle to the periosteum of the pubis, then forward through the tissue overlying the femoral vein. This is the first stitch; the others are placed in exactly the same manner, a quarter of an inch apart from the outer angle of the femoral ring to the pubic spine. (Fig. 6.) When the sutures are tied the lower edge of the inner end of Poupart's ligament is brought in contact with the pubis (Fig. 7), and the femoral opening is obliterated. It is immaterial whether the continuous or the interrupted suture is employed. Personally, I prefer the continuous, but for the sake of greater clearness have shown the interrupted suture in the illustrations.

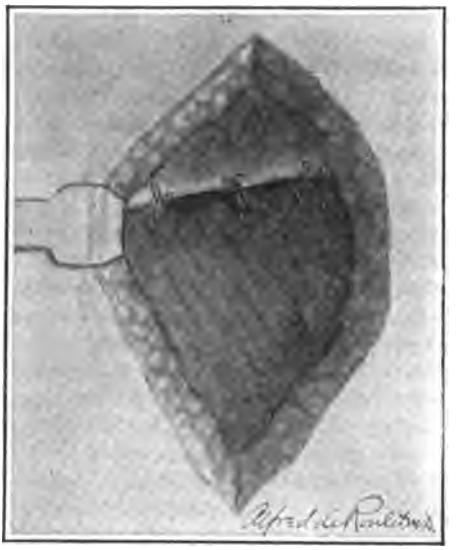

Fig. 7. Sutures tied, and Poupart's ligament drawn down on horizontal ramus of pubes.

In some instances it would seem advisable to bring the edges of the superficial fascia together with a continuous catgut suture. The skin is closed with a running catgut or silk suture.

The wound should be dressed with a large compress of gauze wrung out of a hot, saturated solution of boracic acid,

Fig. 8. Dressing applied.

over this several layers of dry cotton, and the whole held in place with a binder, as shown in Figure 8. This binder is simply a piece of heavy, unbleached sheeting,

four feet long and eighteen inches wide, with a strip four inches wide torn along the lower edge to a point eighteen inches from the end. A reference to the illustration renders any explanation as to its application unnecessary.

The dressing should not be disturbed for ten days, unless the patient complains of pain, or develops a temperature of over 100° F., or wound secretions show through the dressing. Frequent changes of the dressing only delays healing in an aseptic wound, to say nothing of fatiguing the patient and increasing the possibilities of infection.

At the end of ten days the first dressing is removed, and the wound should be found practically healed. If silk has been employed for closing the skin the stitches may now be removed, and a small, dry dressing, with a firmly applied binder for support, may now be applied.

If healing has progressed satisfactorily the patient may be allowed to sit up after the tenth day, but should not be allowed to leave her room for at least two weeks after the operation. She may resume ordinary housework in from four to six weeks, but should not attempt violent exercise or very hard work for at least three months.

The use of a truss after operation is not advisable. Its more or less problematic advantages, in the way of furnishing support to the parts, are more than counterbalanced by its very evident deleterious effects in the production of pressure atrophy.

The best ultimate results follow a properly-performed operation, followed by four to six weeks' rest and three months' abstinence from violent exercise.

Some Remarks on Colles Fracture.

BY W. S. WIATT, M. D.,
Professor of Fractures in St. Louis College of Physicians and Surgeons.
East St. Louis, Ill.

Since the description of fracture of the lower end of the radius by Colles in 1814, possibly no fracture has given rise to more suits for malpractice. The reasons for this may be given as follows:

1. Improper or incomplete reduction.
2. Improper retention apparatus.

The cause of this injury is indirect violence, the patient falling on the pronated hand. This has an important bearing on the position which the fragments assume in most cases. The line of fracture is transverse, the lower fragment generally mounting upwards behind the lower end of the upper fragment, or impaction may take place.

The symptoms are pain, localized, and increased on pressure; numbness and tingling sensations may be present through the thumb and index finger. Abnormal mobility and crepitus are difficult to elicit at times, and if impaction be present they are absent. Loss of function is manifested in the patient's inability to use the hand and forearm.

The deformity is characteristic and has been described by Liston as a "silver fork" deformity. It is due to the position of the lower fragment lying on the back of the lower end of the upper fragment. This bulging on the back of the forearm and corresponding depression on the front produces a curvature of the wrist resembling the back of a fork. Frequently laceration of the internal lateral ligament of the wrist joint accompanies this fracture. It may also be associated with fracture of the styloid process of the ulna. If the ulna be dislocated inward, due to laceration of the internal lateral ligament, the styloid process can be felt prominently and the deformity readily made out.

The lower fragment, when situated as it is, on the back of the lower end of the upper fragment, most generally has a bridge of periosteum extending from its posterior surface to the posterior surface of the upper fragment. This should al-

ways be remembered, for if manipulations are not made to relax this bridge of periosteum, reduction may be difficult or incomplete.

This bridge of periosteum, which Pilcher has shown to be present, extending from the back of the lower fragment to the back of the upper fragment, is put upon the stretch, so to speak, so that if reduction be attempted by making straight traction on the fragment, it will be impossible to pull the lower fragment down so as to get it in correct apposition with the upper fragment without tearing in two this bridge of periosteum. In order to relax this bridge, the surgeon must hyperextend the hand, and with the hand hyperextended as far as possible, make straight traction, and then flex the hand.

By the first maneuver, hyperextension, this periosteal bridge is relaxed.

By the second maneuver, straight traction, the lower fragment is pulled from the back of the upper fragment, thence into the position it should occupy, between the carpus and the upper fragment.

By the third maneuver, flexion of the hand and wrist, the lower fragment is pushed into position, making correct apposition of the fragments complete.

Sometimes this fracture is produced by a fall on the back of the hand, then the lower fragment, instead of mounting up behind the lower end of the upper fragment, mounts up in front of the lower end of the upper fragment. This position of the fragments is so rare, however, that it scarcely need be mentioned.

After securing correct apposition of the fragments, the next step in the rational treatment of any fracture is to keep the fragments in end to end apposition.

Numberless splints have been suggested and used for the treatment of Colles fracture. We believe that none of these splints has any feature of sufficient value to especially commend it. We use a straight splint on the flexor side of the forearm, applied as follows:

Lay the patient's forearm on a shingle, mark the shingle on either side corresponding to the contour of the forearm, allowing the ends of the splint to extend from the ends of the fingers to the internal condyle of the humerus. The splint is padded. The fracture is reduced, and if there is an internal dislocation of the ulna, the ulna is pushed back into position, cotton padding is placed under the carpus to fill up any concavity which may be due to the natural contour of the wrist at this point. The wrist is then secured for an inch below the site of the fracture, as well as an inch above, to the splint, with surgeon's adhesive plaster. A spiral reversed bandage then secures the splint to the forearm, and the forearm is then placed in a sling, the thumb pointing to the chin.

This adhesive plaster insures correct approximation of the fragments and prevents any displacement.

If the ulna be dislocated inward, the adhesive plaster will prevent a recurrence of this dislocation, if proper reduction is made before it is applied.

The author has treated a number of cases of Colles' fracture, and has found this to be the most suitable apparatus for retention of the fragments in apposition and has had no case as yet to be followed by deformity or impaired mobility.

The Pathology and a Satisfactory Method of Treating External Hemorrhoids.

BY LOUIS J. KROUSE, M. D.,
Professor of Proctology in the Cincinnati Polyclinic and Post-Graduate School.
Cincinnati, Ohio.

There is little question but that hemorrhoids are dependent upon some pathological alteration of the hemorrhoidal veins for their origin, and these pathological changes being present any undue pressure may cause an aneurysmal dilatation of the vein. It is true also that the internal coat of the vessel being altered, there is more tendency for the coagulation of blood with the formation of a clot; also that the sexual activity of an individual increases the intravenous pressure and causes a stagnation of the blood which favors the development of the tumor. It is therefore a disease of adult life.

External hemorrhoids are usually divided into two distinct varieties, the acute

or sanguineous, and the chronic or connective tissue variety.

The acute or sanguineous are usually found single, of globular shape, tense in outline, bluish in color, and very sensitive to the touch. The size varies from a pin's head to that of a small walnut.

The chronic or connective tissue type is the later stage of the acute sanguineous variety.

The acute or thrombotic piles are connected with the inferior hemorrhoidal veins, and are due to a thrombosis forming in an aneurysmal dilatation of the vein, and are situated in the vessel and not in the connective tissue outside of the vein. In other words, the clot is found in the vein and is not an extravasation of blood in the connective tissue.

In order to have a thrombotic hemorrhoid it is necessary to have a diseased condition of the walls of the vein. The pathological causes producing this are the same as those which produce a varicose condition of the long saphenous vein of the leg, and the spermatic veins of the cord.

The majority of authorities state that external piles are due to a rupture of the blood vessel with extravasation of blood in the surrounding connective tissue. Nowhere else in the body do we find a similar clot formed from an extravasation. Artificially we can not produce a clot in this region by lacerating the vessels. In the preliminary step for all operations on the lower end of the rectum the sphincters are dilated, and, as a consequence, the blood vessels are ruptured. We merely see a discoloration of the parts due to extravasation of blood, similar to that met with in other parts of the body, but we do not meet with the little clot as we see it in external pile. This, to my mind, proves conclusively that external hemorrhoids are not due to extravasation, but to a thrombosis formed in the vein.

While there is very little likelihood of an error in diagnosis, it not infrequently happens that sentinel piles, on the border of an irritable ulcer, or venereal warts or condylomata, are mistaken for them.

Treatment is simple, consisting mainly in keeping the bowels open, and applying soothing lotions to the parts. When medicinal treatment does not avail, operation is to be recommended. That consists in the removal of the offending parts.

The connective tissue variety being the later stage of the acute thrombotic, is less painful, and can be removed, under local anesthesia, by means of a scissors, the tissue being cut to the level of the surrounding skin.

In the sanguineous variety, the first step is the injection, with a hypodermic needle, of a local anesthetic, cocaine or sterilized water, after a thorough cleansing of the parts. With a tenaculum the tumor is transfixed and the top of the pile is cut off.

A method very commonly advocated is to split the tumor with a sharp bistoury, turn out the clot, and insert a small gauze drainage, which is permitted to remain for a day or two.

My preference for the first method is based upon the fact that the external wound is constantly open, and allows free drainage; there is little possibility of a reaccumulation of blood in the sac.

The Value of Gynecological Examinations.

BY BEN L. DORSEY, M. D.,
Professor of Gynecology Barnes University.
St. Louis, Mo.

Owing to a lack of knowledge of various gynecological conditions, many physicians refrain from interceding in their patient's behalf. In many locations where valuable counsel is unavailable, physicians do not enter into details in making proper examinations. How often are we confronted with gastric symptoms found in patients who have been treated year after year with various remedial agents in the hands of many physicians. In such cases had these physicians used palpation, percussion, or even availed themselves of the assistance of anesthesia, they could have determined beyond a doubt the existence of a floating or wandering kidney, and a condition be revealed which no amount of anti-dyspeptic treatment could remedy.

Again, modesty is also a factor which may prevent many sincere physicians

from making a proper diagnosis, and the results secured are not those which have a tendency to elevate the physician in the eyes of his patient.

Many symptoms are so slight as to pass unnoticed by the patient, and yet are of marked interest to the physician. Especially is this true in the younger cases. Occasionally we are confronted by certain conditions, the symptoms of which are almost pathognomonic of a widely dissimilar condition. Many patients, women in particular, are not quite sincere, and their statements may not be confined to any point which may be of interest to you from a diagnostic standpoint. On the other hand, we may find patients who are sincere so far as their knowledge is concerned, who have years previously been treated for conditions of which they were not aware, and as a consequence, these patients are not prepared to make a proper statement when questioned by you for diagnosis. We see this illustrated every day in our clinics. How many cases of salpingitis, due to gonorrheal infection of many years standing, have you treated? And yet the patient may declare that no such infection had ever occurred. Nor are women always honest with the physician regarding the number of abortions which may have occurred, nor the time of their occurrence. How frequently will a little laceration of the cervix, or a discoloration of the mammary glands, or Montgomery's follicles, cause the physician to pause? Many times have I noticed the stria gravidarium in certain cases in which the husband would have been shocked had you informed him that his wife had given birth to a babe at full term, or that an abdominal cystic condition had formerly existed.

Subjective symptoms are often of no importance in making a diagnosis. We should depend largely upon palpation, bimanual examination, the microscope, cystoscope, anesthesia and inspection.

Position during examination is of importance. The knee-chest position enables us at times to discover certain tubal conditions which had not been suspected.

Even the recto-vaginal examination may determine certain forms of anti-flexion which have been mistaken for uterine fibroids. Patience is also a factor, and if more generally exercised early operations for fibroids, fibromas and cystic conditions would not terminate when pregnancy was discovered. In cases where the physician is in doubt and no symptoms exist which indicate an early operation, it is wise to be cautious before submitting the patient to a celiotomy or any operation.

A Few Important Details Necessary for Infant Feeding.

BY LOUIS FISCHER, M. D.,
New York City.

The problem of infant feeding is one that requires thought and consideration. When breast milk can be procured, then the problem is usually solved. On the other hand, when we must resort to "hand" feeding, then the details necessary must be carefully studied.

It is strange that the food in a given formula will be digested and retained, and give marked evidence of "agreeing" with the baby. This same formula prepared in the same manner and prescribed for an infant of the same age and apparently the same development, may cause marked gastric or enteric disturbance, and give no end of trouble.

The question, therefore, arises, why is this so? Is it because there are different degrees of assimilation, or is it because the gastric or enteric secretions are not as well developed, or are of a different quality; or, is it because of the various methods of heating the milk?

That this is usually so is proven by the fact that the formula heated to a temperature of 212° F. will, usually, induce constipation. Whereas, the same formula, heated to a temperature of 150° F. (usual temperature of pasteurization), or simply warming the mixture to blood head (temperature, 100° F.), gives a soft, homogeneous stool.

To be sure, regarding the proper assimilation of any food in an infant, it is necessary to study its individual requirement. In my book* on infant feeding

* Louis Fisher, "Infant Feeding in Health and Disease," third edition, F. A. Davis & Co., on p. 103.

I lay down a series of rules that should govern the feeding of infants in general.

Each child is a law unto itself and its individual wants must be studied.

One child will gain on the same mixture on which another will lose weight.

The infant must appear satisfied after taking its bottle.

There should be no vomiting, nor severe colicky pains.

The bowels must move unaided, at least once or twice in twenty-four hours. The stools should be yellowish white and medium soft.

The infant should sleep from four to eight hours, at one time, during the night.

The weight must be taken regularly once a week. If an infant thrives it should gain at least four to eight ounces every week. When the child's weight shows no increase, then study the reason, and by all means change the food. It may require more substantial food.

In a discussion on the subject of infant feeding before the Academy of Medicine, October 18, 1900, a few points were mentioned which I should like to emphasize.

First, how should food be heated? A good plan to follow is to imitate Nature. In this way we know what an infant should receive and digest. The breast milk of a woman is *raw*. It is neither boiled nor sterilized. For a number of years I have carefully noted the effect of sterilized milk on the stomach, and more especially on the bowels, and have invariably found a slower movement of digestion, more gastric disturbance, less thorough assimilation of food, as evidenced by cheesy, curded particles of casein, which can be seen in the stools.

The general development of an infant reared on sterilized milk is poor. None will deny that the majority of children fed on sterilized milk develop rickets. Such rickets may be manifested in the earliest stages by constipation. Years ago constipation was looked upon as an early sign of rickets. To my mind it is simply an atony of the stomach, and more especially an atonic condition of the muscular linings of the intestines. The same flabby muscular development which pervades the whole system, the muscles of the arms, back and legs, the muscles of the abdomen show a loss of tone and loss of strength. When such stagnant stool exists and it can be traced to the use of sterilized food, then the remedy is very simple.

I have frequently found cases of scurvy which could be traced to super-heated milk. This over-heating destroys the digestibility of the food and gives the stomach and intestines more work. When it is apparent we are dealing with a case of scurvy then the usual remedy is to substitute raw milk, or simply warm milk, instead of the boiled or sterilized milk, which has caused the trouble. I, therefore, have been led into the habit of giving sterilized milk, which usually results in rickets or scurvy, and then treating the condition by giving raw milk. It seems to me, therefore, that we should impress upon those who modify milk that the principle of sterilization should be employed in the stable; to the cow, to her udder, to the milker's hands, the pail, and to every utensil brought into contact with cow's milk. In other words, it is our duty to prevent contamination, which means prevent filth from entering the milk. It is self-understood that if manure or dirt is in the milk that we can not produce a healthy baby by boiling such filth with the milk. Fortunately, by the aid of the Milk Commission and the efficient service of the New York Health Board, we are receiving certified milk, which is carefully inspected, and can be fed in the raw state without fear of causing tuberculosis or other diseases.

A Variety of Findings Between Cause and Effect.

BY PATRICK T. MELDON,

An Experimental Medical Scientist.
San Bernardino, Cal.

We often meet a man who is a very swift runner, or quick walker, but in his physical appearance we see nothing out of the ordinary. He may be rather a short, stout man, or he may be rather tall, tapering and slender. As a rule, the short man has solid flesh and tense and well-developed muscles; the tall man's flesh and muscles are, so to speak, six or eight

imaginary degrees less solid and tense. Another rule which applies to this class of individuals—it should be noted—is their antipathy for physical labor, and their quiet solicitation for a comfortable position in which to sit or to sleep.

In following up a series of investigations among this class of individuals, I noticed a young man of the tall type—a swift runner—in his natural position of sleep. He was so contorted and twisted in the bed clothes it puzzled me to determine which end of him his head was on. "Wake up, Joe," I called lowly and touched him gently. And then stepped aside, remaining perfectly quiet to watch his every action. He slowly sat up in bed, drew up his legs and rested his hands and chin on his knees for all of three minutes. I expected to see him step out of bed at once and stretch and relieve himself after his long-endured contorted position. He stepped out, finally, humped up and stooped over, and gruntingly got into his breeches. He then walked out of his room almost as silently as an owl on wing and, apparently, as swift as a falcon. And, after all, it took him all of twenty minutes before he could straighten himself up perfectly and walk in his natural bearing.

Continuing those investigations showed that this class of individuals—all of them —prefer to sleep, or instinctively sleep, in a contorted position. The contorted position maintains the contractile power of the muscles; while the stretched straightout position strains and exhausts them. A man who sleeps only five hours with his legs well drawn up will get up more refreshed and rested than the man who sleeps eight hours with his legs stretched straight out.

Those findings—without confliction—showed plainly the power which underlies swift running, or quick walking; it is an extraordinary development and well-preserved power of muscular contractility.

An extraordinary development of muscular contractility is no criterion of longevity, yet no man can expect to attain a great age without it. A constitutionally relaxed condition of the muscles means poor health and, of course, not more than moderately long life. It is needless to mention how agile some men are, even at eighty years of age. And in tracing back their life's history we find that they had been very swift runners and quick walkers. Have you ever listened to a very old man tell of how fast he could run in his day and think him only senile and boasting?

The muscles and nerves are co-ordinate with each other, so if a mechanical position of the body—while sleeping—will favor the muscles, it must also favor the nerves. When the muscles are strained and relaxed the nerves are also strained and relaxed; the legs stretched straight out in sleeping the nerves are painfully influenced by the mind, and the resultant suffering is termed rheumatism.

There are two forms of rheumatism—and only those we shall consider—which are evidently manifest in a strained condition of the muscles; those forms are inflammatory and muscular rheumatism. It is the same disease in either case, but its manifestations differ, according to the constitutional nature of the individual. It is inflammatory rheumatism in those who are fleshy, and muscular in those who are lean. The disease easily inflames the plethora in those who have it, and the result, of course, is inflammatory rheumatism. A want of plethora leaves the disease little of anything to inflame; so, in this case—in muscular rheumatism —we see only the muscles apparently affected.

Impure blood is generally regarded as the cause of rheumatism, and it may be so, but since toning the blood to the best possible condition will not even relieve that disease, I do not much credit impure blood as a cause of any rheumatic affection.

The potency of the mind, in this disease, is always directed toward recovering her lost muscular power of contractility. She often does this perfectly, but she often works instinctively, and frequently does her work imperfectly. We often hear a man say, "I have had rheumatism, but it has left me entirely." In that case the instinctive power of the mind worked a perfect cure. In other cases the muscles retrograde, the digitals and other bones are twisted, and joints forced out of their sockets. Here the mind works on faithful and blindedly, and does her work imper-

fectly. It may be said, she works on faithfully, constantly and instinctively, and never knows when to stop. She instinctively works on, often doing more than is necessary; for instance, in uniting broken bones. And in the same way she instinctively works on, often doing more than is necessary—actually an injury in disease of the muscles.

In treating rheumatism as a loss of muscular contractility, one gets the best results. But one ought to have a clear knowledge of the instinctive action of the mind in this disease, and treat the disease accordingly. With this knowledge one can realize the drugs indicated in the incipiency of the case; he sees how long to continue them, when to suspend them, and when to counteract their action with other drugs, if the influence of the mind is going against him.

There are three stages of rheumatism. They are the first, second and third stages. The first stage is from the incipiency of the case to the subsidence of the acute pains and a stiffening of the joints. The second stage sets in as the joints begin to stiffen. While the third stage begins as the joints are being forced out of their socket.

This disease is decidedly curable in its first stage, and with our present knowledge of it, we have the satisfaction of knowing that it can at least be treated thoroughly scientific, with yet the possibility of curing it in any of its stages.

I have closely watched this disease for several years, yet I have treated it only in its first stage. In fact, I have made no attempt to treat it in recent years, as the result of special confinement to other investigations.

Treatment—First Stage.—Inflammatory case: Put the patient on a substantial, nutritious diet; sweat him judiciously, and compel him to sleep in a contorted position, with his legs well drawn up; a mechanical covering of the patient in bed will force this position. Cover him according to the temperature of the weather. If the weather is wintry cold, cover full length of his body with a double blanket of ordinary weight. Fold the next blanket back from his neck, so that the other end of it reaches between his knees and his ankle. The next cover must be folded back so that it reaches only to his knees. On that principle cover the patient in any condition of weather and he will, instinctively, draw up his legs while sleeping.

Every rheumatic patient is disposed to sleep, or rest, stretched straight out; so by simply opposing this disposition an essential step is taken in curing his disease. In fact, too much can not be said in favor of the contorted position in the treatment of rheumatism. Even if the disease is only located in the ankle or wrist, a drawing up of the legs and a drawing inward of the arms will afford it astonishing relief. Next to this treatment are the drugs which assist the mind in recovering her lost muscular power of contractility. And in this strychnin, nux vomica, ergot and dilute phosphoric acid have given the very best satisfaction.

In some cases the muscles retrograde very rapidly in rheumatism, and on that account those drugs are safest when given in their minimum doses; they are contraindicated when the joints evidence the slightest sign of stiffening. As an internal remedy, give three drops of fluid extract of cactus on three to six grains of powdered cubeba three times a day. It stimulates the heart, warms the circulation, and reduces the inflammation by a copious increase in the flow of urine.

Give the patient as many complete immersion hot baths as thought advisable, being careful not to reduce him too severely by this treatment.

The importance of sound sleep in the treatment of rheumatism can not be overestimated; always see to it promptly. From two to five drops of tincture of deodorized opium has given good result in most cases. The patient should be told to take it on his tongue and resist swallowing it as long as possible. In that way its hypnotic influence is had with the least nauseating effect.

Keep the bowels always in a soluble condition, and for this give whatever you think best adapted to the individual case, yet for my part I have found the fluid extract of dandelion to be a very reliable all-around remedy.

Muscular Rheumatism.—It seems to me as if this form of the disease is most rapid in its progress; the muscles are likely to

retrograde rapidly, or the case goes rapidly on to recovery. On this account strychnin, nux vomica or ergot should be used with the utmost caution. One ought to know just how far the disease has progressed before using them, if at all. Hot baths and copious sweating are not advisable in muscular rheumatism, but the rest of the treatment—cubeba and cactus, and dilute phosphoric acid—can be continued.

Always make a reliable diagnosis before offering treatment; the haphazard treatment of rheumatism is constantly causing untold misery. When the second stage makes its appearance in rheumatism it would be best not to treat it at all, if not to treat it consistently. The second and third stages, no doubt, can be treated as one, yet they should, apparently, be treated with drugs opposed to the action of strychnin, nux vomica, and ergot. And, as a matter of suggestion, it seems as if cimicifuga, potassium bromide, chloral, and amyl (nitrite) nitris could be well employed in those stages.

The second and third stages of rheumatism are the result of imperfect sleep. Sleep is the curative influence of the mind over the body. And it is during the awful pain in rheumatism and its attending discontented sleep that the mind does her instinctive injury in disease of the muscles. For that reason I have suggested the use of chloral, and apparently it should be used in time.

Of course, it is needless to say that muscular relaxation is "not" the cause of rheumatism; it is simply the effect of whatever causes the muscles to relax. The muscles may be relaxed, or strained, by constantly maintaining a stretched-out position while sleeping, by hard manual labor, or by exposure to sudden extremes of cold and heat. But exposure to rain and cold, and frequent contact with fresh water—hot or cold—is one of the worst causes of rheumatism, and also a cause of various neurotic affections. Exposure to salt water, as we see in the case of sailors, has just the opposite effect. Sailors, as a result of constantly breathing a salty atmosphere and frequent contact with a blinding salty spray, have solid muscles, steady nerves, and sound and clear lungs.

Sodium chloride is evidently Nature's greatest prophylactic; and in that it seems to be essential in protecting the blood serum against the inoculation of a disease from without, or against the absorption of it from within. But what is most significant in this respect is: Salt unquestionably aids in conducting the impulses of the mind throughout the body, just as molecules of metal aid in conducting a current of electricity from pole to pole. Contact and exposure to rain and fresh water washes the blood serum, as it were, clear of its salt, enfeebling the influence of the mind over the body, causing the nerves and muscles to weaken and resulting in neurotic and muscular affections.

The following table shows how sparingly ailing individuals had been in using salt in excess of the salt used in the cooking of their food:

	Patients.	Used salt moderately.	Never cared for salt, used it only seldom.
Neurotic Affections	100	29	71
Rheumatic	100	15	85
Tubercular	100	18	82

This table would indicate that salt is not quite as essential to the nerves as it is to the muscles.

[Written for the MEDICAL BRIEF.]

Histories of and Deductions From Thirty Operations for Hypertrophied Prostate.

BY M. R. BARKER, M. S., M. D.,
Chicago, Ill.

In previous papers we have given our ideas concerning prostatectomy, and shown our methods in thirty perineal operations. In this paper it shall be our aim to give short and concise clinical histories of these patients, before and after the operation. To do this it will be necessary to abridge, as much as possible; also, to classify the cases. We have stated, in a previous paper, that there were three kinds of hypertrophied prostates, based upon the kind of tissues that enlarges in each case. First, the large, soft prostate, due to hypertrophy of the muscular tissue and over-cell growth. Second, a smaller and more dense form, due to the hyper-

trophy of both muscular and fibrous tissues. Third, a very small and dense form, due to the hypertrophy of fibrous tissue alone. Our first classification will be made upon this basis.

Fig. 1. One-third size.

Of these thirty cases, there were twenty-two of the first-class, or of the large, soft variety. As a matter of course these prostates were not all of the same size, nor shape, neither were they of exactly the same consistency, but they all belong to this general class. Figures 1, 2 and 3 illustrate very well this general class of prostates. Each lobe of these prostates was removed separately and then put in as nearly the same relation to each other as they occupied before being removed, and photographs taken.

There were six cases of the second general class, the prostates in this group being much smaller, harder and more nodular. Figures 4 and 5 illustrate quite well this class of cases. Figure 4 illustrates that class of cases where there are two lateral lobes enlarged and a middle lobe. Figures 3 and 5 have no middle lobe; each lateral lobe is enlarged.

Of the third general class, there were two cases. We can not illustrate this class with photographs, as we had to remove them by morcellement.

These three general classes we shall subdivide into three other classes, according to the physical condition of the patients when presented for operation, as follows: The feeble, incapacitated and partially incapacitated classes.

Of the first general class, that is, of the large soft prostates, there were eight in the feeble, ten in the incapacitated, and four in the partially incapacitated, classes. Of the feeble in this group, there were all degrees of feebleness, from the patient who is able to totter around with a cane, to the one who could not turn in bed without assistance. They were from sixty to eighty years old, and had led catheter lives from six to eleven years; that is, the shortest catheter life among them was six, and the longest eleven years. They had been troubled with enuresis from one to five years. They were all septic. Six of them had from three to five ounces residual urine; micturition from every fifteen minutes to an hour and a half, day and night. Smarting, burning and tenesmus accompanied micturition. All were emaciated. All of this group but two were treated for two weeks before the operation, by means of a catheter through the urethra. Their bladders were irrigated with some antiseptic solution three times daily. We have used in these cases, with equal success, permanganate of potash, and boric acid solutions. Large quantities of water and milk were given. It was impossible to pass the catheter in the other two cases, hence supra-pubic cystotomy was done for drainage and treatment of the bladder. One of these cases died of senile pneumonia four days after the cystotomy, and before we had attempted to remove the prostate. Perineal prostatectomies were done on the other seven cases.

Results in these eight cases: One died as above stated; three were cured of all urinary troubles within one month; two had perineal fistulæ lasting, respectively, six and eight weeks after the operation;

Fig. 2. One-third size.

one had enuresis four months after the operation; one had dysuria, and was compelled to use the catheter about three times a week, for three months, after the operation. Seven were completely cured

of all urinary troubles within four months after the operation. We must remember that this was the feeble class. They had lost their grip, and had given up the fight.

The per cent of cures within one month after the operation, mortality and post-operative troubles, in this group, based upon the thirty cases treated, is as follows:

Cured, ten per cent; perineal fistulæ, six and two-thirds per cent; enuresis, three and one-third per cent; dysuria, three and one-third per cent; died, three and one-third per cent.

Of the ten in the incapacitated group of the first general class, there was not a wide range in their disability. They were incapacitated for business and pleasure by reason of the frequent necessity for passing urine, or using the catheter. Four of this group had never used the catheter, but were compelled, during the day, to use the urinal every hour, and at times more frequently. The six who were using the catheter could not tell when they would have to use it—sometimes once an hour, and sometimes the interval would be longer. The sensation of wanting to urinate, and a dribbling of urine, would come at the same time, thus compelling them to wear something either to absorb or to catch the urine that escaped before they could use the catheter. Each one of the six gave histories of cystitis, from one to five attacks, which had been relieved for the time. They had led catheter lives from two to five years. Each had residual urine from three to six ounces. None of this whole group of ten were septic when presented for operation. The oldest of this group was eighty-two, and the youngest fifty-five years. Perineal prostatectomy was done in each case. Results of the operation in these ten cases were: Nine were cured of all urinary troubles within one month; one had a perineal fistula for two months after the operation. The per cent of cures within one month after the operation, and post-operative troubles lasting longer than a month after the operation in this group, based upon the thirty cases operated upon, is as follows:

Cured, thirty per cent; perineal fistulæ, three and one-third per cent.

The histories of the partially incapacitated group, of the first general class, are about as follows: Ages, from sixty-two to sixty-eight years. For a number of years all had dysuria—more or less severe—not sufficient, however, to cause any alarm, or to arouse any suspicion other than that they were growing older, and they attributed their trouble to that. This is the history of most prostatics. Each of the four gave a history of exposure to wet or cold, which was followed by complete urinary stoppage. A physician was called, passed the catheter and relieved the patient. After this followed catheter life for from one month to ten weeks. After one month one of the group could pass his urine quite well, and the other three at different times during the ten weeks. These patients had now intervals of from six weeks to four months before the trouble returned, and catheter life again commenced. During these intervals these patients attended to their duties as usual. They had led this interrupted catheter life for from two to four years when they were operated upon. They were all in good condition, none of them having had cystitis, and none of them were septic. Each one had from three to five ounces residual urine. Perineal prostatectomy was done in each case.

Results of the operations: Three were cured of all urinary troubles within one month. The fourth was operated upon February 13, 1905, and has been troubled with enuresis to the present time, July 9, 1905, but is nearly well. This patient remained in the hospital three weeks and made a very favorable progress, nearly all of the urine passing through the natural channel. I dressed the case at his home twice the next, or fourth week, and advised him to come to the office for further dressings. He came once, but did not return. After two or three weeks I dropped him a note asking him to come in, as I wanted to know how he was getting along. On examination I found an abscess had formed, deep in the perineal wound. This I opened. It discharged an ounce of pus. This was treated and it promptly healed up, also the perineal fistula, but enuresis continued, as above stated. I believe the abscess was the

cause of the long-continued enuresis in this case.

The per cent of the cures within one month, and post-operative troubles lasting

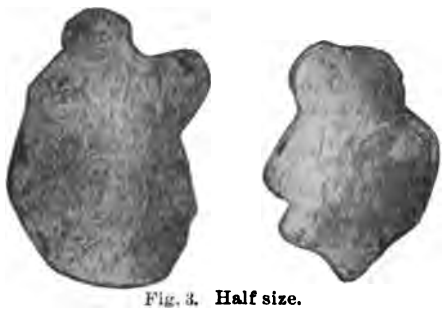

Fig. 3. Half size.

longer than a month in this group, based upon the thirty cases operated upon, is as follows:

Cures, ten per cent; enuresis, three and one-third per cent.

Taking up now the second general class, or that class of cases due to hypertrophy of the muscular and fibrous tissues, and subdividing this class, as we did the preceding, into the feeble, incapacitated, and partially incapacitated, we have, in this general class of six cases, one feeble, three incapacitated, and two partially incapacitated.

The only feeble one in this class was seventy-one years old; catheter life seven years constantly, and two years interruptedly; history of repeated attacks of cystitis; almost constant enuresis; septic condition of bladder marked; patient could only walk a few steps without resting; patient was put to bed, bladder constantly drained by means of residual catheter. Passing the catheter in this case caused great distress, and produced much irritation of the prostatic urethra, hence we used the residual catheter, which did not irritate or cause suffering. The bladder was washed three times daily with a solution of permanganate of potash. Water was given freely, also milk. This treatment was continued for seventeen days, when perineal prostatectomy was done. The gland shown in Figure 4 was taken from this case. Result: The patient made a good recovery, with the exception of a perineal fistula, which continued two months after the operation. The per cent of post-operative troubles, lasting longer than a month, based upon the thirty cases treated, is as follows:

Perineal fistulæ, three and one-third per cent.

Of the three incapacitated, of this general group, each had been leading catheter lives from three to five years. Their ages were, respectively, fifty-six, sixty-two, and sixty-seven years. Each had residual urine, from three to four ounces. Frequent catheterization characterized each case. Each gave a history of several attacks of cystitis, which had been temporarily relieved. None of them were septic when presented for operation. Perineal prostatectomy was done in each case, with the following result:

All recovered within one month, having perfect control of urinary apparatus. Per cent of cures within one month in this group, based upon the thirty cases treated, is as follows:

Cures, ten per cent.

Of the partially incapacitated group, in this general class of six cases, there were two cases. Each was sixty years old. Each gave a history of dysuria for several years, then complete stoppage of the urinary flow, following exposure to cold. Relief was gained by the use of the catheter. Interrupted catheter life followed for two and three years, respectively. During the periods of catheter life there was tenesmus, sometimes of the rectum, and often of the bladder. These patients were incapacitated during the periods of catheter life. There was three and four ounces residual urine, respectively. Perineal prostatectomy was done in each case, with the following results: Complete relief from all urinary troubles within one

Fig. 4. Half size.

month. Per cent of cases in this group cured, based upon the thirty cases treated:

Cured, six and two-thirds per cent.

Of the third general class, in which there is hypertrophy of the fibrous tissue alone, there were two cases. Making the subdivisions of this class, we have made of the other classes, into feeble, incapacitated, and partially incapacitated, these two cases belong to the incapacitated group: Their ages were, respectively, sixty-three and sixty-five years. Each gave a history of cystitis which had been relieved temporarily. Each had three ounces residual urine, and tenesmus of bladder and rectum much of the time, for which both were using opium suppositories. Micturition, painful and frequent in each case. Bladders were not septic when presented for operation. Perineal prostatectomy was done in each case, with the following results: Both cases were cured within one month. The per cent of cures in this group, based upon the thirty cases treated, is as follows:

Cured, six and two-thirds per cent.

Of these thirty cases, the following summing up is of interest. Twenty-two, or seventy-three and one-third per cent of these cases, belonged to the class of large, soft prostates. There were in this class one death, or three and one-third per cent, of the thirty cases treated. There were six cases of post-operative troubles, lasting more than one month, or twenty per cent of the thirty cases treated.

Six, or twenty per cent, of the thirty cases treated, belonged to the second general class, or to that class in which there is hypertrophy of the muscular and fibrous tissues. In this class there was one case, or three and one-third per cent of the thirty cases treated, that had post-operative troubles lasting more than one month.

Two cases, or six and two-thirds per cent, of the thirty cases treated, belonged to the third general class, in which the fibrous tissue alone hypertrophies. There were no post-operative troubles in this class.

These figures show that in these thirty cases there was not quite three times as many cases in the first general class, or group, of large, soft prostates, as were in the other two general classes, but that the per cent of mortality and post-operative troubles, lasting more than a month in this class, was seven times greater than in the other two classes combined.

These figures show that of these thirty cases operated upon, nine, or thirty per cent, of them belong to the feeble class, and that of these nine, one died, or three and one-third per cent of the thirty cases treated; and five, or sixteen and two-thirds per cent, of the thirty treated had post-operative troubles, lasting longer than one month, placing twenty per cent of the thirty treated, who died or had post-operative troubles, in the feeble class. In the other two classes of incapacitated, and partially incapacitated, there were twenty-one cases, or seventy per cent of the thirty cases treated, with no mortality and only two cases, or six and two-thirds per cent of the thirty cases treated, that had post-operative trouble lasting longer than a month.

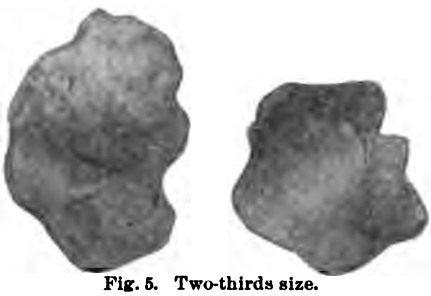

Fig. 5. Two-thirds size.

Another estimate with these figures gives us the following:

Of these thirty cases treated, there were nine feeble, one of whom died, or eleven and nine-tenths per cent. Five of the nine had post-operative troubles, lasting longer than a month, or fifty-five and five-ninths per cent. There were twenty-one cases in the other two classes of incapacitated and partially incapacitated. Two of them had post-operative troubles, or nine and one-half per cent. In other words, there were not quite half as many cases in the feeble class as there were in the other two classes combined, but the per cent of mortality and post-operative troubles, lasting longer than a month, is more than seven times greater in the feeble class than in the other two classes combined.

Of these thirty cases, two, or six and two-thirds per cent, had enuresis. Three, or ten per cent, had perineal fistula. One, or three and one-third per cent, had dysuria for more than one month after the operation.

cause of the long-continued enuresis in this case.

The per cent of the cures within one month, and post-operative troubles lasting

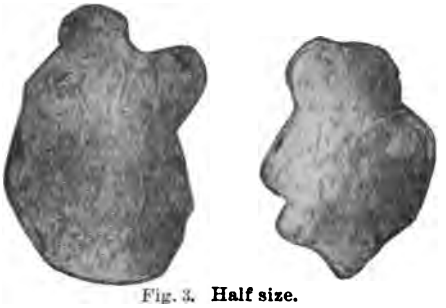

Fig. 3. Half size.

longer than a month in this group, based upon the thirty cases operated upon, is as follows:

Cures, ten per cent; enuresis, three and one-third per cent.

Taking up now the second general class, or that class of cases due to hypertrophy of the muscular and fibrous tissues, and subdividing this class, as we did the preceding, into the feeble, incapacitated, and partially incapacitated, we have, in this general class of six cases, one feeble, three incapacitated, and two partially incapacitated.

The only feeble one in this class was seventy-one years old; catheter life seven years constantly, and two years interruptedly; history of repeated attacks of cystitis; almost constant enuresis; septic condition of bladder marked; patient could only walk a few steps without resting; patient was put to bed, bladder constantly drained by means of residual catheter. Passing the catheter in this case caused great distress, and produced much irritation of the prostatic urethra, hence we used the residual catheter, which did not irritate or cause suffering. The bladder was washed three times daily with a solution of permanganate of potash. Water was given freely, also milk. This treatment was continued for seventeen days, when perineal prostatectomy was done. The gland shown in Figure 4 was taken from this case. Result: The patient made a good recovery, with the exception of a perineal fistula, which continued two months after the operation. The per cent of post-operative troubles, lasting longer than a month, based upon the thirty cases treated, is as follows:

Perineal fistulæ, three and one-third per cent.

Of the three incapacitated, of this general group, each had been leading catheter lives from three to five years. Their ages were, respectively, fifty-six, sixty-two, and sixty-seven years. Each had residual urine, from three to four ounces. Frequent catheterization characterized each case. Each gave a history of several attacks of cystitis, which had been temporarily relieved. None of them were septic when presented for operation. Perineal prostatectomy was done in each case, with the following result:

All recovered within one month, having perfect control of urinary apparatus. Per cent of cures within one month in this group, based upon the thirty cases treated, is as follows:

Cures, ten per cent.

Of the partially incapacitated group, in this general class of six cases, there were two cases. Each was sixty years old. Each gave a history of dysuria for several years, then complete stoppage of the urinary flow, following exposure to cold. Relief was gained by the use of the catheter. Interrupted catheter life followed for two and three years, respectively. During the periods of catheter life there was tenesmus, sometimes of the rectum, and often of the bladder. These patients were incapacitated during the periods of catheter life. There was three and four ounces residual urine, respectively. Perineal prostatectomy was done in each case, with the following results: Complete relief from all urinary troubles within one

Fig. 4. Half size.

month. Per cent of cases in this group cured, based upon the thirty cases treated:

Cured, six and two-thirds per cent.

Of the third general class, in which there is hypertrophy of the fibrous tissue alone, there were two cases. Making the subdivisions of this class, we have made of the other classes, into feeble, incapacitated, and partially incapacitated, these two cases belong to the incapacitated group: Their ages were, respectively, sixty-three and sixty-five years. Each gave a history of cystitis which had been relieved temporarily. Each had three ounces residual urine, and tenesmus of bladder and rectum much of the time, for which both were using opium suppositories. Micturition, painful and frequent in each case. Bladders were not septic when presented for operation. Perineal prostatectomy was done in each case, with the following results: Both cases were cured within one month. The per cent of cures in this group, based upon the thirty cases treated, is as follows:

Cured, six and two-thirds per cent.

Of these thirty cases, the following summing up is of interest. Twenty-two, or seventy-three and one-third per cent of these cases, belonged to the class of large, soft prostates. There were in this class one death, or three and one-third per cent, of the thirty cases treated. There were six cases of post-operative troubles, lasting more than one month, or twenty per cent of the thirty cases treated.

Six, or twenty per cent, of the thirty cases treated, belonged to the second general class, or to that class in which there is hypertrophy of the muscular and fibrous tissues. In this class there was one case, or three and one-third per cent of the thirty cases treated, that had post-operative troubles lasting more than one month.

Two cases, or six and two-thirds per cent, of the thirty cases treated, belonged to the third general class, in which the fibrous tissue alone hypertrophies. There were no post-operative troubles in this class.

These figures show that in these thirty cases there was not quite three times as many cases in the first general class, or group, of large, soft prostates, as were in the other two general classes, but that the per cent of mortality and post-operative troubles, lasting more than a month in this class, was seven times greater than in the other two classes combined.

These figures show that of these thirty cases operated upon, nine, or thirty per cent, of them belong to the feeble class, and that of these nine, one died, or three and one-third per cent of the thirty cases treated; and five, or sixteen and two-thirds per cent, of the thirty treated had post-operative troubles, lasting longer than one month, placing twenty per cent of the thirty treated, who died or had post-operative troubles, in the feeble class. In the other two classes of incapacitated, and partially incapacitated, there were twenty-one cases, or seventy per cent of the thirty cases treated, with no mortality and only two cases, or six and two-thirds per cent of the thirty cases treated, that had post-operative trouble lasting longer than a month.

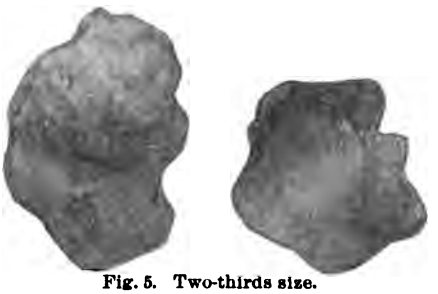

Fig. 5. Two-thirds size.

Another estimate with these figures gives us the following:

Of these thirty cases treated, there were nine feeble, one of whom died, or eleven and nine-tenths per cent. Five of the nine had post-operative troubles, lasting longer than a month, or fifty-five and five-ninths per cent. There were twenty-one cases in the other two classes of incapacitated and partially incapacitated. Two of them had post-operative troubles, or nine and one-half per cent. In other words, there were not quite half as many cases in the feeble class as there were in the other two classes combined, but the per cent of mortality and post-operative troubles, lasting longer than a month, is more than seven times greater in the feeble class than in the other two classes combined.

Of these thirty cases, two, or six and two-thirds per cent, had enuresis. Three, or ten per cent, had perineal fistula. One, or three and one-third per cent, had dysuria for more than one month after the operation.

The final outcome of the thirty cases is as follows:

Died, three and one-third per cent; well within one month after the operation, seventy-three and one-third per cent; well within two months after the operation, ninety per cent; well within four months after the operation, ninety-three per cent; well within six months after the operation, ninety-six and two-thirds per cent.

The history of these thirty cases teach us several things:

First, that the hypertrophy of muscular tissue, together with over-cell growth, is the pathologic condition in a very great majority of troublesome hypertrophied prostates. That in this class we should expect the largest per cent of post-operative enuresis, for the reason that in this class the prostate is much larger and heavier, and produces the greatest amount of damage to the musculature and nerve supply of the bladder wall, prior to its removal, tending to prove that post-operative enuresis is due to damage done by the prostate during its diseased condition in the body, and not to damage done the tissues during the operation.

Second, that while the per cent of mortality and post-operative troubles are high, in the feeble class, they are not so high as to deter us. While the mortality of the feeble in this group of thirty cases shows a mortality of nearly twelve per cent (which we have, perhaps, wrongfully charged to the operation), there would have been one hundred per cent of mortality due to the disease without the operation.

Third, that if patients are to reap the best results, with the least possible risk, they must seek the operation before they reach the feeble class. Hence, the necessity of the family physician, who sees these cases first, advising the operation before catheter life is commenced; for after that it will not be accepted in most cases until it fails, at which time many of these will have entered the feeble class.

Fourth, that the per cent of cases in the third general class, or small prostates, due to hypertrophy of fibrous tissue, is very small. From this class we expect most post-operative troubles, due to traumatism and hemorrhage at the time of the operation.

[Written for the MEDICAL BRIEF.]

Asthma.

BY J. H. JERGESEN, M. D.

Milwaukee, Wis.

[No. III.]

Hay fever, or hay asthma, as it is often called, is purely a neurotic affection and the seat of trouble is strongly suspicioned to be in Meckel's ganglia; and probably, in some individuals, the olfactory are involved; for example, in such cases where the odor of roses and new-mown hay brings on an attack. I said that there is a strong suspicion that hay fever is caused through an irritation of Meckel's ganglion. This interesting organ, we know, lies in the spheno-maxillary fossa, at the outerside of the spheno-palatine foramen, and in front of the anterior end of the Vidian canal.

It may not be necessary to say any more about these nerves but for a few whose Gray or Morris occupies a place of prominence on the top shelf. Which reminds me of an old woman who was visited by her pastor. She answered his admonishment to study the Bible, that she had lost her spectacles five years ago and was too poor to buy new ones. When the pastor reached for the Bible it was covered by a half inch of dust and when it was opened, lo and behold, there he found her old glasses! For the benefit of such isolated cases we shall append our reflexion in connection with the formation, anatomy and distribution of the nerves connected with Meckel's ganglia, as being a probable factor in hay-fever.

The ganglion receives its motor fibers from the Vidian nerve, and its sensory fibers from the maxillary nerve. Its sympathetic root is the great, deep petrosal portion of the Vidian, also, while the motor root comes from the great superficial petrosal, which also is incorporated in the Vidian nerve, and has its origin in the geniculated ganglion of the seventh nerve. The sensory root, as stated, is a filament from the second branch of the fifth (maxillary). The sympathetic has its origin in the carotid plexus, it unites with the great superficial petrosal, being a branch of the seventh to form the Vi-

dian nerve. The seventh nerve, we know, gives a branch to the vagus, and the vagus, as we know, has its origin in, and is intimately connected with, the respiratory centers at the bottom of the fourth ventricle in the medulla oblongata.

St. John Brooks and Arthur Robinson hold that Meckel's ganglia, together with its four associates—cilliary, spheno-maxillary, otic, and sub-maxillary—are vagrants which have separated from the Gasserian ganglia at an early period of development, associated, as they are, with the fifth nerve. This may be so. Certain it is that all are more or less affected in hay-fever. The branches of Meckel's ganglia are ten or eleven in number, and supply the nasal cavity, the pharynx, soft and hard palates; it anastomoses with the olfactory nerves in the superior turbinate region, and with the nasal in the inferior turbinate region. Practically all of the parts supplied by the nerves given off from Meckel's ganglia are involved in an attack of hay-fever.

Reading about hay-fever, one invariably encounters such statements: Hay fever is caused by the pollen being inhaled. In what manner can pollen produce hay fever? asks another; now that the pollen is with us, hay fever is also, etc.

I, for my own part, do not see my way clear to implicate the pollen in the crime any more than I can the roses. Odor from fried pork, odor from new-mown hay, the glare of the mid-day sun, arc-light glare, change of air from hot to cold or reversed, cold night air after a warm, bright day; even an approaching thunder storm is, in many individuals, a certain factor. We know hay fever consists in a burning sensation in the mucous membranes of the nose, pharynx, fauces, hard and soft palate, and conjunctiva of the eyes. The outward symptoms are: Lachrymation, red and swollen eyes, coryza, and sneezing, sneezing and sneezing without end.

Every individual has his own idiosyncrasy as to which of the numerous causes will produce an attack in them. Hay fever, as all other neurotic conditions, are of a progressive nature, and may, if they are let alone, assume an enormous possibility.

I was called to see a patient suffering from hay fever for eighteen years. It was a bright summer day in August. I found him in the cellar, blowing his nose for all he was worth. I sprayed his nose with a two per cent cocaine solution and put a few drops in each eye. The paroxysm soon ceased, when he told the following story:

"I had my first attack when I was about eight or nine years old; I was attacked while playing in some new-mown hay. My first attack was a severe one, but it only lasted about half an hour, and it was the only attack I had that year. The following year I had many fits of the same kind. And every year since that I have suffered in the same degree, only one year is a little worse than the other. At the age of eighteen I had my first attack of spasmodic asthma, and now I must fight against hay fever in daytime so as not to suffer from asthma at night; then, as sure as I succumb to the day attack I will surely wake up with asthma in the night.

"Three or four weeks, generally the last week in July, and three first weeks in August are spent in sneezing and fighting sneezing from nine to ten in the morning until four or five in the afternoon. Does the sneezing once get the best of me then I am lost for the day and the night, also, for surely I will wake up in the night with asthma; but am I able to overcome the tendency to sneeze I may within an hour be able to give my attention to other things and have a good night's sleep the following night. The most prominent symptoms are itching; itching in the nose, itching in the throat, itching of the soft palate, of the hard palate, of the chin, down the spine—itching, itching everything. The sensations are, as before said, itching, but if not relieved by sneezing, coryza and lachrymation, the sensation is as if red pepper had come in contact with the membranes mentioned.

"To fight off an attack it is necessary to be on my guard from early morning, especially if it is a bright day. As soon as I feel the first tingle in my nose I get out my handkerchief and begin blowing my nose, while I am making for this dark room. Here in this dark room I sit with my eyes closed, pinching my nose and blowing all the while and with all my force; if I can continue this desperate blowing without interruption, in the

course of about fifteen to twenty minutes I often have overcome the strong tendency to sneeze. While I am exerting myself in the first fifteen or twenty minutes to avert the act of sneezing, I dare not inhale through my nose; therefore, I must keep my mouth wide open and the struggle goes on. If I lose I have lost much, I will sneeze nearly continuously until three or four o'clock in the afternoon, and in the night wake up with the asthma, which means three or four hours additional suffering. Under these first minutes I dare not let anything interrupt me. If I am interrupted I am lost; only if I cough or listen to something the next thing is a sneeze, and I am lost. Can I, however, thwart the first attack I am, as a rule, successful in all other attacks that day.

"As before said, the case is progressive, and from year to year I find the attacks become harder and last longer, and when ten years ago I counted on five to six weeks, now I count on eight and nine weeks."

Hysterical asthma, or nervous dyspnea, occurs mostly in women between the age of puberty and thirty, but I have seen a few cases in women at the menopause. The time of occurrence in fifty per cent, at least, is the first week after menstruation, and very often the last day of menstruation, but the remaining fifty per cent may come on at any time, and often during the month. It comes on suddenly, generally during waking hours, when in company; seldom when alone.

Fear, grief, jocundity, shock of some kind, may bring on an attack. Such an attack may last a few minutes only, or may last for hours, or even days. No pathological evidence of the existence of a disease can be discovered, neither while attacked, nor after. There seems to be no impediment to the air in the bronchiales, the rhonchial and sibulant sound, in spasmodic asthma are absent, and so are the gurgling sounds in catarrhal asthma. After one has examined a case for all probable and improbable causes and found none, one comes to the conclusion that the patient can breathe if she wanted to, but may be she can not. Often, I have thought, when I have witnessed an hysterical asthma patient struggle for breath, What would happen if she all at once should find herself deprived of air? Or unable to breathe? Such a patient is very unlike a patient suffering from other forms of asthma. She is subsultant in a high degree. She will scream: "Help, help! I am choking," etc. She will claw at her throat, throw herself on the floor, and often act in an unseemly manner; become boisterous and vicious, slap the faces of friends if she does not think they show concern enough for her welfare. At other times she may resign herself to her fate and she will become still, not move a muscle, and apparently not breathe for minutes at a time. This, however, generally brings forth a quick response from friends who look on: "Doctor, why don't you do something for her? She will die!" etc. My experience is, if you try to do something for her you and your successor will have a job your lifetime. If, however, you show little or no concern for her, make light of her condition, refrain from giving her disease a name, tell all in the room to depart because she should be disturbed as little as possible. Then, when you are quite alone, go up to her without saying a word and snap the lobule of her ear a smart crack (hard enough to hurt her). If she asks in surprise, "Why did you do that?" hit her another and another until she flinches. Her asthma, in all probability, has ceased by that time, and you pick up your hat and cane and join the others as soon as you can. If you have the confidence of the family, tell them: "If she should get into another fit of the same kind do not call for me, or tell anyone to leave her room and leave her strictly alone and do not disturb her. This procedure will help her more than any other thing you can do for her.

I have a case in mind now in an unmarried lady of thirty-five; short of stature and stout of build; of a nervous and often unreasonable temperament; health good, but for a heavy cold of recent date. She had her first fit in a doctor's office. She was brought to my office, thinking that it was spasmodic asthma. At her first visit she had a fit in my office. She squatted down on the floor, assuming a knee-chest position, clawing at her throat, pulling at her hair, screaming: "I can't breathe. I am dying. Help! help! I am

choking," etc. She had many subsequent fits in my office.

The last spell I witnessed her have ended in this manner: She was attacked in the usual way; her company (her aunt) had never seen her in a fit before, was loud in her sympathy for her, and insisted something should be done for her. I, on my side, was as sure that nothing should be done. That she would be relieved the quickest if we let her strictly alone. The old lady looked at me with scorn in her eyes, and asked: "For what purpose have we got doctors, then?" when luck came to my assistance. In an adjoining room I had piled up several dozen empty bottles, which at that moment fell down with a terrible crash. Her aunt and I ran to the room and forgot, in our excitement, our patient, who was suffering. When we looked around there she was, standing, terrified, inquiring what had happened.

735 Third Street.

[Written for the MEDICAL BRIEF.]

Tuberculosis.

BY J. W. LOCKHART, M. D.,
St. John, Wash.

The idea that tuberculosis is a contagious disease is no new thing. Dr. Watson asked the question more than fifty years ago, and answered it with an emphatic "No." But said, however, that the Italians were as afraid of one having consumption as of one having the plague.

Neither is the germ theory of tuberculosis a very new idea. Lænnec believed in it nearly one hundred years ago, as we learn from the following quotation from "Tweedies' Practical Medicine," published more than sixty years ago. "It may be collected from his (Lænnec's) writings that tubercles are parasitical bodies originating in an unknown way, possessing a life and structure of their own, growing by attracting matter to them, and tending by their own inherent properties to go through a certain series of changes."

With this cue to work from, and the modern improvements in the microscope, it does not seem that Koch's discovery of the bacillus tuberculosis was such a wonderful thing after all. A further quotation in regard to this theory of Lænnec, and the argument in refutation of it, may be of interest to some modern students of medicine: "The transparent miliary granulations of Bayle, the gray miliary tubercules, the gray diffused indurations, and a kind of gelatinous infiltration, he looked on as varieties of these bodies in their first stage, and all tending, *per se*, first to become opaque and yellow, or crude tubercule, which is still hard; and afterwards to soften into a cheesy or pasty liquid, which is the mature tubercule." The author says: "Now this view involves several assumptions little supported by analogy; for instance, that bodies so different in physical character and texture are the same; and that the stages through which they pass are produced by assumed inherent properties, and not by the modified properties of the tissues of the organ—and it further assumes what has been disproved by extended observation—that the opaque yellow tubercule is always preceded by the gray, or semi-transparent, and that the gray indurations must always in time become yellow tubercule."

It would seem from what we know of the pathology of low grade inflammations at the present day that the author had the best of the argument. There are yet some things in connection with the pathology of tubercular deposits which seem to produce (intellectual) blind staggers in the bacteriologists.

Modern writers on the subject of tuberculosis seem to attribute all the pathological conditions which take place in the lungs of consumptives to the presence of the bacillus tuberculosis, and that, too, with a superlative disregard of the fact that such changes actually do occur, in many instances, where no bacilli can be found. With an utter disregard for statistical facts, some writers assert that one death in seven in the United States is caused by consumption; while the truth is, that according to the United States census for 1900, a little less than one death in 9.5 is caused by this disease. Pneumonia ranks next to consumption in fatalities in this country; that disease causing one death in 9.8 of all the deaths.

It has been stated by competent authority that sunlight, heat and carbolic acid are the agents most destructive to the

germs of consumption. Allow me to suggest that it may be some particular ray of sunlight that is so destructive to these germs, and the man who discovers it may immortalize himself. And if carbolic acid is as destructive to these germs as it is said to be, why would not its persistent use by inhalation, and internally, or some of its derivatives, if the acid could not be administered, be a rational treatment for this disease? In some forms of bronchial catarrh I have seen great good accomplished by the inhalation of steam saturated with this acid, when other remedies seem to be of no avail. With me the internal use of salol, with the solution of the sulphocarbolate of zinc as a gargle, has accomplished all that is claimed for anti-toxin in diphtheria. I have reason to believe that carbolic acid, salol and the sulphocarbolates are not alone intestinal antiseptics, but that they exert a depurative influence over the whole system. I notice, however, that in the matter of treatment, the bacteriologists do not follow their theories to logical conclusions. Their suggestions in regard to treatment are but little, if any, improvement over those of a hundred years ago. And, in proof of this, let me quote again from one of the old writers: "But even in the cases in which the phthisical lesions are the most limited and merely nascent, we must never forget that it is not these lesions alone which we hope to remove. . Their very presence in the system, or the operation of the constitutional or local causes that produced them, may lead to the formation of more; and in our treatment of the local causes, we should ever endeavor to remove those low degrees of vascular irritation, or that unhealthy condition of the nutrient matter of the blood, which, singly or combined, occasions the deposit of tubercular indurations. But the constitutional treatment is also of the utmost moment; and in this we should seek for all the circumstances and agents that may best promote the due action and balance of all the functions. The purest air and the most suitable climate for regular and ample exercise in it; the most nutritious food that the digestive organs can assimilate, and that the vascular system can bear without excitement; and such remedial agents as give at once tone to the system, and promote the free action of all the secreting organs, together with friction, exercise, and proper clothing to maintain the activity of the superficial circulation—these are the means which are rationally indicated to fulfil the object of improvement of the general health.

"But these means must be varied to adapt them to the wants and capacities of individual cases, and it is in the study of these and in the power of adapting the means to them that the ability of the practitioner is seen."

Here, in my opinion, is the essence of the rational treatment of pulmonary tuberculosis, and I firmly believe that if physicians would pay proper attention to "removing those low degrees of irritation, or that unhealthy condition of the nutrient matter of the blood," which almost invariably follow colds, pneumonia, bronchitis, la grippe, and other catarrhal conditions of the lungs, there would, in a short time, not be one death from consumption where there is now ten. "A consummation devoutly to be wished." It seems to me that by a judicious course of after-treatment, in these cases, much more might be done than generally is done to "remove those low degrees of vascular irritation" that form a possible nidus for the germ or the deposition of tubercular matter. For this purpose some of the older authors recommend the use of some of the preparations of iodine; and I have noticed that in those cases in which it was prescribed in combination with other remedies, or during convalescence, the patients, generally, made a better and more complete recovery. Especially is this marked in those of scrofulous diathesis, who are peculiarly liable to low-grade inflammations.

The death rate from consumption varies slightly in the different States, and frequently we see the extremes of difference in localities in the same State. The rate is a little higher in the cities than in the rural districts, but varies greatly in the different wards of the same city. And this variation is an instructive study; disproving, beyond the shadow of a doubt, the generally accepted view that the death rate from this disease is much greater in the crowded tenement and slums than in

the better class of resident wards. The fact is, substantiated by the most reliable statistics, that not infrequently the very best resident wards, containing but little more than the palaces of the rich, show a larger death rate from this disease than do the most objectionable wards of the city. For illustration, we will take a prominent Eastern city, which need not be named here. The death rate from pulmonary tuberculosis for the entire city was one hundred and fifty-eight per one hundred thousand of population.

In Ward One, which was on very low and flat ground, in many places not more than three feet above the water, and which was a cheap tenement district, densely populated by Hungarians, Poles, Italians, negroes and prostitutes of the lowest kind, the death rate from consumption was one hundred and seventy-one, being only thirteen above the average for the entire city.

Ward Two, which was only a little better in physical and social conditions, had a rate from this disease of only one hundred and eight, or fifty below that for the city.

Ward Three, which was much better in physical conditions and but little better socially, containing many prostitutes, gas and coke works, breweries and malt houses, had a rate of ninety-nine per one hundred thousand of population.

About half the houses in Ward Four were occupied by the class of prostitutes known as "roomers." Here the rate from consumption was eighty-four.

For purposes of condensation let it be understood that the rates given are per one hundred thousand of population, and for consumption alone.

Ward Five was a cheap tenement district, occupied chiefly by a poor class of laborers. The rate was two hundred and fifty-one.

Ward Six was among the best residence wards of the city, occupied chiefly by the wealthy. The rate was eighty-nine.

Ward Seven was chiefly residential in character, occupied by a good class of people, in moderate circumstances. The rate was one hundred and fifty-four.

Ward Eight was a cheap tenement, occupied by a poor class of laborers. The rate was one hundred and forty-nine.

Ward Nine was a very similar district, and the rate was only sixty-two.

Ward Ten was similar in most respects, and the rate was two hundred and thirty-two.

Ward Eleven was residential, and occupied by a good class of people, in moderate circumstances. Here the rate was one hundred and sixty.

Ward Twelve was well built up, principally with the residences of wealthy people. The rate was two hundred and sixty-five.

Ward Thirteen was mostly occupied by residents of a good class, mostly owning their own homes. The rate was one hundred and ninety-three.

Ward Fourteen was on high ground and well built up with handsome residences. The rate was only ninety-four.

Ward Fifteen was residential and occupied by dwellings of the middle class. The rate was two hundred and seven.

Ward Eighteen was in the best residence section and on high ground. The rate was fifty-nine.

Ward Nineteen was similar in nearly all respects and the rate one hundred and sixty-two.

Ward Forty contained large stock yards and slaughter houses, which emptied their filth into an open creek that in part sewered the ward. The residents of this ward were principally a poor class of laborers, and the rate was only sixty-nine.

It is unnecessary to give the rate for all the wards in the city. The figures given are sufficient for comparison.

It will be noticed that Wards Nine and Forty, which of all the wards in the city, according to prevailing ideas, were most favorable to the production of pulmonary tuberculosis, show a death rate of only one-fourth that of Ward Twelve, where the rate should have been reduced to a minimum if the prevailing dictum is correct. This is the most striking example, but a careful study of the other figures given, lends no support to the assertions so often made, that the large death rate from consumption in our large cities is due to over-crowding of the tenement and slums districts. Only one ward of the entire best residence portion of the city compares favorably, in this matter, with the vilest and most filth-polluted wards.

What is here proved to be true of this particular city is also true, to a greater or lesser extent, of other cities and other diseases. Here, then, is a hard nut for the bacteriologists and pure food commissions to crack. Perhaps some of our officious State boards of health (?) would like to crack it for them.

[Written for the MEDICAL BRIEF.]

Inspection of Beef By Microscope.

BY EPHRAIM CUTTER, M. D.,
New York City, N. Y.

(1) 1905, Feb. 11. Collector, Deacon George W. Fowle, Jamaica Plain, Mass. Claim, good, sound healthy beef. Test, color pale, white as a sheet. Cross marks half obliterated. Finely granulated fat inside of fibers, but not excessive. Fat looking like butter abundant outside. Not up to standard. Should be red. Crossmarks perfect. No fat inside. No buttery nor ameboid oil outside.

(2) 1905, April 19, New York City. Collectors, Mrs. and Miss Penfield. Beef from their butcher. Pale; cross marks good; considerable fat in oval forms; abundant oil globules; substance of fibers finely granular.

(3) Same date. Chopped beef, collected by Mrs. and Miss Penfield. Pale; oily like butter; substance finely granular with fat; no cross marks; longitudinal markings—striæ, plain. Not so good as (2), as might be expected, naturally.

(4) Veal. Collected by Mrs. and Miss Penfield. Very pale and bleached; no cross marks; striæ faint; fibers finely granular with minute masses of fat.

(5) Same. Pork. Very pale; no cross marks; striæ present; oil.

(6) Mutton. Same. Pale transparent; not much fat nor oil globules.

Note. 5 and 6 are introduced here as they were examined with 2 and 3. Six was a surprise, as many oil globules are generally found and make mutton secondary to good beef as a food for treatment of disease.

(7) 1905, April 27. Mrs. Grouten's beef that she feeds me on. Pale, but perhaps with more color than the average; cross marks not all present as they should be; some striæ; buttery fat; granular fat outside and inside of the fibers.

(8) 1905, April 27. Specimen from Prof. B. Cutter, Boston, Mass. Color, slight red; no cross marks present; oil in interspaces between fibers; fibers somewhat granular inside; much better than the average Boston beef, but by no means a normal specimen.

(9) 1905, April 25. Specimen from Mrs. Blank, of Philadelphia, Pa. Claim: first-class beef killed in Philadelphia; color pale; plenty of oil like butter; cross marks faint; few granules of fat inside the fibers. April 27, 1905, second examination of the same specimen; some oil; some granular fat; cross marks fair. This was not kept on ice. It came from cold storage. But it did not meet the standard as expected.

(10) April 26, 1905. Beef from the Bronx, Mrs. C. C. Merritt, collector. Color pale; cross marks faint, as a rule; buttery oil plenty; free oil globules outside of fibers, that were finely granular inside. This was hamburger and examined before eating.

(11) May 1, 1905. Another specimen from the Philadelphia noble woman. Beef declared to be kitchen meat of standard goodness, fresh killed at Philadelphia. Color very fair; cross marks plain; granular fat everywhere present inside the fibers; no striæ; fair specimen.

(12) May 5, 1905. Beef from E. Q. Norton, Daphne, Ala. Color more red than the average; cross marks large and plain; little free oil; some granules of fat in fibers. Came in fine condition through the mail. Good. This was a pleasant surprise.

(13) May, 1905. Beef from C. M. Bliss, A. M., Bennington, Vt. Color pale; cross marks plain; some free oil, not excessive; no granular fat in fibers.

(14) May 4, 1905. Specimen from Mrs. Penfield, New York City. Color pale; cross fibers; oil in globules and buttery shapes; granular fat.

(15) May 5, 1905. Truant School, Brooklyn. Color pale; striæ and cross marks; buttery oil, but not abundant.

(16) Same as (15), another sample. Color, paler red; cross marks present; oil globules abundant; granular fat inside fibers.

(17) May 6, 1905. From Mrs. P. W. Pierce, Harwichport, Mass. Color pale as white paper; striæ marked; cross fiber marks plain; some buttery fat but not as much as usual; granular internal fat slight.

(18) May 10, 1905. Country beef from Mrs. Cyrus Coe, Middlefield, Conn. Color very pale; no cross marks; infinitesimal granules in fibers; not much free oil.

(19) May 12, 1905. From Miss Sarah Veghte, Somerville, N. J. Color pale; striæ marked; some cross fibers; some buttery oils; fine granular matter in fibers.

(20) May 18, 1905. Miss Veghte, New Jersey. Beef, fresh killed. Color very pale fibers; few cross marks; some striæ; buttery fat abundant.

(21) May 18, 1905. Mrs. H. L. Levy. Rabbi or kosher beef. Color better; cross marks distinct; some striæ; slight oil; no granular fat inside fibers. Should say this was much better than the average beef.

(22) May 18, 1905. Beef from H. Sprudle, Superintendent Truant School, Brooklyn. Color paler than it ought to be; cross marks all very fine; striæ marked; generally an absence of buttery fat; no granules. Good beef.

(23) May 18, 1905. Another specimen from Mr. Sprudle. Storage beef. Color distinct but not fully red; little fat of both kinds; cross fibers marked.

(24) May 18, 1905. Another specimen from Mr. Sprudle. Tenderloin beef cooked rare and taken from the dining table. Color good; all fibers cross marked; little or no fat nor oil. This is the nearest to the standard yet found by me.

(25) May 18, 1905. Specimen of beef from the cuisine of a patient of Dr. R. L. Watkins, of New York. Color pale; some cross marks, not many; striæ; oils globular ameboid buttery granular. Typical specimen of fat beef.

(26) May 27, 1905. Mr. H. Sprudle. Kosher beef, fresh killed in Brooklyn. Good color with one inch objective, but was thought not quite up to the standard; cross marks distinct; some striæ; not much oil; fine granular fat in fibers.

(27) June 6, 1905. Beef from Och's, 90th and Park Avenue. With one inch objective; color reddish; little oil; cross marks distinct; with one-quarter inch objective; some oil and buttery fat; granules abundant; cross marks clear.

(28) June 8, 1905. Och's beef. Hamburg steaks. Color under cover pale red; outside cover on the slide quite red; some cross marks and striæ; fat in ovals; ameboid oils; granular fat in fibers.

(29) June 9, 1905. Och's beef. Hamburg steaks. Some fibers pale and some red; some cross marked fibers; some striæ; most fibers finely granular; buttery oils.

(30) June 8, 1905. Beef from Siegel & Cooper Department Store. Color palish; cross marked; striæ; little oil; some granular fat. Triple phosphate crystal, such as is found in urine; mycelial filament of yeast very white and pale, probably foreign.

(31) Another sample beef from Siegel & Cooper Department Store. Color pale; cross marks and striæ present; no oil globules.

(33) June 17, 1905. Och's beef. Color pale; cross marks present; little oil or fat in granular form.

Note.—This beef removed the albuminuria of a patient of mine when eaten.

(34) June 17, 1905. Porterhouse steak from a patient of Dr. R. L. Watkins, New York. Muscular fibers, some pale and some reddish; cross marks present; one-half of the field under the microscope was filled with oil in globes, globules, granules; also ameboid and buttery.

(35) June 17, 1905. Best beef in Rutherford, N. J. Politeness of Dr. Armstrong. Color pale; some cross marks; striæ; not much free oil; some granular fat inside fibers.

(36) June 24, 1905. Beef from Mrs. E. B. Grannis. Claimed to be perfect. Color pale; cross marks not always present; some striæ; field full of granular fat; ameboid oil globules present.

(37) June 22, 1905. Joseph Stern & Co. by the politeness of Dr. Darlington, President New York City Board of Health. Chicago stock killed here. Specimen only a short time in the iced storehouse. Color fair; cross marks abundant; some striæ; not much oil on fibers, though some of them were ameboid; granular fat inside fibers none. This firm deserves help.

(38) June 24, 1905. Examined after keeping away from the cold storage. Color pale; striæ somewhat in evidence; cross marks less numerous; globar oil large and small, abundant; granular fat everywhere present inside fibers.

Note.—This goes to show that beef decomposes by fatty degeneration. The smell of this specimen was not bad, while the odor of some control beef kept in the open for two days by the side of (38) was almost unbearable.

(39) Beef from Dr. Jordan, Boston Board of Health, kindly sent in reseponse to a request for a sample to photograph as typical of good sound, wholesome beef. Examined June 27, 1905, at once upon receipt. Color pale; few cross marks; some striæ present; some granular fat in the fibers; some oil globules, not many; ameboid forms plenty on the cover glass. Later examination: Color pale; striæ more abundant; granular fat everywhere inside the fibers; oil globules abundant but far less than in the average sample. Thanks rendered to these officials for their aid.

(40) July 4, 1905. Beef from Plymouth, Massachusetts, per B. Cutter. Hot weather. Color good; cross marks generally present; no striæ; some free oil globules, none amebic; none granular; sample stank; a good specimen considering the environment.

(41) July 9, 1905. Received by mail from Alexandria, Minnesota, through the politeness of Mrs. F. B. Van Hoesen beef mailed on the sixth instant. Came in good order, though slightly tainted. Color to the naked eye grayish red and slightly glazed. Color under the microscope reddish pale; cross marks good; striæ none; no granular fat inside the fibers; hardly any oil globules. Considering the distance sent and the season of the year, this is a remarkable showing. Again it proves that a deep scarlet red color of the meat to the naked eye is not a sign of the tissues being free from fatty degeneration. This the writer has found out many times to his sorrow in his own kitchen and on his own table.

(42) July 12, 1905. U. S. army purveyor beef. Politeness of Mr. J. L. Jordan. Claim to be perfect in quality. Color pale; oil in globules very abundant; oil in granules inside the fibers very abundant; cross marks mostly absent; striæ abundant.

(43) July 7, 1905. Another sample like (42). Color to the naked eye grayish red; under the microscope the best red the observer has seen for years; cross marks universal; striæ few; few oil globules; no granular fat; smell good. Observation made at ten A. M. At one P. M. the same day, the sample having been kept away from storage, very fine fat granules were found pervading the fibers; the other appearances being held.

(44) July 19, 1905. Beef from West Falmouth, Mass. Said to be embalmed. From Mrs. Anna L. Cutter. Color fair and pale; cross marks general; some striæ; no granular fat in fibers; some globules of oil.

(45) July 22, 1905. Politeness of Mrs. F. B. Van Hoesen, from Alexandria, Minn., grass fed and only four days in the cold storage. Color fair; cross marks few; striæ present; oil in globules; not much fat in granules inside fibers; many crystals of triple phosphate; fibers fused together, some of them evidently doctored; not much smell of decomposition; not so good as (41).

(46) July 29, 1905. Another specimen from Mrs. Van Hoesen. Color to the eye grayish red; under microscope fair; cross marks plain; some striæ; hardly any oil or fat in globules or granules. A good specimen.

(47) August 3, 1905. Beef from Faneuil Hall Market, Boston. Politeness of Mr. S. Dustin Goodenough. Color palish red; cross marks few; striæ more abundant; oil in globules and buttery shapes; all fibers finely granular with minute particles of fat.

(48) Another specimen same kind as (45). Color medium pale; cross marks plain; few striæ; some granular fat in the fibers.

(49) In this number are lumped examinations made for several years past, all of which may be summed up as undergoing fatty degeneration. Since the beef business has been amalgamated under one head, or partially under one head, microscopical examinations show that it is difficult to obtain the hale beef of previous date, whose fibers were a decided

red; not undergoing the granulated condition such as the writer has found in the substance of cataracterous lenses. There was little or no oil free upon the fibers. This latter beef American physicians have found useful to help cure heart, lung, kidney and nerve diseases, and some have found themselves unable to do the good they think they ought to do by using the diseased beef of the present shambles. These studies were for the purpose of securing the beef of the right quality. They must be taken as such. If any doubt, all that they can do is to go over the same ground and see if the reports are incorrect. The Lord knows that the writer wishes they were and that normal beef could be found in the shambles as it formerly was found.

(50) Date forgotten. Mr. F. A. Dunham, of Brockton, Mass., said that his butcher furnished good, sound, wholesome, healthy beef. This he was assured of by the butcher himself, who was a man to be trusted, as he was a man of his word. Knowing the informant to be entirely trustworthy, the writer gladly availed himself of this opportunity to obtain a normal specimen for study and use; he arranged to have a four-pound roast sent from the said butcher. When it came it looked all right to the naked eye, but the microscope showed it to be of the color of butter; to have no cross marks; no striæ even; nothing but a fatty mass that had every appearance of common butter, so completely had the process of fatty degeneration gone on. When the writer and the butcher met, he would not yield an atom from his position, and he died holding fast to the same contention, that it was good, sound, wholesome beef.

Flat Iron Building.

[Written for the MEDICAL BRIEF.]

Cerebro-Spinal Meningitis.

BY WM. PROTZMAN, M. D.,

Lincoln, Neb.

In the discussion of this subject I shall not pretend to substitute mental suggestion for remedial measures, nor that I am possessed with a cogitative mind; neither do I want to be capricious, inexorable, nor paradoxical. All I ask of my professional critics is to go with me into the physio-pathological field for a retrospective view of the fundamental principles of scientific medicine. Cerebro-spinal meningitis, or spotted fever, has caused much anxiety in the medical profession during the past three or four months, on account of the great mortality and diversified treatment. I have been waiting with indefatigable patience for some member of the BRIEF family that is much better qualified than I to discuss this disease and treatment from a scientific standpoint, but in vain. On account of time and valuable space in the BRIEF, I shall not attempt to give symptoms, diagnosis, nor prognosis, but confine myself to the physio-pathological conditions according to *post-mortem* appearances under the lens of the microscope. According to chemico-physio-pathological investigations, all acute inflammations involve the same physiological laws of nature, that differ only in degree, which depends on the locality and nature of the tissue, more than on the etiology. The premonitory symptoms are as follows, viz.: first, congestion of the meninges, cord and brain; second, effusion, adhesion, extravasation, inflammation, and suppuration; the same conditions that are found in any and all acute inflammations. The etiology of this disease is claimed by bacteriologists to be caused from a pathogenic microbe; but whether it is caused from a pathogenic germ, or any other cause; whether located in the inflamed tissue or remote part of the body, either of which involves the same dynamic force and physiological laws of Nature, found in any acute inflammation.

Now, then, that we may understand the true condition of any acute inflammation, we must go back to physiological anatomy. According to anatomy every artery has three coats, viz., middle, internal, and external. The middle or muscular coat is spiral, very elastic, and governs the flow of blood into its capillary vessels and, according to physiology, every artery of the human body is controlled by the factor of irritability, governed by the vasomotor nerve; therefore, when the irritable factor of an artery is unduly excited, it causes constriction of the artery, and a

corresponding dilatation of its capillaries, causing congestion of the capillary vessels, and the first stage of inflammation. The factor of irritability is not only confined to the arterial system, but we find it in every muscular and nerve fiber, in every atom and molecule; the life of each depends upon the factor of irritability. The high and low pressure of an artery and its capillaries is exemplified in the secretion of urine; when the renal artery is constricted and its capillaries are dilated, which cause a normal flow of urine, but when the constriction and dilatation of the renal artery and its capillaries are reversed we have suppression of urine. Also, the application of cold relieves capillary congestion on the same physiological principle. In cerebro-spinal meningitis we find both heart and arteries intensified, forcing an undue amount of blood into the capillary vessels of the brain, meninges and cord, preventing a free circulation of oxygenated blood, and forming a compound known as carbon dioxide, a nutritive soil for pathogenic microbes, toxines, and ptomaines. Neither pathogenic microbes, toxines, nor ptomaines can exist in nascent oxygen or the free circulation of oxygenated blood.

Now, then, before entering upon the treatment of this disease, allow me to repeat with emphasis that every muscular or nerve fiber, every strand of protoplasm, health, disease and death of every tissue depend upon the factor of iritability, and that excessive or deficient liberation of the irritable factor lays the foundation for pathological tissue changes. Neither should we forget that oxygen of the blood is not only the graveyard for pathogenic microbes, toxines and ptomaines, but is one of the most essential elements for tissue metamorphosis, and to keep the blood in a fluid state.

Treatment.—Judging from the different kinds of treatment recommended, it forces us to conclude that there must be different kinds of this disease, or else we are using "shotgun remedies." One writer will tell us never to give physic, another will tell us never to give opium nor quinine. Another gives us this or that; hardly two that will recommend the same remedy. At last the New York Medical Department of Health has solved this great secret; they advise the lumbar puncture, etc. Now then, it does appear to me that the lumbar puncture is neither diagnostic, nor curative; the puncture may relieve the cord and intercranial pressure; if so, for a short time only. If the lumbar puncture would evacuate the effused product of inflammation without disturbing the cerebro-spinal fluid that is so essential to the cerebro-spinal nerves, cord and brain, or if the puncture would relieve the irritable artery that keeps up the congestion and inflammatory condition of the cord and brain, I could readily recommend the lumbar puncture.

A retrospective view of the different theories and treatment, therefore, is positive proof that the physio-pathological and therapeutic action of remedies are not well understood.

Now then, while I am giving my views and experience on the treatment of this disease, I hear a voice exclaiming, "Holy horrors, back number, old style, behind the times, relegate him to the rear, not fit to practice medicine," etc. For what? Because I recommend bleeding. Yes, I repeat with emphasis, *bleed.* Yet I do not advise venesection for every pain or ache, like the up-to-date doctor that plunges the knife into the abdominal cavity irrespective of pathological conditions, simply for the fee. Another contributing factor for the cure of this disease is calomel in five or ten-grain doses, with sulphate of magnesia to establish free catharsis; also, five-grain doses of iodide of potassium every four or five hours, with pounded ice to the head. Some preparation of opium, moist heat to the wrists and feet, sponging the body with hot water every couple of hours. But here is another voice exclaiming, "Take him out, he is crazy; put him in the asylum for advising calomel."

Now, gentlemen, before taking me to the asylum or drowning me in a duck pond, allow me to place myself on the witness stand, ready for your interrogatories. Question number one. Why do I recommend venesection? Answer. To reduce the excited condition of the heart and arteries that supply the congested tissue, as well as the muscular fiber of the

rigid muscles, to attract the circulation to the bleeding arm; to equalize the circulation that destroys the carbon dioxide, pathogenic microbes, toxines, and ptomaines. Question number two. Why do I recommend calomel? Answer. To awaken the dormant functions of the liver, for the antiseptic properties of bile, to stimulate the glandular system, for its own antiseptic properties, and to equalize the circulation. Question number three. Why do I advise large and repeated doses of iodide of potassium? Answer. For its alterative effects on the glandular system, for its own antiseptic properties and absorbing function of effused fluid. I apply ice to the head for the patient's comfort, to abstract the heat, to constrict the capillary vessels, to relax the irritable factor of the arteries, promote free circulation of oxygenated blood, and to encourage physiological metamorphosis of tissue. I sponge the body to invite capillary circulation and relieve constricted arteries. I prescribe opium to keep the nervous system quiet and to relax the irritable factor of the muscular fibers.

Now then, if my physio-pathological theory is a back number that has passed its day of usefulness, etc., I will ask my sagacious critic how anti-toxine cures pathogenic diseases; or how does the lumbar puncture cure cerebro-spinal meningitis, or how any of your new theories and remedies cure disease, if I am wrong.

Years ago when I was practicing medicine in Southern Ohio we had an epidemic of this spotted fever that proved very fatal. My first case was a young man about twenty-five years old. I found him with all the characteristic symptoms of the disease. My treatment was in accordance with our text-books and medical journals, but my patient died the third day after my first visit. Three days later a brother of his, about twenty years old, was taken sick in the same way. Did I treat him in the same way? Oh, no; I opened a vein in each arm; I bled him about a quart, and in less than a minute every muscle of his back and extremities were thoroughly relaxed. I followed the bleeding with large doses of calomel and sulphate of magnesia, which acted thoroughly before morning. I also gave him five-grain doses of iodide of potassium every three hours, with cold cloths to the head and neck, and thorough sponging with hot water. I also gave him small doses of opium. On my return the next morning I found him much better, neither pain nor rigidity of muscles had returned, and he made a successful recovery in about ten days, after which I treated five or six cases on the same principle and all recovered.

And now, in conclusion, I do not wish it to be understood that I am opposed to any new theory, as I am enthusiastic on the advancement of medical science, more especially on bacteriology, yet I am convinced from daily observation and experience that (more especially our younger members) we are chasing the little bacteria, or vegetable fungi, into space of an ethereal medium to get a glimpse of its morphological shadow, neglecting and relegating to the rear some of the most veritable, indefatigable, and fundamental principles of scientific medicine. But to be fashionable and up to date, as we hate to be called an "old fogy or back number," we adopt or use all the new remedies, irrespective of pathological conditions. And, as I have already stated, judging from what I can see almost every day, our noble profession is drifting into empiricism more and more every year; lucubrative hours of study are made unnecessary, physiology and pathology are placed in the same category with bleeding, cups, blisters and calomel, and all the up-to-date doctor will have to do to get a lucrative practice will be to commit big medical words, that common people do not understand, to have a fine office, an X-ray machine, and a big supply of surgical instruments; to wear a plug hat, to advertise extensively, and ride in an automobile, and he will make the "old fogy" doctor "git," (?) with a shovel or spade on his back, looking for a job to support himself and family, or starve (?).

The BRIEF is a practical, up-to-date journal full of meat, and certainly the best thing the country doctor can get for one dollar.—J. S. BALDWIN, M. D., Freeland, Md.

[Written for the MEDICAL BRIEF.]

Effect of Lenses Upon the Oculo-Motor Centers.

BY DAVID KLETZKY, OPH. D.,
Pueblo, Colo.

Lenses have been in use for the improvement of vision since the thirteenth century, but it is within comparatively recent times that their field of usefulness has been extended to wider limits. I say wider limits, because formerly lenses were looked upon as a means of bettering vision only, but modern ophthalmological research and experience, while bringing about great changes in this direction, have also revealed the undisputable fact that lenses exercise a great influence upon the oculo-motor centers. In consequence of this, a lens-therapy came into existence, which, if properly applied, does not only tend to rectify abnormal ocular functions, but with it the amelioration of many reflex nervous disturbances, remote from the eye, is brought about.

Had the eye been a fixed optic system, the problems connected with its deficient refraction would have been very easy of solution. But as it is, a pair of normally functioning eyes have the power, with the aid of fourteen muscles (two ciliary and twelve recti), to vary their dioptric and rotary action, as in the act of accommodation and convergence, and at the same time maintain a state of parallelism of the visual axes with far greater accuracy than is required of any organ of the system.

The principle, and, we might say, the only factor which influences ocular sensation and ocular dynamic action, is light. But this subtle fluid, in order to satisfy the sensory centers of visual perception, must not only enter the eye and focus properly upon the most sensitive part (the macula lutia of the retina), but also, when entering the two eyes, according to the law governing binocular vision, must impinge upon the same identical spots of the two retinæ in order to produce a single visual impression.

The reader can thus readily understand that the function of a pair of eyes depends greatly upon the behavior of light entering within their chambers. Any deficiency in refraction or abnormal muscular enervation tends to so disarrange the rays of light within the eye, that clear and accurate visual impressions are no longer possible without subnormal muscular contraction. It is here that lenses exercise a great influence over the rays of light entering the eye, and thus direct the proper impingement of images upon the necessary physiological positions of the two retinæ. They not only accomplish this, but, at the same time, cause a relaxation, or depression of undue muscular contraction—thus acting as oculo-motor depressants.

In fact, the various lenses used for the refraction of the eye can be classified as oculo-motor depressants and excitants. Thus, plus or convex lenses, besides converging rays of light, tend also to relax muscular over-action—as in latent hyperopia with excessive convergence; hence, we can class them as oculo-motor depressants. Minus or concave lenses, besides diverging rays of light, have a tendency to excite muscular action, and while they are seldom knowingly prescribed to be worn constantly for that purpose, nevertheless they are useful as oculo-motor excitants for diagnostic purposes—such as exciting action of the ciliary muscle, and thus measuring the accommodation of the eye; hence, they can be classed as oculo-motor excitants. Prismatic glasses have the qualities of the two, *i. e.*, they act as excitants and as depressants, depending much upon their position before the eye and upon the mode of their application. When the base of the prism is placed in a direction against the rotation of a heterophoric eye, the prism acts as a depressant. When it is placed in the direction of the rotation of the same eye, the prism acts as excitant.

In summing up the effects of lenses upon the oculo-motor centers, we find that while they have a definite physical action upon light, they also have a primary psychological effect upon the visual centers, *i. e.*, the mind becomes cognizant of the changes of the retinal image the lenses at first produce, and, as a result of these changes, a secondary physiological function is immediately established;

this is brought about (according to the kind of lenses used) by relaxation or contraction of the sphincter irides and the ciliary muscles, and also of the extrinsic muscles of the eye.

Thus the thoughtful reader must be impressed with the fact that lenses, in the hands of the well-educated ocular refractionist, are as much of an armamentarium as the "medicine case" is in the hands of the physician.

Alcohol in Medicine.

BY W. C. COOPER, M. D.,
Cleves, Ohio.

In my late work, "Preventive Medicine" —still in the hands of the printers—I have taken a strong position against the use of stimulants, either in health or sickness. This will bring down on me an overwhelming wave of unfriendly criticism from the straightly classical therapeutists, because of its bold heterodoxy. On the other hand, it will call out the plaudits of all *temperate* lovers and defenders of temperance. I use the qualifying adjective, "temperate," in the foregoing, because there is a considerable class of *intemperate* temperance people. A certain proportion of people born into the world are idiosyncratically extremists. They can not step a foot without stepping a yard. The *ungoverned* momentum generated in stepping the foot carries them into an extreme. An extreme is necessarily antithetically related to sober sanity. Extremes always represent dead points, such as the limits of a pendulum's arc. These dead points are merely recoil epochs and are essentially self-annulling, so far as positive significance is concerned. It is exactly as unfortunate to be an extremist as it is to be an ultra-conservatist. The golden mean is the pivot on which the world turns.

These thoughts have been suggested by the more or less frequent appearance, lately, of articles in which a decided stand is taken against fluid medicines because of the alcohol contained in them! The zeal of some of these extremists has driven them to the monstrous assertion that a dose of a tincture may contain as much alcohol as is held in a glass of beer. Now, let us reason a little. I have never chemically tested beer with reference to its alcohol, but there is a practical and very impressive way of getting at it. Give any one not accustomed to stimulants a glass of beer and it will make him or her a *little* boozy. At another time give the same person two teaspoonfuls of brandy, or whisky, and it will affect him or her not more (generally less) than the beer did. I know what I am talking about, for I have instituted this test on myself and others many times. Try it fairly and you will see my statement verified. I infer that a glass of beer contains at least as much of the intoxicating principle as is contained in two drachms of brandy or whisky. In this connection it is proper to say to beer champions that the salicylic acid and other deleterious substances contained in beer are more baneful than its alcohol.

There is advertised certain makes of "bitters," in the large dose of which (a tablespoonful) there may be two drachms of alcohol. They are drunkard-makers, and can not be too severely condemned. No legitimate physician ever recommends them to his patients. They are sold by their proprietors directly to the laity.

There are few official tinctures the maximum dose of which is more than ten drops. In all fluid medicines the alcohol is reduced to merely the extracting and preserving point. One reason for this is because the preparation is given for the sake of the drug (not the alcohol) it contains; another reason depends on commercial prudence. It is conjecturally safe to divide by two if you want to get the amount of alcohol contained in a given quantity of the usual tincture or fluid extract. It will be seen that you would have to give a patient at least twenty doses of the official tinctures in order to get into him the amount of alcohol contained in a glass of beer.

But most modern physicians use the concentrated fluid medicines, such as Lloyd's specific medicines. Merrill's normal tinctures, or the fluid extracts of responsible manufacturers. Of many of these medicines the patient gets only the fraction of a drop at a dose, and only oc-

casionally more than three to ten drops. Our homeopathic friends give in still smaller quantities. It is perfectly conservative to say that the *average* dose of fluid medicine does not contain more than five drops of alcohol. The usual patient, therefore, must take twenty-four doses of medicine in order to get his glass of beer from his doctor.

There is a class of very excellent remedies—some of them proprietary—the dose of which is a teaspoonful. At the most, a teaspoonful of these does not contain more than twenty drops of absolute alcohol. If a less quantity will preserve the drug, be assured a less quantity will be used. A patient would have to take at least six doses of any of these to get his glass of beer. It is very rare that a patient is given more than three doses a day of any of these preparations, so that he would occupy two days in consuming his glass of beer. That is pretty moderate drinking, even if he took the straight beer, instead of getting it through a disagreeable circumlocution.

None but drug nihilists can champion non-alcoholism in the preservation of drugs. They practically hold that the minute quantity of alcohol the patient gets with his medicine infallibly does more harm than the drug does good. It is true that there is a class of drugs from which the isolated active principle can be reduced in powder form, but it is the opinion of a large proportion of practical physicians that this isolating process sacrifices very important associated elements. At any rate the profession is not going to drop the galenicals for the trivial reason that the patient gets with them the ghost of a hint of alcohol. If there is *any* promiseful reality in the use of drugs, it offsets a thousand fold any possibility of harm that may inhere in the alcohol fact, as connected with them. You get as much alcohol in the bread you eat at a meal as is contained in the usual dose of a tincture medicine.

I think the medical profession can be safely trusted for both its intelligent and its conscientious interest in the physical and moral weal of humanity. It represents the concentrated sanitary and salubrious wisdom and efficiency of all the ages, and by virtue of its humane and philanthropic relationships, it is the peculiar friend of the race. Its perpetual study is the physical, and consequently the moral, betterment of human conditions. Let us lean on the intellectual sufficiency, the moral inflexibility, and the all-involving kindliness of this oldest and noblest of the professions.

Importance of a Thorough Examination of the Throat in Diseases of Children.

BY C. DEARBORN WARREN, M. D.,
Houston, Texas.

The startling prevalence of the affections of the nasopharynx as adenoids and tonsillitis, and the grave conditions which are caused by postponement of treatment, is a sufficient apology for the introduction of so time-worn a subject.

Chronic naso-pharngeal obstruction is found in about three per cent of children. Although the specialists have sufficiently elucidated this important condition a great many practitioners fail to give it the attention that it deserves.

The object of this paper is not to elaborate new features of diagnosis or innovation of treatment, but to call especial attention to the well-known facts. All children, regardless of the symptoms or presence of a disease, should receive a thorough examination of their throat; digital, if swollen larger over the rhinoscope, is preferable.

Enlarged tonsils may be seen by inspection, but there may not be much enlargement of the tonsils and fail to observe anything abnormal when the pharynx is blocked. By digital examination it can be felt as flat, round and sometimes resembles grape-like papilloma. The family must be warned of the condition that follows and unless this is done they realize that the child will be deformed and stupid, they will readily give their consent to their removal.

The dangers of the operation are very small. To temporize is useless.

[Written for the MEDICAL BRIEF.]

A Discussion of the Most Leading Questions Which Confront the Human Mind.

BY G. H. MORGAN, M. D.,
Knoxville, Tenn.

What is organic life?

Organic life is the result of a physiological association of the specific chemical constituents in an organism.

When did life originate?

All life originated in the beginning of creation, and will continue in an organism as a result of a union of elements, but when dissoluted must return to the fount from which it came.

What constitutes an individual?

A union and agreed association of those specific chemical constituents associated with the spirit man, originate consciousness and consciousness ripens up to responsibility, and thus forms the individual, or a perfect unit of being.

What is the prime cause of the heart's action?

The prime cause of the heart's action are due to the stimulus found in the constituents of the blood, which exerts an influence upon the internal sensorial nervous cardiac region, and thus produces the systole, or first sound of heart. The diastole, or second sound of the heart, is but a rest or a period of repair. The molecule stimulus of the blood produces that regular equilibrium and perpetual action of the heart, and is no less phenomenon than is demonstrated in the untold millions of worlds floating out in space.

What relation do we sustain to the earth?

We sustain the same relation to the earth that a child sustains to its parents. Every molecule of the body is of the earth and truly belongs to the earth, and must return to the earth.

What would result if our relation with the earth were severed?

If our relation with the earth were severed, the required stimulus of the blood would be wanting, hence the contraction of the heart would cease and death would ensue and all vitality come to a rest; just as a planet would cease to move if the centrifugal and centripetal forces were removed.

What is death?

Scientifically speaking, there is no such a state as death, but, relatively speaking, death is a dissolution of the specific chemical constituents in their physiological association in the organism. The relation and conditions of the molecule in death is the reverse to that in life. In life they build, but in death they dissolve. The dissolution is always the result of violation, producing a disagreement in the molecule of the organism. A house divided against itself can not stand; when union ceases death ensues.

Which is the most natural, to live or die?

It is more natural to die than to live, since all conceivable forces or motion is hastening to a final rest.

What is pain?

Pain is the result of a disagreement in the equilibrium of the physiological combination of the specific chemical constituents of the organism, and in which there must be union to sustain life or vitality.

Does pain tend to destroy life or hasten a dissolution?

Pain does not tend to destroy life or hasten a dissolution, but is only the result of the causes hid in the organism, which causes are destined to hasten a dissolution of the physiological relation of the specific, chemical constituents of the organism. Pain is man's best friend; it is a signal, warning man of his approaching danger, and often continues until the organic lesion is removed. Pain is not a true measure of approaching danger, but often exaggerates.

To what degree have medicinal remedies relieved or profited humanity?

In the aggregate, medicinal remedies have not profited humanity, but rather degraded the character and crippled the organism.

There are at present about ten thousand six hundred and sixty-two remedies discovered, and they are expected to contend successfully against twenty-one hundred and fifty-one diseases or morbid conditions of the organism, but in my opinion two of those leading remedies alone, stimulants and sedatives, have degraded and

impoverished the organism physiologically, and thwarted man's being decidedly more than all the combined diseases of earth; while the unwise use of the many other remedies conducted by unsafe hands have softened the osseous structure, weakened and dethroned the nervous systems, and crippled the circulation, and thereby increased the malignancy of disease and often hasten decay and death. Yes, man has sought relief through remedies and often found death. Yet much and lasting good has been accomplished by the hand of the honest and skilled surgeon, aided by the true effort of the good and wise physician.

What relation is sustained between the body and mind?

The relation sustained between the body and mind is of such a character that the conditions found in the body truly moulds or shapes the destiny of the mind (no body, no mind). Like body, like mind. There is a minute cause hid away in the organism of every living individual which defies analysis and confounds speculation, and yet is sufficient to develop or control every emotion of the individual. Professor Elma Gates has succeeded in proving the temperament of an individual by analyzing the saliva.

Our weakness or failures are due to a morbid condition, or a deformity of the molecule of the organism, and is always the result of violation.

The former generations are highly responsible for our failures, while we are responsible for the failures of those who are to come after us.

Is the doctrine pertaining to the resurrection of the body, as we are taught in the Bible, sustained by a demonstration of natural laws?

The doctrine of the resurrection of the body is fully and reasonably taught in the Bible, but to my mind is clearly proven by the demonstrations of natural laws.

One drop of water reduced to its minute chemical constituents and transformed, even into other formations, and scatter it to the four winds of the earth and let it remain for a period of millions of years; its contents is neither hid, nor lost, but at the bidding of two natural laws, evaporation and condensation, which is only but the power and will of God, it comes forth and presents its former appearance.

Heat when diffused in space will return to its former state at the bidding of natural laws. Light, when radiated, may wander through the dark, cold region of space for all time to come, yet not a ray is lost. Vibrations may continue through time and sweep eternity; a single thought winds its way, like a blazing star, and yet never dies. In all creation there is neither gain, nor loss, but a broad field of eternal facts sweeping on to a perfect intent.

The body is as immortal as the soul, it can not be annihilated. This is clearly proven by every demonstration of natural laws. Yes, to the finite mind the act of resurrecting is far less wonderful than the act of creating and reasoning according to natural science; man shall hear the still voice of God, and shall come forth and shall present his former appearance, and which act will be, to the finite mind, the most superior and crowning effort of God in all his works.

Is there a permanent change in our climate and if so, what are the causes and what will be the ultimate result?

The climate in every nook and corner, not only of our globe, but of all other globes found in space, are undergoing a permanent change rapidly, in proportion to the reduction of their internal temperature. The moon at one period was a beautiful orb, possessing all the qualities and beauty of the earth on which we live, but due to the smallness of its size, it has long since cooled out sufficiently to drink into its substance all the water that ever existed on or about its surface, leaving the moon a cold, barren field. Its death as a planet is due to the fact that no water is found on its surface to create or modify its atmosphere.

The earth at one remote period, like a flying, blazing ball, surrounded its surface, but held many miles far away.

All the water and constituents which go to make up our atmosphere, but at a later cooling the refreshing showers first fell upon the pools and continued to increase until there were formed beautiful lakes, and continued to move toward the equator and increase in quantity until the

entire earth was covered, like an ocean deep; and the continual fall of internal temperature, aided by absorption of the soil, resulted in beautiful islands and, later, into magnificent continents.

And this cooling and absorbing process will progress increasingly until all the water which once contributed to a beautiful world, will be hid deeply in the bowels of the earth, or resting on the surface in the form of perpetual frozen fields of ice. The appearance of all former water beds to a casual observer prove this fact to be an axiomatic truth. Yes, our beautiful world on which we live is hastening on to its everlasting death; and those who will view us from more magnificent distant worlds will exclaim of the earth, as we do of the moon: "She is dead, but will continue whirling on through space as a dead planet for a period which is incomprehensible by a finite mind."

It Was Intuition.

BY ALEXANDER WILDER, M. D.,
Newark, N. J.

Many years ago, Nathaniel Hawthorne was summarily dismissed from his position in the Custom House at Salem, Massachusetts. He had been honest, faithful and efficient, but a new administration had come into power at Washington, and Mr. Hawthorne was a Democrat. Friends sought to procure his reinstatement, but one individual opposed the endeavor with the remark that the man was a "visionist."

Probably my attempt to solve the question of Dr. Wilmans in a recent issue of THE MEDICAL BRIEF will subject me to the like imputation of visionary, as believing in the reality of things of the imagination. Perhaps I am credulous; I am anxious to believe, but have an almost morbid fear of being deceived or mistaken.

Dr. Wilmans states that his patient was suffering from a gangrened limb, intensely painful and emitting a putrid odor that could not be endured. Physicians had treated it without success, and Dr. Wilmans being called to the case, dressed it with carbolic acid. Being summoned again some days later, he applied a lotion of persulphate of iron, instructed the patient to apply it himself, and hastened away to get into a tolerable atmosphere. On the eighth day afterward, the patient met him and showed him the limb, almost entirely recovered.

The doctor asks whether others have had similar experiences, and whether it was "intuition" on his part, or "faith" on the part of the invalid, that performed the cure, or whether it "just happened." I do not relish the practice of referring matters which are hard to explain to "coincidence." It is a species of wilful disbelief. Such would find my evidence, even of their own eyesight, incredible. I am willing to ascribe wonders to the power of faith to effect cures, but it appears to me that if this patient had been a case of faith, he would have begun to recover when Dr. Wilmans applied the wash of carbolic acid. We are shut up, as candid individuals, to the conviction that Dr. Wilmans followed intuition.

There are two great classes of human beings as distinct, and yet, perhaps, as essential to each other as the opposing poles of the magnet. One class is susceptible to mental suggestions and telepathic communication, the other scouts everything of the kind, like the Sadducee, believing in neither angel nor spirit, and even venturing to eliminate the Supreme Being from the universe. To the former of those classes, the true physician must belong. Of this I would be exacting; I care little for his diploma, and absolutely nothing for his paid-for license, when the individual himself is up to the mark. Licenses do not create physicians, or even show they are good and deserving ones. Dr. Wilmans is evidently of the former class; and if I were to have occasion for treatment of a character analogous to that which he describes, I would like to have him, or some one like him, within call.

It can be no extraordinary concept that the mind is more a reality than the body. It is permanent—always identical, the same entity in the octogenarian as in the ephebos. The body is always changing, and perishes totally when the mind is gone. Being the true entity of the individual, it is able on its own account to communicate with other minds and re-

ceive suggestions from them. This may possibly explain the point in Dr. Wilman's procedure. Or it may be that there was some secret knowledge or concept hidden away in his own mind, which, like a forgotten reminiscence, only required an exigency to bring it into conscious remembrance sufficiently to enable him to put it in practice. I think it was intuition.

[Written for the MEDICAL BRIEF.]

Vitality.

BY F. L. GOURLEY, M. D.,
Waukegan, Ill.

Vitality is the name ascribed to the power or force of a cell, or a collection of cells, which go in different shapes and forms to make up the different tissues of the body, to resist germs which might under other than a healthy condition produce their characteristic disease. That power or force lies in the protoplasm of the cell, with the nucleus as a center. Germs, or bacteria, are active cellular organisms found in air, water, milk, foodstuffs, etc., which pass from one place to another as long as they retain their life, seeking some favorable media upon which they can thrive and propagate their kind. Good, healthy cells make up healthy tissues. Now, an inflamed or abraded surface is a good media, where germs can thrive, or a route by which they can enter the blood or lymphatic circulation, and there they can go to work, or be carried to other organs of the body which may be a more favorable location.

There are two kinds of vitality: Localized and general. A diseased condition of a localized tissue produces a localized lowered vitality of the affected part; that is, the tissues in a state of inflammation are using their power endeavoring to repair the condition already present, without the extra effort of endeavoring to destroy or hold off the effects of germs other than those already present, which are looking for just such a media. An example of this is a tubercular bacillus endeavoring to get hold on a case of chronic bronchitis. Another example would be a case of typhoid bacillus endeavoring to work on an inflamed intestine, such as chronic enteritis. General lowered vitality we find in such cases as rickets, chronic gastritis or such diseases as produce malnutrition. In these cases we have six cells all over the body, making the individual a compound of six cells; therefore, general lowered vitality, for in such state the individual's entire body is composed of poorly nourished blood and nerves, a media for many kinds of germs.

Therefore, we have vitality, whether local or general, the fighting power of the cells or tissues. When in perfect health the vitality is highest, when through disease, malnutrition or injury it becomes lowered until death of the cells or tissues are reached, or by repair they again regain their normal health, or highest vitality. In the treatment of these diseases the first and most important thing is to make a diagnosis of the part or parts effected, whether local or general. If localized, then we should prescribe, or apply, such medicinal remedies and give such attention to those parts as is necessary to effect a cure. If it be malnutrition, correct that by out-door exercise, cod liver oil, stimulants and good, nutritious foods. Vitality, then, is found to be energy, force, or the resisting power of cells and tissues to keep in health and starve out the germs which are constantly present, and not succumb to a lowered state, where they become a favorable media.

A Singular Case.

BY R. A. CLOPTON, M. D.,
Milan, Tenn.

I have just had a singular case of which I wish to tell you.

Mrs. S., aged forty-two, married fifteen years, no children, has been in bad health for several years. She has been treated by half a dozen different surgeons and gynecologists without much, if any, benefit.

She came to my sanitarium on April 2, this year, in a very weak, debilitated condition, bordering on complete nervous prostration, and weighed eighty-five pounds. She was suffering with constipa-

tion and stricture of the sphincter muscles of the anus.

She could scarcely walk, even with the aid of a support, and could not stand more than a minute or two at a time.

She was without appetite and subject to nausea. Her menstruations had ceased about eight months ago.

Upon examination I found that she had a double vagina, *i. e.*, there was a septum between the two openings to the os uteri, and on digital examination the os could be felt through both openings.

The septum extended to within one-quarter of an inch of the os, and on introducing the sound the womb was discovered to be scarcely two inches deep, yet was in a normal condition; no ulceration.

This patient and her husband, on account of her age, refused to submit to an operation to sever the septum, and thereupon I began and pursued treatment as follows:

I gave static and galvanic electricity; also, the indicated internal remedies; also, having her use, at bedtime, anal dilators of different sizes, which have overcome the constipation, nausea, etc., and she has improved remarkably fast. She has gained more than ten pounds in flesh, walks with ease about the place without support, eats heartily and digests her food quite well. She has regained her spirits and is as cheerful and hopeful as a child.

Now, what do you think of this case? Is it a rare or common one? In all my practice I never had but one case similar to this one before. The other surgeons who examined her never discovered the peculiar septum.

A Matter of History.

BY CHAS. S. MACK, M. D.,

La Porte, Ind.

In Luther's day a question arose as to union between one and another body of Protestants. "The matter, said Butzer, was a mere dispute about words, and was so difficult only because they had 'abused and sent each other to the devil too much' "—(*Kostlin.*) Has this bit of history a lesson for us moderns in a divided medical profession?

[Written for the MEDICAL BRIEF.]

An Interesting Case.

BY H. H. HARMAN, M. D.,

Shellman, Ga.

The following history of a case, which occurred during the Civil War, may prove of interest to BRIEF readers.

Mr. Jasper Swords, of Company H, Fifty-seventh Georgia Regiment, was shot the second of July, 1863, at Gettysburg, viz.: two inches from root of nose to the entrance of the bullet in center of cranium, was rendered unconscious for awhile and found himself behind a rock not far from where he was shot, and seeing no enemy near got up and made for the rear under a fusilade of musketry and grape shot, and but for his belt, which saved his life, this history would not be written. He walked from Gettysburg, Pa., to Staunton, Va., and never rode in a wagon or ambulance; thence by rail to Lynchburg, and in four days left for Georgia, and with the exception of a few pieces of bone that came away, had no trouble. He returned to Virginia in the latter part of 1863, and the first of October found him in the ranks with his company, with no impairment of mind or body, and on October 19, 1864, had a leg shot off and was paroled in March, 1865, and in the evacuation of Richmond was recaptured and returned to prison and was not released under two or three months.

Now, as to the subsequent history of this now old man. He came home and ploughed an ox until the State gave him a one hundred dollar pension, and he invested in a mule, and has raised seven or eight children and worked on the farm until three years ago, when he had an attack of rheumatism, which has permanently disabled him. Last year he had a slight stroke of paralysis on right side, but has gotten well enough to walk on his old wooden leg. During April he awoke one night and found a piece of lead in his mouth, and on examination found nearly one-half of a minie ball in his mouth, which had escaped back of his uvula. He now has some nasal discharge of a purulent character, but goes about wherever he pleases. The size of the bullet is three-fourths of an inch long and

one-half of an inch wide, with the under surface rather rough. Now, in what part of the brain has this piece of lead been these forty-two years, showing no inconvenience until some time last year. All these years, except a few chills and fever, he has been very well and is now seventy-one years old. His vision is somewhat impaired and has been for three or four years.

[Written for the MEDICAL BRIEF.]

A Nut to Crack.

BY W. T. DAVIS, M. D.,
Harrodsburg, Ky.

I noticed in the October MEDICAL BRIEF an article upon yellow fever, written by J. H. White, M. D., of Mobile, Ala. Dr. White states, in regard to the etiology of yellow fever: "As to its etiology, it is conveyed *solely* by the mosquito known as *stegomyia fasciata*." This fact was proven by the experiment of Walter Reed, Surgeon U. S. A. Now Reed's experiment showed that a mosquito, to become infectious, must bite a yellow fever patient during the first three days of his fever. The medical fraternity all know that a mean annual temperature of about 72° F. is necessary to its activity, and that cold —a frost—suffices to destroy it. We also know it occurs only south of 48° north latitude.

Now, I wish to learn something in regard to the cause of such a fatal disease; that being my object, I wish to ask a few questions. Does the mosquito (*stegomyia fasciata*) go beyond the bounds of yellow fever at no time? When the mosquito wings its way as far as south of 48° north latitude, does it halt there? If the mosquito can and does go further north, why is it we have yellow fever *only* south of 48° north latitude? The mosquito could bite a yellow fever patient and then cross the line. If it can and does cross and bite people unlimited, and they would be just as liable to take the yellow fever as those that were bitten in the yellow fever district, and then emigrated somewhere north before it showed itself again. The first frost puts an end to yellow fever. Does it put an end to the mosquito also? If yellow fever is conveyed *solely* by the mosquito after it has bitten some yellow fever patient, where does the mosquito find the first yellow fever patient to bite? What caused the first case of the yellow fever to make its appearance, so the mosquito could have the chance to bite it? It reminds me of the Irishman's cow. A lady in the presence of an Irishman, remarked: "I would like to own a cow, giving milk, that had never calved." The Irishman spoke up very fiercely: "Begad, madam, I have the identical cow you are wanting; she is now giving milk and never had a calf; neither did her mother before her." How did the Irishman's cow come? How did the first case of yellow fever come for the mosquito to bite?

Gentlemen, we had better combat diseases after they make their appearance than to waste our time after causes of diseases, when we are very little nearer knowing the causes of diseases now than we were fifty years ago.

[Written for the MEDICAL BRIEF.]

Malaria and the Mosquito.

BY JAMES A. HOPKINS, M. D.,
Milton, Del.

We see that many of the medical journals of the day are inclined to bring many charges against the pesky mosquito, not so much for his mischievous habits, but as one of the causes of malarial fever and much of the trouble that it brings. We often see diseases which, for convenience, we call malaria; it may be so, and lay it at the door of the mosquito world. We have never had much love or regard for him, yet we are inclined to think that he is a very much persecuted insect and stands charged with sins, many of which he is not guilty. While this does not worry him very much, for his life is short, at best nine days reckons their length, and the end of time with him.

We happened to arrive in this world on a farm, very near a salt and fresh marsh, where all sorts and kinds of mosquitoes were raised, or grew up, in great abundance. At that time chills and fever prevailed, as well as many other malignant diseases. We were compelled to use large

quantities of calomel and quinine, as well as other drugs, to make our patients well. This state of affairs continued through the fall months of each year. Nearly every house was a hospital at that season. Agricultural interests ran low, but Necessity, the mother of Invention, brought about a condition where an improvement of the soil was a necessity, or no crops; hence the use of lime to replenish that which had been exhausted from the virgin soil, when the malarial troubles gradually began to decline. The pesky mosquitoes continued. A few years after this the farmers began the growing of wheat and other crops, where fertilizers were used, when the malarial fevers abated more and more, and have continued up to this time. Now, they are almost unknown (as an epidemic), and instead of one ounce of quinine each a week, we do not use one a month in all of our practice. The marshes yield about the same crops of mosquitoes every year, but chills and fevers are *non est*. While we will not excuse the mosquito entirely, for there may be a case traced to his embrace, we have seen ugly sores and blood poison occur from his bites and stings, but must say we believe him to be a much-persecuted insect, and that the mosquito has its origin from the malaria, and not the malaria from the mosquito.

[Written for the MEDICAL BRIEF.]

"The Psychology, Chemistry and Magnetism of Love."

BY AXEL EMIL GIBSON, M. D.,

Los Angeles, Cal.

[A few reflections *apropos* Dr. Lindsay's paper on this subject, published in the July number of MEDICAL BRIEF.]

While the manifestation of the affectionate emotions, with their fluctuating desires and attractions, may resemble the affinities exhibited in electrical and chemical action, the semblance, however, is confined to the surface, as the principles involved in the two processes are fundamentally different. Thus love, being a psychic power, can never be considered molecular, while chemistry and electricity, with their basis in the elemental world, undoubtedly are. The one set of forces, the molecular, influences the mind through the body; while the other, the psychic, influences the body through the mind. The former constitutes the universal rebound of spiritual forces reflected by matter; the latter, the original action of these forces on their passage from their point of emanation to their work on the substances and entities of natural evolution.

Electro-chemical forces furnish the basis or environment by and through which the elemental action of life is rendered possible. But the forces of environment are dormant and must be elicited by external stimuli. Now, if these forces were derived from no other source of power than their own combustion, the elemental forces of evolution would gradually exhaust their storehouse of dynamics, and the impulse at work in forming and breaking up molecular affinities, be arrested, with the subsequent cessation of evolutionary activities.

Without this original, ever fresh, ever constructive impulse in natural evolution, the ascent of life, with all its specialties of growth and progress, would be impossible. Through this impulse new fuel is continually poured into the evolutionary furnace to sustain the vital combustion of substances in the ensuing structures. To regard this impulse, however, as self-generative and self-directing, would have no support in any known condition of growth and unfoldment. As the chemist in his laboratory conducts the paths of his bases and acids, his solids and fluids to form combinations of purpose and usefulness to life and culture, so in the "chemistry of love," to use Dr. L.'s nomenclature, the processes of emotions and feelings, affections and disaffections, etc., are guided by the "chemist of the mind"—the planning, directing, executive genius of life—the human soul.

Now, if the soul be the chemist of love, the mind is his chemical laboratory, and emotions, feelings, passions and desires are the elements by which the compounds of human characteristics—the vices and virtues—are formed. And the combinations do not ensue haphazard, but in minutest accord with the mental and moral attitude of the mind. No emotions enter the self-conscious mind, or are capable of

swaying it, with less invited by the moral attitude of the individual. For the mind is an Apollo's harp, on which every passing strain of emotion, every quiver of passion and feeling, if permitted, may evoke harmonies or discords, in accordance with the shades of the involved consciousness. And the strength of character, freedom of will, and power of determination arising from this play of con sciousness indicate our attitude to the moral issues of existence.

Plato was right, ideas rule the world. Impulses and thoughts, if tolerated, take possession of us, using our mind as arena for their tournament of suasion. And though the ensouling power of thought is love, the thought, as a vehicle, is capable of sustaining and promoting ignoble impulses. If the mind, however, be serene and pure, the idea entering it will transmit a message of the true, the good, and the beautiful, with a distinctness corresponding to the strength, purity and motive of its manifestation. Responsive to the beautiful, the mind becomes a receptacle for the art-idea, impelled and gauged by the power of love, and the man thus inspired becomes a lover of art, an artist. Likewise, the poet, the philosopher, the scientist, attain their respective powers of genius by receiving the ideas of the true and the good in their minds, under the guidance of love. In fact, all originality in thought or action, all inventive genius in art or construction, is due to the power of the soul to hold the mind attuned to the streams of creative ideas passing through its sphere.

Hence, love means something more than sex-instincts and conjugal personal relations. In fact, the more lust and passion involved in human affections, the less real love is present. Love, in itself, is ever true, ever unselfish, ever pure and, like the sun, with which it has an unmistakable semblance, diffuses its warmth and radiance over every object within its zone of energy. For what is love but a universal sun of soul-light, diffusing with unvarying intensity rays of truth, beauty and goodness to every receptive mind. And, as the physical sun in itself remains undiminished in its integral strength and brilliancy, whether its rays in their passage becomes obstructed, or not, so the sun of love, in its real, eternal nature, remains above the changes of time and circumstances, unaffected by the emotions, feelings and passions of the creatures moving in its sphere. For the changes of feeling to which it may give rise spring from its nature of expression, not from its nature of being.

Consequently, whatever is personal and selfish in the feelings and affections of men are not due to the nature and essence of love, but to the individual minds in which love finds a temporal expression. And as the sun—to continue the simile—depends for the clearness of its expression on the clearness of the medium in which its image is reflected, so the sun of love, reflected in the minds of men, will give rise to such expressions of feelings, emotions, sympathies, passions or compassions, lusts or affections, as find a basis of response in these minds.

The genesis of passion and lust in human nature is thus readily traced. For what are these low emotions but the distorted image of love mirrored in the turbid waters of a selfish, impure mind. The very power by which passion is found to wreck or thwart human destinies reveals unmistakably the source of its origin. Its strength, however, holds the same relation to love as a convulsive mountain torrent —rendered useless by its very forcefulness—holds to the ocean, which by its very calmness and placidity renders immeasurable service to the world. Love expands and universalizes, passion contracts and isolates. Love proceeds from the individual to the universal, lust from the universal to the personal. The one constructs, the other destroys; the one constitutes the driving force in evolution, the other its retarding factor—the dead weight on the train of life.

But while love is thus associated, directly or indirectly, with the various forces and powers of universal nature, it would be unphilosophical to identify love with any of these forces and to hold with Dr. Lindsay that it (love) is "purely magnetic, due to the affinity of positive and negative electricity." For if love is generated by electric polarity, what would give rise to the action of the latter? Or

how can the lesser contain the larger? The forces of chemistry and electricity give birth to a power by which they, in their turn, are conducted and governed. For is not love the governing power of life; the prism of consciousness, at once gathering and scattering the numberless forces manifested in universal evolution? The whole sweep of cosmic energy, to be constructive and purposive, requires the presence of a co-ordinating, adjusting intelligence. And what power of intelligence is more universally manifested than love, the influence of which is felt in the breath of every flower, in the affinity of every atom, in the sympathy of every heart? And, lastly, if love has its birth and genesis in electrical affinities, by what miracle did it evolve a power through which the very forces of its alleged origin are held in abeyance?

In itself unregenerate and indeterminable, the nature of love is intellectually appreciable only through its forms of expression. Its relation to these forms is ever that of silent method, and depends for its influence on the passive receptivity which the latter hold to the imparted impulse. Affinity does not take rise *by* the molecule, but *through* it; our affections are not generated *by* us, but *through* us. Philosophically considered, we do not love—*it loves* in us. Conforming to certain conditions of life, in thought and conduct, we grow receptive to the action of love, and its influence becomes manifested in our nature. In a lesser degree, the same also holds good with regard to the molecule, though the similarity between the molecule and the human creature lies beyond the form, in the universal essence vivifying the form. Furthermore, as the purity of human affections are due to the purity of the mind, so the qualitative value of inorganic elements springs from the ratio of vibration by which the molecules of these elements respond to the pressure of the universal life impulse.

This, of course, removes every trace of accident or chance from the process. For the difference in the powers by which the molecules respond to the vital impulse must be due to some inherent difference in the constitution of these molecules, which again must refer to some still deeper and ulterior cause. And this places the whole series of vibrations, molecular and hyper-molecular, with their corresponding expressions in affinities and affections, within the domain of laws, as cause and effect—the process of an occurrence unfolding into its appropriate sequence—forms the chain of events which constitute the reign of law. Hence, love and affinity, though *per se* ungenerate and indefinable, are, nevertheless, manifested in the affairs and destinies of men under the auspices of universal law.

In his argument for the molecular-magnetic nature of love, Dr. Lindsay makes the statement that "Two men with magnetic polarizations, falling into each other's arms in the dark, and each thinking the other to be a woman, would experience the same thrill of attraction as if opposite in sex. This takes much of the romance out of the usual love affairs," concludes Dr. L., who, while trying to prove the electro-chemical-molecular character of human affections, on the contrary (by the very situation used in his illustration) furnishes the most powerful argument in favor of love as an unique and self-sustaining soul-power. For if affection and affinity, love and polarity, are identical in nature, a deception, such as quoted by Dr. L., would be unthinkable, as neither electric polarity or chemical affinity depend on daylight for their processes. The masculine molecule in the one man would find no greater inducement in darkness than in light to combine with the equally masculine molecule of another man; not more so than a negatively-charged particle, through the cover of darkness, would be induced to combine with another particle, charged with similar polarity. Hence the very fact that darkness did not interfere with the workings of the affections of the two men, is certainly a good argument in favor of the view that the forces engaged in their natures were moral and psychic, rather than electro-chemical in character. Had molecular affinity been the determining factor in the case, a continuation of the attraction between the similarly polarized molecules of the two men would be scientifically impossible. For while human affections, under certain condi-

tions, may be blind, no such infirmity can ever be postulated in the workings of chemico-electrical affinities.

Love is a force, *sui generis*, and manifests under conditions and environments all its own. Ungenerate and eternal, it is not an output of evolution, but the cause and mover of it—the force *par excellence* by which the lower forms and substances of existence are propelled into ever higher and purer states and stages of consciousness. Its emergence in the human mind is not in the form of gift, but of attainment; the results of a culmination in an individual's life of universal virtues. Gradually, and with infinite care, preparations are made to render the mind fit for a dwelling place to the monarch of life and destiny. Hence, only the pure in mind can truly love. "A great love," says George Eliot, "does not necessarily mean a great intellect, but it certainly means a great nature;" a thought which received its highest amplification in the judgment of mercy pronounced by the sage of Nazareth on the woman who had sinned: "Her sins, which are many, are forgiven; for she loved much."

Sexual Hygiene of the Hebrews—The Sex Question

BY SILAS HUBBARD, M. D.

East Aurora, N. Y.

It would be a very long story to give the general hygiene of the Hebrews as given in the Pentateuch. Therefore, I will only comment on some of the sexual hygiene as given in their laws. I will begin with Exo. xx:14: "Thou shalt not commit adultery." This, according to Christ, means neither in word, thought nor deed—Matt. v:27.

It is written that Jacob peeled strips of bark off from green poplar and willow rods and set them up before the sheep and goats, that when they conceived they should conceive progeny ring-streaked and speckled—Gen. xxx:37-43. This was four thousand years ago, and very many modern physicians believe that very many mothers mark their offspring by what they see during conception and the early months of gestation, which ought to be a caution to mothers.

In Gen. xxxviii:4, 8-10, is given the account of Onan practicing "withdrawal," *i. e.*, committing race suicide. The Lord was displeased with that man and slew him. In race suicide by women many evils are frequently brought upon them. I will mention extra-uterine conceptions, and also weaknesses that can be traced to preventive means.

Very great care was taken of the hymen of virgins and very great dissatisfaction was found by the husbands to find the hymen absent—Deut. xxii:13-21. I will say the hymen was given for a purpose, and I will say even at the present day if possible it should not be ruptured out of wedlock. It at least betokens chastity. The Hebrews displayed more human nature in the protection of the hymen than did the ancient Spartans, who permitted their slaves to rupture the hymen of their virgin wives. The Spartans are lost; while the Hebrews at the present day are on top financially, notwithstanding the violent persecutions by the Russians, Roumanians, etc., etc. The United States is about the only exception where they have not been persecuted.

The Hebrew children were circumcised on the eighth day after their birth to forever remind them of their covenant with God; however, it also had the hygienic effect of cleanliness, and also frequently obviated the necessity of modern surgeons performing the operation to cure certain diseases.

The man or woman who laid with a beast carnally should be executed—Lev. xviii:23. The laws of our own land would severely punish such.

Sodomism was severely punished—Lev. xviii:22. Our modern laws severely punish the same if proved against them.

A penalty is put upon masturbation and incontinence, that a man shall not scatter his seed about wastefully—Lev. xv:16-18.

The Hebrew laws were comparatively lenient to a man who seduced a virgin, provided she was not betrothed—Ex. xxii:16. But if she was betrothed or another man's wife, then both the seducer and the seduced shall be executed—Lev. xx:10; which to some seems like a very

cruel law; but it is no more cruel than the laws of human nature, for the juries of our land acquit the near offended relation for executing the offender.

The Hebrew laws were apparently rather severe on the flirtation of wives—Num. v:12-31. I suppose it was a better outlet to the jealousy of certain husbands of those days than the course of certain husbands of the present day.

Lev. xviii:6-18: None shall marry near of kin; which are good laws, which very much prevents the deterioration of the race by intermarriage, and much other good advice is given in the same chapter.

Lev. xv:2-15: Gives the quarantining of a man with gonorrhea, which is far more efficient than any rules we have in modern days.

Lev. xv:19-27: Gives the quarantining of women during their menstruation and for seven days after, also the quarantining of any who have metrorrhagia, and seven days after their cure, during which time they shall not have sexual intercourse. Now let us see some of the effects of this quarantining; viz.: no children would be conceived during menstruation, nor metrorrhagia, nor short the eighth day after. There would be about twelve days of exemption from conceptions. The law in those days, three thousand five hundred years ago, when the women had no syringes, was a good law, and in obeying it they did very much better than very many women of the present day, in not cleansing themselves, and thus bringing diseases on themselves and frequently ophthalmia neonatorum and blindness of their newly-born children. Another effect of keeping these laws is that many more males are born among the Jews than among the Gentiles, or the world in general, because males are mainly conceived during the last half of the intermenstrual period and girls during the first half, and in this way the Hebrew laws compel them to give more chances for male conceptions than occurs to other nations. To prove this assertion, see my article in the MEDICAL BRIEF, Vol. XXXII., page 1024, and if all the Jews would strictly obey their laws there would even be many more male conceptions among them than at present.

In Lev. xii: The woman, after childbirth, is pronounced unclean twice as long after the birth of a female child than after a male child. The late John Stockton Hough, of Trenton, N. J., declared that this was because the placenta accompanying a female child is larger in circumference than the placenta accompanying male children; and he (Dr. Hough) thought he proved it, and he also thought that he proved that women aborted females oftener than males. I accounted for all this by saying that the placenta accompanying a female child is generally situated nearer the center of the uterus than that accompanying a male child, and therefore had more of an opportunity to expand than when it is situated in the upper part of the uterus, as is usually the case with the placenta accompanying male children. On page 7, Vol. XVI. of the MEDICAL BRIEF, I give the why and wherefore of the placenta accompanying a female child being broader and larger than that accompanying a male child, and why she oftener aborts females than boys, and why, according to Hebrew laws, she is unclean twice as long after the birth of a female as after the birth of a male.

Moses, in giving the laws to the Hebrews, made no distinction between leprosy, syphilis and certain other infectious diseases of the skin—Lev. xiii:14. He quarantined them all and treated them all in the same way, which was the best they could do three thousand five hundred years ago.

By these laws and all other hygienic laws of the Hebrews they maintained much better health than the surrounding nations—Deut. vii:15. And we could borrow many good hints from these ancient laws of the Hebrews.

THE SEX QUESTION.

Patrick T. Meldon, on page 752 of September BRIEF, says: "Marine scientists note the tides according to the moon, and this science is founded on the science of astronomy."

T. E. Reed, M. D., in the same number, page 751, contradicts him, and says: "The theories advanced in our works on astronomy are *presumptuous*."

Drs. Reed and Meldon oppose my remark that "the perfection of the flow of the tide is in the daytime, under the attraction of the sun," which statement

was merely designed to be understood that the tide, under the conjoint influence of the sun and moon, rises higher in the daytime than in the night under the sole influence of the moon.

Dr. Reed advises us to buy a certain large pamphlet, which gives us a summary of the tides along the whole coast of the Atlantic, including Canada and the West Indies. I would like to know how that would help us, living in the interior States where we can not perceive the tides, and also when the tides are not the same in time in any two places. In fact, I know of no other way of being certain in this latitude and longitude except to make a trip to the Atlantic coast, and enter the tides in a boat and there demonstrate the problem of the sexes, according to Dr. Reed's theories. I expect this would be cheaper and more certain than consulting Dr. Reed, the autocrat of the tide theories, for during the last ten or twelve years of his preaching these tide theories I have not heard of any physician being converted to them. I will say that I could name a number of talented physicians who have adopted, as facts, the larger portion of the theories which I advanced in the *Buffalo Medical Journal* in 1850, 1852 and 1855. I see they have come to stay.

[Written for the MEDICAL BRIEF.]

Pneumonia, Fatality In.

BY S. J. BROWNSON, M. D.,
Elkins, Ark.

Dr. E. V. Pennington, in the March BRIEF, has well-expressed the first half of what I have been trying to get time to say for several months on the treatment of pneumonia. I, too, used to wonder why there were so many deaths from this disease in New York and other Eastern cities, until I found about the same percentage died all over the country, wherever the same system of treatment was pursued. I have thought what Rev. Henry Ward Beecher used to say of Presbyterian graduates for the ministry could, with great propriety, be said of a very large number of medical students when they get their "sheepskins." The great divine said the Presbyterian minister, when he entered the ministry, "took an oath never to make any progress." Certainly the doctors who allow all the way from fifteen to forty per cent of their pneumonic patients to die, or even this ratio of their typhoid cases to pass over, have made no progress since leaving their *alma mater*. Far better, "let Nature take its course," than actually hasten poor, suffering humanity into its grave, as many of these young and old "fogies" evidently do.

In my practice of many years I have not lost two per cent of my pneumonic cases. This includes all I have had, except occasionally a case where I have been called in at the eleventh hour—in consultation—and I have saved a very large proportion of even this class of patients.

Now for my treatment. It is eclectic in the main. And this is quite a confession for me to make after graduating from an alopathic college. But I found the methods I learned in my college were not satisfactory, so I began to reach out for something better, and I found it. "Not ethical," does some one say? Well, what do I care for that; and the patients I cure care still less. The first and the supreme thing with me is to cure my patient. I care not a fig what I use, who discovered it, who advocates it, or who condemns it. I never think of medical ethics, or "pathies," when at the bedside of my patient. Morerover, I treat diseased conditions as indicated by certain symptoms rather than names simply.

In the pneumonic condition, as soon as the diagnosis is well made, I envelop the diseased lung in a thick, hot plaster, well-covered with several thicknesses of hot flannel or cotton—anything to keep the heat in and the air out. A bandage keeps it in place for two or three days, until it is dry, then it should be taken off. Within twenty minutes the patient says, "I feel so much better." Of course I see that the *prima via* is opened with one-tenth to one-half grain of calomel and soda bicarbonate, given every one to three hours for a few doses, unless contraindicated. If not indicated, I use chionanthus, podophyllin, or salts, and such a disinfectant as is needed. If patient is strong, with pulsating carotids and high fever, veratrum is my best sedative. If not, aconite or aconite and veratrum. If nervous, with

bright eyes and hot head, gelsemium Bryonia and asclepias I most always use for sharp, cutting pains on coughing or moving, and hard, vibratile pulse. If there is tendency to congestion anywhere, especially in the brain, indicated by dull pain back of eyes, dull look, or impaired capillary circulation, belladonna is the remedy; ipecac, lobelia, sometimes sanguinaria, or sticta are my standbys for cough.

The plaster is used only in the sthenic stage. I frequently abort the disease or jugulate it before the fifth day. I seldom have to use any digitalis, or other heart tonics. Explicit instructions are given as to diet, cleanliness, nursing, fresh air, etc. Occasionally a tonic is given for a few days in convalescence, consisting of quinine, or iron, strychnia, or Fowler's solution of arsenic, or all combined, as the condition demands. But sunshine, fresh air, light exercise and foods appropriate, such as old, well-baked whole wheat flour bread, eggs raw or lightly cooked, fresh milk, beef tea, cream of wheat, etc., and later fruits and vegetables, all well masticated, constitute the best tonic. Sometimes, in the aged, good whisky or eggnog is allowed.

This is my usual treatment. It is mainly eclectic—I give credit to whom credit is due—and hygienic. Old Dr. Nature is my great instructor. So I save about all my patients. Has Dr. Pennington anything better?

[Written for the MEDICAL BRIEF.]

Digitalis in Acute Bright's Disease.

BY W. S. ROBINSON, M. D.,
Nashville, Ark.

In the treatment of acute Bright's disease, you should hasten the elimination of urea and counteract the effects of urea and waste products upon the nervous system. The eliminative function of the kidneys is greatly increased by the administration of digitalis, and I regard it as the most valuable drug for this purpose; however, its action must be watched.

If the amount of urine is not increased, its use should be discontinued; but in nearly all cases it increases the secretion of urine without stimulating the kidneys to any great extent—and thus carries out of the system the urea and its allies.

In chronic Bright's disease, Tyson says the chief indications are, first, to improve the quality of the blood, which may have become anemic and contaminated with urea and allied effete matter; and, second, to combat the symptoms and complications which form a source of great inconvenience and danger to the patient. I have recently had a case of Bright's disease (locomotive engineer) who was pronounced hopeless by the railroad hospital physicians, and my treatment was iron, quinine and strychnine, in small doses, with strictly milk diet, and I have never seen a case improve faster. Now, whether it is the treatment or the milk diet that is doing the work, I am not able to decide. My opinion is, that milk diet in these cases is very important in the treatment.

[Written for the MEDICAL BRIEF.]

Chills and Fevers.

BY J. A. BURNETT, M. D.,
Cecil, Ark.

In "chills and fevers," when the liver is sluggish and there is constipation, the following gives good results:

℞ Quinine Sulphate ..... 72 grains.
Acetanilide ..... 48 grains.
Capsicum ..... 24 grains.
Podophyllin ..... 3 grains.

M. Sig.: Divide into twenty-four powders. Give four doses two hours apart before each chill. Beginning so that the fourth dose will come one or two hours before the chill is due. At other times give a dose every three or five hours.

[Written for the MEDICAL BRIEF.]

Depilatories.

BY T. HENRY WHITING, M. D.,
Elgin, Ill.

For the removal of facial hair or in minor surgical operations:

℞ Bari Sulphide ..... 2 ounces.
Oxide of Zinc ..... 1 ounce.
Starch (Pulv.) ..... 6 ounces.

Mix and pass through a sieve, pour the powder on a saucer, about a thimbleful, add a little water, enough to make a thick paste.

Spread on the skin with a flat tooth pick over the growth of hair. Allow the paste to dry three to five minutes, then remove by washing.

[Written for the MEDICAL BRIEF.]

Examination Questions of the University of the State of New York.

Answer any ten of the questions under each heading, but no more. Check the number (✓) of each one of the questions you have answered.

ANATOMY.

TUESDAY—9:15 A. M. TO 12:15 P. M.

1. Describe the differences between the sacrum of the male and that of the female.
2. Locate and describe Cowper's glands.
3. Describe the sternum. Mention *four* muscles attached to the sternum.
4. Give the minute anatomy of the skin.
5. What veins return the blood from the head and face?
6. State the origin of the internal iliac artery. Mention *five* branches of the internal iliac artery.
7. Give a general outline of the trifacial nerve, mentioning its principal subdivisions.
8. Describe the tongue as to its (*a*) muscular connections, (*b*) nerve supply, (*c*) blood supply, (*d*) structure.
9. Mention the coverings of a femoral hernia.
10. Describe the pancreas.
11. Give the boundaries of the axillary region and mention its contents.
12. What are the valvulæ conniventes and how are they formed?
13. Describe (*a*) aponeurosis, (*b*) fascia.
14. Give a description of the thyroid gland.
15. Give the relations of the heart to adjacent organs and tissues.

PHYSIOLOGY AND HYGIENE.

TUESDAY—1:15 TO 4:15 P. M.

1. Describe the red blood corpuscles as to (*a*) origin and fate, (*b*) form, (*c*) size, (*d*) number, (*e*) function.
2. What is understood by endocardiac pressure? State the causes of the pressure in the arteries, capillaries and veins.
3. Give the elementary structure of all secreting glands and mention an example of the changes that take place in any one of them during secretion.
4. Give the minute structure of the kidney. State the accepted theory regarding the mechanism of the secretion of urine.
5. Through what channels and by what processes are the end products of digestion conveyed to the blood?
6. Mention and describe (*a*) the superficial reflexes, (*b*) the deep reflexes.
7. State the function of (*a*) the vas deferens, (*b*) the vesiculæ seminales, (*c*) the prostate gland.
8. What are enzyms? State the special function of each enzym concerned in digestion.
9. Describe normal pulmonary sounds.
10. Give a dietary for people beyond sixty years of age.
11. What diseases may be transmitted through the agency of (*a*) the soil, (*b*) insects, (*c*) water, (*d*) air, (*e*) fomites?
12. State the significance of the presence in drinking water of (*a*) nitrates and nitrites, (*b*) excess of albuminoid ammonia, (*c*) excess of chlorin.
13. Mention the principal causes of infantile mortality. What hygenic regulations would tend to reduce the high mortality rate among infants?
14. How should a patient who has been rendered unconscious by heat be treated?
15. What constitutes a thorough inspection of milk as to (*a*) food value, (*b*) purity?

CHEMISTRY.

WEDNESDAY—9:15 A. M. TO 12:15 P. M.

1. What inorganic salts enter into the formation of human bone?
2. Give *two* tests for recognizing the presence of albumin in urine.
3. Define specific gravity. Give methods of determining specific gravity.
4. How is bromin prepared? What important salts of bromin are used in medicine?
5. Give the formula and the method of preparation of calcium carbid.
6. Give the sources and uses of carbolic acid.
7. Give the uses and chemical properties of sulfur. Where in the body is sulfur found?
8. Define chemistry, molecule, physical change, chemical change, positive element.
9. What conditions favor (*a*) crystallization, (*b*) efflorescence?
10. Give the method of preparation and state the uses of monoxid of lead.
11. What is formaldehyde, how is it prepared and what are its uses?
12. Give the formula, properties and preparation of each of *two* of the following: (*a*) potassium chlorate, (*b*) potassium sulfate, (*c*) potassium iodid.
13. Give a detailed test for arsenic in a mixture of food taken from the stomach at a *post-mortem* examination.
14. What is glycogen? Where in the body does it occur? How is glycogen prepared?
15. What alkaloid is common to tea and coffee? From what are cocoa and chocolate derived?

SURGERY.

WEDNESDAY—1:15 TO 4:15 P. M.

1. Describe anthrax and give treatment.
2. Give a classification of tumors conforming to the type of embryonic connective tissue.
3. Describe the technic of exploratory puncture in general and discuss the value of such puncture.
4. Give the diagnosis and prognosis of fracture of the base of the skull.
5. Describe a dislocation of the ankle joint.

6. Describe the effects on the lumbar spine of flexing and extending the diseased limb in hip joint disease.

7. Describe (*a*) genu valgum, (*b*) genu varum. Give the treatment of *one* of them.

8. Give the diagnosis and treatment of aneurism of the femoral artery.

9. Give the treatment of deep urethral stricture.

10. What are the indications for (*a*) cholecystectomy, (*b*) drainage of the biliary passages?

11. Give a classification of hemorrhoids. Give the symptoms, diagnosis and treatment of hemorrhoids.

12. Mention in order of frequency of occurrence *three* of the most common tumors of the vulva. Give the treatment of *one* of the conditions mentioned.

13. Give the diagnosis, prognosis and treatment of corneal ulcer.

14. Describe an operation for the radical cure of hallux valgus.

15. Give the technic of *two* methods of skin-grafting.

OBSTETRICS.

THURSDAY—9:15 A. M. TO 12:15 P. M.

1. Define and describe pelvimetry: state the objects and methods of pelvimetry.

2. What are the physiologic processes of fecundation up to and through segmentation?

3. State the possible causes of death of the fetus in utero.

4. Give the causes, prognosis and treatment of albuminuria in pregnancy.

5. Give the objective signs of pregnancy in the order of their appearance and state their relative value.

6. Explain the significance of the various hemorrhages from the uterus that may occur during pregnancy. Give the non-medicinal treatment of uterine hemorrhage.

7. Define puerperal eclampsia and give its management, both prophylactic and curative.

8. Give the signs that indicate a breech presentation and outline the treatment.

9. Describe the symptoms and management of placenta previa.

10. What should be done to prevent infection of the puerperal breast? How should mastitis be treated?

11. Define atresia of the vagina and state its causes, symptoms and treatment.

12. What is trachelorraphy? Describe its technic.

13. Mention some of the causes of sterility in the female and state what can be done to correct them.

14. Differentiate menorrhagia and metrorrhagia and give the treatment of each condition.

15. Mention the causes and give the treatment of epithelioma of the cervix uteri.

PATHOLOGY AND DIAGNOSIS.

THURSDAY—1:15 TO 4:15 P. M.

1. Mention the structural changes that occur in tuberculous joints.

2. Mention the pyogenic cocci and describe the types of inflammation produced by them.

3. Describe the blood changes in pernicious anemia.

4. Give the histologic characteristics of (*a*) sarcoma, (*b*) fibroma, (*c*) adenoma.

5. What are the causes of stenosis of the larynx? Give the pathology of stenosis of the larynx.

6. Describe the formation of a metastatic abscess.

7. Give the pathology of lobar pneumonitis.

8. Distinguish between hematuria and hemoglobinuria. State the causes of each.

9. What abnormal products may be found in the urine as the result of (*a*) diabetes, (*b*) acute parenchymatous nephritis, (*c*) chronic interstitial nephritis?

10. Enumerate the diagnostic sounds in a diseased respiratory apparatus and describe *one* of the sounds mentioned.

11. Describe and locate the pain in (*a*) appendicitis, (*b*) renal calculus, (*c*) gallstones, (*d*) ovaritis, (*e*) cystitis.

12. State the practical diagnostic value of a laboratory examination of the feces. Illustrate.

13. Give the area of normal heart dullness. What conditions increase the area of heart dullness?

14. What causes contribute to obesity? What tissues are most frequently invaded in obesity?

15. Give the signs and symptoms of floating kidney.

THERAPEUTICS, PRACTICE AND MATERIA MEDICA.

FRIDAY—9:15 A. M. TO 12:15 P. M.

"* * * in therapeutics, practice and materia medica all the questions submitted to any candidate shall be chosen from those prepared by the board selected by that candidate, and shall be in harmony with the tenets of that school as determined by its state board of medical examiners."—Law of 1893, chapter 661, section 146.

Questions prepared by the board of examiners representing the Homeopathic Medical Society of the State of New York.

1. Give the treatment of shock following a surgical operation.

2. Give the liver symptoms of chelidonium majus.

3. Give the therapeutic sphere of cina.

4. Describe the treatment of a case of pneumonitis.

5. Give the therapeutic sphere of psorinum.

6. Give the symptoms and treatment of multiple neuritis.

7. Mention three remedies having a pathogenesis of green diarrhea and give the characteristics of each.

8. Give the symptoms and treatment of acute gastritis.
9. When should rhus toxicodendron be given in scarlet fever?
10. Describe the headache of iris versicolor.
11. Describe the skin symptoms of graphites.
12. Give *two* remedies for collapse during typhoid fever, with the indications for each.
13. Differentiate gelsemium and natrum muriaticum in intermittent fever.
14. Give the treatment of chilblain.
15. Give the indications for *three* remedies curative in nasal catarrh.

THERAPEUTICS, PRACTICE AND MATERIA MEDICA.

FRIDAY—9:15 A. M. TO 12:15 P. M.

Questions prepared by the board of examiners representing the Medical Society of the State of New York.

1. State the pathologic conditions for the relief of which diuretics are administered.
2. Give the causes and treatment of palpitation of the heart.
3. State the dose of (*a*) tincture of benzoin, (*b*) benzoic acid. Give the therapeutic uses of benzoic acid.
4. Give the therapeutic uses of apomorphin hydrochlorate.
5. Give the causes and treatment of deficiency in excretion of urea.
6. Mention the alkaloids of pilocarpus. What alkaloid of pilocarpus is most frequently used in medicine?
7. Give the therapeutic uses of eserin and name its chief antagonist.
8. Give the etiology and treatment of rachitis.
9. State the dose for an adult of (*a*) acetanilide, (*b*) tartar emetic, (*c*) silver nitrate.
10. Give the source, the physiologic action and the therapeutic uses of oleum ricini.
11. Describe the treatment of neurasthenia.
12. What is the source of camphor? State the dose of spiritus camphoræ.
13. Give the therapeutic uses of chloral hydrate. How does a toxic dose of chloral hydrate affect the body temperature?
14. Give the source and the therapeutic uses of gum arabic.
15. Describe the treatment of cystitis.

THERAPEUTICS, PRACTICE AND MATERIA MEDICA.

FRIDAY—9:15 A. M. TO 12:15 P. M. ONLY.

Questions prepared by the board of examiners representing the Eclectic Medical Society of the State of New York.

1. How is salicylic acid produced? State its uses in medicine.
2. Give the treatment of a case of peritonitis.
3. What is mastitis? Give the treatment of mastitis.
4. Describe scarlatina and give its specific treatment.
5. Give the symptoms and treatment of acute nephritis.
6. Describe hydrothorax and give its treatment.
7. State how sodium bromid is obtained and give its uses.
8. Give the composition and the therapeutic uses of Seidlitz powders.
9. What is the alkaloid of mandrake? Give the specific indications for the use of this alkaloid.
10. What is echinacea angustifolia and when is it specifically indicated?
11. Describe rheumatic arthritis and give its treatment.
12. Describe chronic meningitis and give its treatment.
13. What preparations of phosphorus are used in medicine?
14. Describe the preparation and uses of tincture of iodin.
15. Describe the symptoms and treatment of angina pectoris.

In Memoriam of Dr. Ben. H. Brodnax—We Must Certainly Die.

We notice, with much regret, the death of our old-time friend, Dr. Ben H. Brodnax, of Brodnax, La. His articles to our columns were received by all readers and searchers after practical knowledge in an "I-thank-you" manner. His "Acid Iron Tonic" will stand the test of time, and we are happy to know that during his life we had the pleasure of giving our readers a half-tone portrait of the Doctor. He died on October 7th, 1905, of a complication of typhoid fever and bronchitis. He was seventy-four years of age, and thirty-five of them had been spent in the practice of medicine. We feel like quoting Cicero: "*Supremus ille dies non nostri extinctionem sed commutationem affert loci.*" (The last day does not bring extinction to us, but change of place.)

[Written for the MEDICAL BRIEF.]

Tonsillitis or Quinsy.

BY W. B. WOOD, M. D.,
Los Angeles, Cal.

Commence treatment with one-half grain of calomel and soda every hour until three grains have been taken, followed by comp. syr. senna. For fever, headache and pain give one teaspoonful of elix, acetanilide every two hours. To abort or prevent the tonsil from gathering, use the following:

℞ Tr. Phytolacca ..... ½ ounce.
Tr. Iodine ..... 1½ ounces.
M. Sig.: Apply to the tonsil with a brush or cotton tipped probe every two hours.

Corner Forty-Fifth and Central Avenue.

Book Notices.

GRAY'S ANATOMY. Descriptive and Surgical. New American from the Fifteenth English Edition. Revised, enlarged and rewritten by J. Chalmers Da Costa, M. D., Professor of Surgery in the Jefferson Medical College, in collaboration with a corps of specially selected assistants. In one very handsome imperial octavo volume of sixteen hundred pages, with eleven hundred and thirty-two illustrations, five hundred of which are new in this edition. Philadelphia and New York: Lea Brothers & Co., Publishers. Price, with illustrations in black: cloth, $5.50; leather, $6.50. With illustrations in black and many colors: cloth, $6.00; leather, $7.00.

Ever since an anatomy of medicine has been published, and we wish to refer to the past fifty years, Gray's Anatomy has stood the test, even though others have tried to enter the field. It has guided the teaching of anatomy in all English-speaking lands so exclusively that Gray on the subject has become the standard. Henry Gray died young, but he has left his masterpiece as a means of imparting a knowledge of anatomy that will be lasting. The subject of anatomy is perpetually advancing and any work on this line needs frequent revision, and in accordance, it has enlisted many of the ablest anatomists on both sides of the Atlantic, but no revision has been so thorough as this of Dr. Da Costa's. He is an anatomist, a surgeon, and a teacher, and he combines all the qualifications necessary to place this work abreast of the latest advances, keeping always in view the requirements of the student and practitioner. Every page has been revised and whole sections rewritten, notably those on the brain, spinal cord, nervous system, abdomen, and lymphatics. Of the magnificent series of over one thousand illustrations, no fewer than five hundred are new in this edition. They are so large that every detail is clear, and they bear the names of the parts engraved directly upon them (a feature peculiar to Gray), whereby the position, extent and relations are seen at a glance and impressed on the mind in a way otherwise impossible. Colors are used more freely than ever before to indicate the muscle-attachments, veins, arteries, nerves and lymphatics. The work is therefore an unrivaled dissector. The old and new nomenclature are both given, the new enclosed in brackets, thus serving all readers better than either system alone. The text has been most carefully arranged, so that its main and sub-headings and its catchwords in heavy type will give the student a systematic grasp of all the subjects in their proper anatomical dependence. In a word, Gray's Anatomy will remain in the future, as it has been in the past, the easiest book from which to teach, to learn, or to prepare for examinations for degrees or license to practice, and likewise the unrivaled reference book for the physician and surgeon.

PREVENTIVE MEDICINE. Including a Disquisition on Therapeutic Philosophy. By William Colby Cooper, M. D. Price, $1.00, postpaid. Address Dr. W. C. Cooper, Cleves, O.

This work on preventive therapeutics should be in every physician's library because it compels you to think. It reflects the vigor of an active mind, and commands your attention as something more than a collection of words. While some of the statements made may strike the reader as being too radical, for that very reason his own ideas will be crystallized and our store of knowledge increased. The second and third parts deserve especial attention, and the Editor urges every reader to send along his dollar to Dr. Cooper to-day and see for himself—you will thank us for the suggestion.

NEUROTIC DISORDERS OF CHILDHOOD. Including a Study of Auto and Intestinal Intoxications, Chronic Anemia, Fever, Eclampsia, Epilepsy, Migraine, Chorea, Hysteria, Asthma, etc. By B. K. Rachford, M. D., Professor of Diseases of Children, Medical College of Ohio, University of Cincinnati. Pediatrist to the Cincinnati Good Samaritan and Jewish Hospitals; Member of American Pediatric Society; Association of American Physicians, etc. New York: E. B. Treat & Company. Price, $2.75.

Owing to the fact that infants and children are predisposed to complicated nerve disorders at times, and such conditions seem to be very little understood by the general practitioner, and are only studied by pediatrists, therefore, this work appeals to the general practitioner in the sense of a go-between. It is a work that should be studied by the physician in general family practice.

HARE'S THERAPEUTICS. A Text-Book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. By Hobart Amory Hare, M. D., B. Sc., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Hospital, etc. New (eleventh) edition, enlarged and thoroughly revised to accord with the eighth decennial revision of the U. S. Pharmacopeia, 1905. In one octavo volume of nine hundred and ten pages, with one hundred and thirteen engravings and four colored plates. Philadelphia and New York: Lea Brothers & Co. Price, cloth, $4.00; leather, $5.00; half morocco, $5.50.

Dr. Hare possesses the invaluable faculty of intuitively discriminating between the important and the unimportant, between the practical and the impractical. This is what every physician and student most desires to learn. It is not surprising that the writings of an author who tells his readers what they want to know, and who puts facts directly and simply, should be in great demand. The work is in its eleventh edition in fifteen years, each edition having been put to press several times to satisfy the demands. This satisactory condition has enabled the author to always keep abreast of the times and is an important matter in such a progressive subject. This edition is revised to meet the requirements of the new U. S. Pharmacopeia. It would be difficult to conceive of a work answering the needs of students and practitioners better than this, either in plan or execution.

HYGIENE AND PUBLIC HEALTH. By B. Arthur Whitelegge, C. B., M. D., B. Sc., London, F. R. C. P., D. P. H.; Late County Medical Officer of Health for the West Riding of Yorkshire; Chief Sanitary Officer of the West Riding of Yorkshire River Board; Medical Officer of Health for Nottingham, and Lecturer on Public Health, Charing Cross Hospital Medical School; and George Newman, M. D., D. P. H., F. R. S. E., Medical Officer of Health of the Metropolitan Borough of Finsbury; Late Demonstrator of Bacteriology and Infective Diseases in King's College, London; Author of "Bacteriology and Public Health." New edition, revised and enlarged, and in great part rewritten. Illustrated. Chicago: W. T. Keener & Co. Price, $1.75.

There is assuredly great progress being made along the lines of public health. The hygienic conditions, the technical details, and the special books on medicine, epidemiology, bacteriology, chemistry, physics, meteorology, geology, engineering, and statistics, all lend encouraging facts to the great advances being made in regard to the betterment of the health of our race as new conceptions are brought forward year by year. Much care has been taken to furnish a reliable working data for the guidance of those who wish to keep up with the progress along these lines. There is a vast amount of valuable information on these pages for the physician and student.

THE ERA KEY TO THE U. S. P. A Complete List of the Drugs and Preparations of the United States Pharmacopeia. Eighth decennial revision (1905). Vest-pocket size; 83 pages. New York: The Pharmaceutical Era, Publishers, 90 William Street. Price, 25 cents.

The publishers announce a new edition of the well-known "Era Key to the U. S. P.," whose object is to further the introduction and employment of the official drugs and preparations of our National standard, the United States Pharmacopeia, the eighth revision of which is now in force. The book comes in vest-pocket size and gives in a "nut-shell" all the essential information required by the physician who desires to prescribe pharmacopeia remedies—their official names, synonyms and constituent parts, with average doses in both metric and English systems. The idea of putting the essential information of the Pharmacopeia in so small a compass is claimed to be original with the publishers, under whose direction the little work was complied. The busy physician will find it both helpful and suggestive in his effort to prescribe official pharmaceutical preparations.

MALFORMATIONS OF THE GENITAL ORGANS OF WOMEN. By Ch. Debierre, Professor of Anatomy in the Medical Faculty of Lille. With eighty-five illustrations. Translated by J. Henry C. Simes, M. D., Emeritus Professor of Genito-Urinary and Venereal Diseases in the Philadelphia Polyclinic. Philadelphia: P. Blakiston's Son & Co. Price, $1.50.

"All physical science depends essentially upon two facts; the particular facts, which are revealed by observation; the general facts, which are discovered by reasoning. Together they increase and

mutually animate all studies. Considered separately, the first is only sterile material, the second only useless hypotheses. Science can not exist with one or the other—it must have both—any more than reasoning can exist without premises or without consequences." Monstrosities are considered as a result of the action of accidental causes, such as do not modify the whole organization, but which modify it during the development of the organization, in giving a different direction to the phenomena of evolution. These are the prevailing ideas of malformations of the genital organs of woman. The study of this subject should be considered by every general practitioner of medicine, as he often comes in contact with such conditions as a family practitioner.

PNEUMONIA AND PNEUMOCOCCUS INFECTIONS. By Robert B. Preble, A. B., M. D., Professor of Medicine, Northwestern University, Illustrated. Chicago: Cloyd J. Head & Co. Price, $1.00.

This work is written in the interests of pneumonia and its infections, and if you were asked the question as to the three greatest problems now engaging the attention of the medical profession you could not refrain from saying tuberculosis, pneumonia and carcinoma, as you all know these diseases have a predominance. Now, if such is the case, why not read up along these lines in authoritative considerations? Of course, tuberculosis is the most important, then why not take a hand in the discovery of some remedy that will alleviate, if not cure, this plague? Do some thinking and read the thoughts of others on the subject.

TEXT-BOOK OF ANATOMY. Edited by D. J. Cunningham, F. R. S., M. D. (Edinburgh and Dublin), D. Sc., LL. D. (Glasgow and St. Andrews), D. C. L. (Oxon); Professor of Anatomy, University of Edinburgh. Second and Thoroughly revised edition. Illustrated with nine hundred and thirty-six wood engravings from original drawings. Many printed in colors. New York: William Wood & Company, Publishers. Price, muslin, $6.00; leather, $7.00; half morocco, $8.00.

English physicians, as well as those of advanced ideas in America, have so favorably received this work that it was found necessary to issue a new edition. In carrying out this idea, it was thought best to carefully revise it and add many new illustrations. The work will sell on sight, owing to the elegant way in which the publishers have produced it. There has been some changes and additions made in this edition, especially on embryology, the joints, the muscles, the brain and spinal cord, the genito-urinary organs, the lymphatics, and applied anatomy. In the section upon the muscular system, a series of illustrations has been added in which the areas of muscle attachment are delineated upon the bones. There are noticeable many new features in this work that will stamp it as among the best textbooks on anatomy.

MANUAL OF CHEMISTRY. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Text-Book Specially Adapted for Students of Medicine, Pharmacy and Dentistry. By W. Simon, Ph. D., M. D., Professor of Chemistry in the College of Physicians and Surgeons of Baltimore, and in the Baltimore College of Dental Surgery; Emeritus Professor in the Maryland College of Pharmacy, Department of the University of Maryland. Eighth edition. Thoroughly revised. With sixty-three illustrations, one colored spectra plate, and eight colored plates, representing sixty-four chemical reactions. Philadelphia and New York: Lea Brothers & Co. Price, $3.00.

Simon's Chemistry has just entered on its eighth edition. Any work that has been sought after to encourage the author and publisher to issue an eighth edition seems a matter of words to express why they have done so. A book must have merit to encourage so many editions, and it seems a self-evident fact that since the work of Simon on Chemistry has justified this, they need make no apology for this edition. It has been found that many changes have been made since the last edition was issued, and a new revision in accordance was necessary; therefore changes have been made in this edition to conform to the latest developments in chemistry, and this edition meets the requirements.

RICHARD WAGNER AS PHILOSOPHER. By Axel Emil Gibson, M. D., Los Angeles, Cal. Price, 25 cents.

"Music, like the rest of the fine arts, is the living presentation of religion, but religions spring not from the artist's brain; their only origin is in the minds of a spiritualized people."—*Wagner.*

OPERATIVE SURGERY. For Students and Practitioners. By John J. McGrath, M. D., Professor of Surgical Anatomy and Operative Surgery at the New York Post-Graduate Medical School; Surgeon to the Harlem, Post-Graduate, and Columbus Hospitals, New York. Second edition. Thoroughly revised. With two hundred and sixty-five illustrations, including many full-page plates in colors and half-tone. Six hundred and twenty-eight octavo pages. Philadelphia, 1914-16 Cherry street: F. A. Davis Company, publishers. Sold by subscription only. Price, extra cloth, $4.50; half morocco, $5.50.

A careful and thorough revision has been made in this edition and every department is made to conform to the latest in surgery. Many new illustrations have been added and much interesting and instructive matter has been added to the text. In the section upon the abdomen, the subjects of gastro-enterostomy and the surgical treatment of diseases of the stomach and intestines have been treated in minute detail; also the operative treatment of the pancreas, spleen, etc. The surgery of the prostate gland receives due consideration. The value of the book has been greatly enhanced by these additions and should prove a leader on this subject.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially-Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and other Topics of Interest to Students and Practitioners, by Leading Members of the Medical Profession Throughout the World. Edited by A. O. J. Kelly, A. M., M. D., Philadelphia. With the collaboration of William Osler, M. D., John H. Musser, M. D., James Stewart, M. D., John B. Murphy, M. D., A. MacPhedran, M. D., Thos. M. Rotch, M. D., John G. Clark, M. D., J. W. Ballantyne, M. D., James J. Walsh, M. D., John Harold, M. D., Edmund Landolt, M. D., Richard Krets, M. D., etc. Illustrated in colors and black and white. Philadelphia: J. B. Lippincott Co. Price, cloth, $2.00; half leather, $2.25.

On receipt of Vol. III, Fifteenth Series of the International Clinics, we wish to express our gratification on the improvements that are constantly made in this series. The authors and collaborators seem to vie with each other in aiming to improve this work. We can not but express our appreciation of the efforts to make this the greatest work on clinical medicine that the American press can produce.

MANUAL OF PATHOLOGY. Including Bacteriology, the Technic of Post-Mortems, and Methods of Pathologic Research. By W. M. Late Coplin, M. D., Professor of Pathology and Bacteriology, Jefferson Medical College, Philadelphia; Pathologist to Jefferson Medical College Hospital and to the Philadelphia (Blockley) Hospital; Director of the Clinical Laboratories of the Jefferson Medical College Hospital; Pathologist to the Friends' Asylum for the Insane, Frankford. Fourth edition. Rewritten and enlarged. With four hundred and ninety-five illustrations, many of which are original, and ten colored plates. Philadelphia: P. Blakiston's Son & Co. Price, $4.00.

Pathology is the name generally accepted for the science of disease, and this work is a text-book on the subject. The author has given, as the title explains, a concise knowledge of the subject. To study pathology to advantage it is necessary that the student be conversant with the facts and principles of physiology, and to make a practical application of this knowledge, that he shall verify those that are capable of being apprehended to our senses of personal observation. In this way he establishes in his own mind a standard of comparison and is enabled to determine variations in disease.

A TREATISE ON THE NERVOUS DISEASES OF CHILDREN. For Physicians and Students. By B. Sachs, M. D., Alienist and Neurologist to Bellevue Hospital; Neurologist to the Mt. Sinai Hospital; Consulting Physician to Manhattan State Hospital East and West; Formerly Professor of Mental and Nervous Diseases in the New York Polyclinic; Ex-President of the American Neurological Association. Second edition. Revised. New York: William Wood & Company. Price, $4.00.

This work has received such praise from the brainy portion of the profession that the author could not refrain from the task of issuing a second edition, in which every chapter has been revised, and much new matter has been introduced. Of course, to accommodate the new matter and not to enlarge the work, some matter had to be eliminated; thus the chapters on anatomy and physiology were sacri-

ficed, owing to the matter which could be readily found in the works of Dana, Gowers, Starr, and Oppenheim. This work is so complete that reference to other authors is not necessary, and Sachs, the author of this work, stands out as an authority, and makes this book an exclusive one.

LEA'S SERIES OF MEDICAL EPITOMES.—MAGEE & JOHNSON'S EPITOME OF SURGERY. A Manual for Students and Practitioners. By M. D'Arcy Magee, A. M., M. D., Demonstrator of Surgery and Lecturer on Minor Surgery; and Wallace Johnson, Ph. D., M. D., Demonstrator of Pathology and Bacteriology in Georgetown University Medical School, Washington, D. C. In one 12mo. volume of two hundred and ninety-five pages, with one hundred and twenty-nine engravings. Philadelphia and New York: Lea Brothers & Co. Price, cloth, $1.00.

The authors and editor have made an earnest endeavor to furnish an authoritative, clear, compact presentation of the essentials of modern surgery. While this little volume is by no means intended to take the place of a text-book, it will be found convenient for study many times when a large book is inaccessible, while for students' use in quizzing themselves or each other, in preparation for college or State board examinations, it will be of the utmost service. As with the other volumes of this excellent and very popular series, the questions are not interspersed with the text, but follow each chapter, thus permitting consecutive reading without interruption.

COAKLEY'S LARYNGOLOGY. A Manual of Diseases of the Nose and Throat. By Cornelius G. Coakley, A. M., M. D., Professor of Laryngology in the University and Bellevue Hospital Medical College; Laryngologist to Columbus Hospital, etc., New York. New (third) edition, revised and enlarged. In one 12mo. volume of five hundred and ninety-four pages, with one hundred and eighteen engravings and five colored plates. Philadelphia and New York: Lea Brothers & Co., Publishers. Price, cloth, $2.75.

The call for three editions in six years shows that this work is firmly planted in the esteem of the profession. It is a widely-prescribed text-book, it answers the need of general practitioners who do throat work, and it is a valuable reference manual for specialists. The author has made a very judicious selection of knowledge from the vast range of laryngological lore. He insists on the importance of thorough diagnosis and furnishes sufficient guidance in all its steps up to and including the final settlement of any doubts by means of microscopic and bacteriological tests. A departure of obvious value has been made in dealing with treatment. From among the multiplicity of medicinal and operative measures the author has chosen those which, in his experience have proven the best, and has given full details for the benefit of those who have not had the advantage of personal and clinical instruction. The revision of this new edition has been very thorough, bringing the book fully to date in all departments. For convenience a special chapter has been added on therapeutics, wherein will be found a classification of drugs according to their local actions, and a number of useful prescriptions, together with indications for their employment. References to these additional remedies have been indicated in the index under the *treatment* of each disease. The excellent series of illustrations has been revised and enriched on a parity with the improvements in the text.

RADIOTHERAPY, PHOTOTHERAPY AND HIGH FREQUENCY CURRENTS. The Medical and Surgical Applications of Radiology in Diagnosis and Treatment. By Charles Warrenne Allen, M. D., Professor of Dermatology in the New York Post-Graduate Medical School. Octavo, six hundred and eighteen pages, one hundred and thirty-one engravings and twenty-seven plates. Philadelphia and New York: Lea Brothers & Co. Price, cloth, $4.50.

Recent discoveries in radiant energy have developed a new and important system of therapy. In fact, such positive results have already been achieved in maladies which were hitherto considered intractable, as to warrant the recognition of Radiotherapy as a very efficient addition to the resources of the profession. Dr. Allen's work is peculiarly opportune. It is based upon practical experience, as well as upon a careful review of the great mass of literature on the subject coming from almost all quarters of the globe. Naturally, in a science so new, much faulty observation has been encountered, and in this volume no effort has been spared to

eliminate the errors and to present the subject correctly and abreast of its position to-day. Ample information is given upon the physical as well as the technical side, to equip the reader for the selection and management of appliances. The object of the work is always practical, and it has been the earnest endeavor of the author to enable his readers to secure for their patients prompt and permanent benefit. Accordingly, much attention is given to questions of diagnosis and treatment, and, inasmuch as such powerful forces as are treated of in this volume may do harm if improperly applied, cautionary directions are carefully given and exact instructions for the determination and measurement of dosage. When you have examined this volume you will find that the author has by no means lost sight of the demands of undergraduate students, and his long teaching experience has enabled him to produce a work which is admirably adapted to teaching purposes.

DISSECTING MANUAL. Based on Cunningham's Anatomy. By W. H. Rockwell, Jr., M. D., Formerly Assistant Demonstrator of Anatomy in the College of Physicians and Surgeons, Columbia University, New York. New York: William Wood & Company. Price, $2.00.

This work should appeal to the student in the dissecting room, from the fact that it divides this subject into five parts: Head and neck, thorax, upper extremity, abdomen and pelvis, and lower extremity. Each of these parts has been subdivided as much as possible, with regard to the avoidance of excessive repetitions, and described completely. Anything from the pen of Rockwell should have profound respect for particulars in the respective branch of medicine that has gained fame for his name.

LABORATORY MANUAL OF PHYSIOLOGY. By Frederick C. Busch, B. S., M. D., Professor of Physiology, Medical Department, University of Buffalo. Illustrated. New York: William Wood & Company. Price, $1.25.

This is a work of physiology for students, and while brief it is concise and sufficiently comprehensive for all the needs of the student or general practitioner. It is a work that should appeal to all who wish a work that is descriptive of the subject. It is especially valuable to students.

PHYSICIAN'S POCKET ACCOUNT BOOK. By J. J. Taylor, M. D. Philadelphia: Published by the *Medical Council*. Price, $1.00.

The important feature of this work is that you have a ready record in your pocket, that will be useful when a debtor attempts to take you by surprise with the question: "How much do I owe you?" You can produce the record on the moment, and often collect when you least expect to do so. It is fully worth the price, and one such opportunity will fully repay the outlay. Send for a copy. The dates are open and it is good till filled.

NEUROLOGY AND METAPHYSICS. By Charles McCormick, M. D., Founder and President of McCormick Neurological College, the First Non-Sectarian Medical College; Editor of *The Ophthalmologist*. Chicago: McCormick Neurological College, 2500 Prairie Ave.

The author says: "The two greatest humbugs of the ages have been and are religion and medicine. Neither is natural —both are artificial. True, they must have their originals in nature, but both have been so distorted by would-be authorities that nature could not recognize the imitations." We think this is a book well worth reading.

CLINICAL TREATISES ON THE PATHOLOGY AND THERAPY OF DISORDERS OF METABOLISM AND NUTRITION. By Professor Dr. Carl von Noorden, Physician-in-Chief to the City Hospital, Frankfort A/M. Authorized American Translation. Edited by Boardman Reed, M. D., Late Professor of Diseases of the Gastro-Intestinal Tract, Hygiene and Climatology, Department of Medicine, Temple College, and Physician to the Samaritan Hospital, Philadelphia; Physician to the American Oncologic Hospital, etc. Translated by Florence Buchanan, D. Sc., and I. Walker Hall, M. D. Part VII. Diabetes Mellitus. Its Pathology and Treatment. Lectures Delivered in the University and Bellevue Hospital Medical College, New York Herter Lectureship Foundation. New York: E. B. Treat & Co., Publishers. Price, $1.50.

PRESBYOPIC TEST CARD. This is an Eye Chart for Testing the Eyes for Reading Glasses only. It is so simple to use that one may test the eyes for reading without any knowledge of optics at all. It enables you to test the eyes for reading at any distance from eight to twenty-four inches, accurately. It does away with trying on glasses to a great extent until one is found to suit the patient. It does not seem to make any difference whether the eye is hypermetropic or myopic, as the test is good for all. Bloomington, Ill.: Dr. R. S. Piper. Price, $2.00.
